There are unconfirmed reports from Poland that Dr Henryk Samsonowicz, rector of the University of Warsaw, has been dismissed for refusing to accept the new rules for the conduct of institutions of higher education laid down by the ruling Military Council for National Salvation Earlier, Dr Samsonowicz was reported to have been among the many academics interned under martial law regulations, while other reports indicate that he has been expelled from the Communist Party

According to Mr Artur Swiergiel, a member of the Mazowsze (Warsaw and home counties) regional executive of Solidarity, who is at present working on animal nutrition in Cambridge (England), the reported dismissal is only the tip of the iceberg He expects a wave of dismissals among the university rectors elected in the past 18 months according to the new democratic procedures, but predicts that the expected purge will be far more sharply felt among junior academics and research students, as it was in 1968 He stresses that Western scientists who wish to campaign on behalf of their Polish colleagues should not concentrate only on the most eminent Current lists include Dr Grzegorz Bialkowski, vice-president of the Polish Physical Society, and Dr Antoni Stawikowski, vice-president of the Polish Astronomical Society, but also their junior colleagues

So far, Western scientists who have approached their local Polish consulates or embassies with requests for further information about interned colleagues have been met with suggestions that if the scientist in question could arrange a job for his colleague in some university or laboratory outside Poland, the authorities would be quite willing to grant an exit visa.

Such an arrangement, Mr Swiergiel stresses, should not be accepted unless there is clear evidence that the scholar concerned definitely wishes to leave Poland, since the army newspaper *Zolnierz Wolnosci* has indicated that Solidarity would have to shed "35,000 intellectual advisers" before it could be allowed to resume "purely trade union" activities This theme has been reiterated by Stanislaw Ciosek, the Minister for Trade Union Affairs, in a recent meeting with "representative workers" from Lodz, who stressed that trade unionism in Poland must return to its "class basis"

Under martial law, scientific exchanges between Poland and the rest of the world have come to a halt In London, the Royal Society has no news of Wieslaw Stanczyk, who was expected to arrive in January to take up an exchange scholarship From Finland it is reported that exchange fellows due in early December failed to arrive, although martial law was not declared until a few days after their expected arrival

Scientific exchanges are based on two types of agreement — the purely academic negotiated with the Royal Society or British Academy and those which form part of the bilateral agreement on trade and technology The financial mainstays of the latter are the various economic agreements negotiated over the past decade These include a licensing agreement between Massey-Ferguson tractors in the United Kingdom and the Ursus motor works in the suburbs of Warsaw In one of the latest moves in "solidarity with Solidarity", workers at the British plant have voted to "black" all spare parts and components from Ursus until martial law is lifted

Vera Rich

UK nuclear power

At last, a plan

At long last the British nuclear industry has a timetable that can be believed in The "wide-ranging" public inquiry into the design and siting of a pressurized water reactor (PWR) at Sizewell in Suffolk will begin in January 1982 The "task force" set up under Dr Walter Marshall, chairman of the United Kingdom Atomic Energy Authority, to speed up the design of the PWR last week reported that its pre-construction safety report was complete and in the hands of the customer for the reactor, the Central Electricity Generating Board This is in line with the timetable set by Marshall last July, as is the date set by the board for the publication of its full safety review — the end of April

The only fly in the ointment seems to be the Nuclear Installations Inspectorate, whose lack of inspectors appears to be putting back the publication of its own, independent safety report The inspectors will now produce a summary review of the generating board's own safety documents in June this year, expressing their reservations (if any), but may produce nothing further before the public inquiry The inspectorate's safety assessment is "an iterative process" says the chief inspector, Mr Ron Anthony. There can be no particular point at which it is best to hold a public inquiry too early, and the inspectorate would have too little time to study the design, too late and it would not be possible to take the inquiry's findings into account without disrupting the project

The task force report will not be published, but Dr Marshall last week outlined its main features His study concentrated on the safety standards and the systems demanded by both the inspectors and the electricity board which — before the task force was set up in July last year — were estimated to imply that the British PWR would cost 50 per cent more than the American Westinghouse/Bechtel Corporation system Marshall estimates that the extra cost will now be only 20 per cent A quarter of that is attributable to measures intended to minimize loss-of-coolant accidents, a quarter to reduce the radiation exposure of workers and the remaining half to the use of two rather than one turbine for converting steam power into electricity.

The emergency core cooling systems will contain four separate high-pressure pumps (twice as many as in French and American PWRs) each feeding one of the four primary coolant loops and backed up by diesel generators, and the outer containment will be a four-foot thick concrete and steel shell, not the double wall originally planned Radiation levels have influenced the British design because the electricity generating board is anxious that exposure at its projected plant should not exceed that at its existing nine plants Thus the task force has attempted to reduce exposure by providing more space within the containment building (150 feet in diameter compared with 140 feet) and by the use of remote maintenance equipment.

The board thus hopes to bring individual operating exposures down to the level of the 0 25 rem per year or so experienced in the old Magnox plants The key factors seem to be good chemical management of the plant, particularly of the primary coolant water, and efficient and fast maintenance procedures Thus the emphasis is now less on the design (the original version of which called for nearly twice as much concrete shielding as the American baseline) than on the efficient operation of the reactor

The eventual cost will be within the target Marshall set himself six months ago — no more than 70 per cent of the cost of an advanced gas-cooled reactor At 1981 prices, this works out at about £1,000 million for 1,200 MW Nevertheless, this is some four times the price of a PWR as estimated by the French, and the National

0028-0836/82/040272-02$01 00

© 1982

Nuclear Corporation (which would build the reactor) and the Central Electricity Generating Board (which would buy it) are now putting their heads together to see how the French do it — and whether the British price might be brought down The generating board intends to announce its final estimate of the cost of the station, and the price of the electricity that it will produce, at the end of February

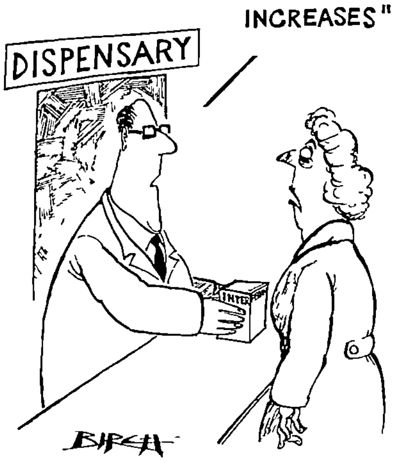
Robert Walgate

Interferon used at last

The Medical Research Council's Common Cold Unit in Salisbury, England, has resumed its trials of interferon as a preventative of rhinovirus infection — one of the causes of the common cold

Ten years ago, the centre proved the effectiveness of leukocyte interferon, prepared from human blood by Dr Kari Cantell in Finland, against rhinovirus — but abandoned further work because of the high cost of the material Trials have been resumed in the belief that genetically engineered interferon will eventually be so cheap that interferon might one day be used to prevent coughs and sniffles

"TAKE THREE TIMES A YEAR, AFTER WAGE INCREASES"



The resumed trials utilize interferon which is much purer than before It is obtained either from white blood cells or from genetically engineered bacteria Both forms are effective at high dosage and the next step at Salisbury will be to test how far the dosage of interferon can be reduced and how late in the course of infection it can be administered Then it will be up to the manufacturers to reduce prices to the level of common palliatives such as aspirin — a tall order, no doubt, but one which may eventually be met The aim is to do better than the Soviets who currently sell, for about $1 a time, interferon of such low dosage as to be useless **Robert Walgate**

US research spending

Problems in public

Washington

Efforts by the Reagan Administration to shift significant responsibility for research from the public to the private sector have produced a new crisis of identity in some national laboratories funded by the US Department of Energy

Established in the early 1950s largely as a means of supporting the research needed for both the military and the civilian uses of nuclear energy, the laboratories expanded the scope of their activities considerably in the 1970s as they were given additional responsibilities

Many of the areas of expansion, however, such as solar energy and conservation, are precisely those whose research budget is being most heavily cut by the Reagan Administration Furthermore, some powerful Republicans are questioning whether it is appropriate for the government to be involved at all in areas which, they claim, should properly be left to the private sector

Budget figures alone tell a significant part of the story For the twelve "multi-programme" laboratories run by independent contractors for the Department of Energy, the total budget for the current fiscal year is $2,803 million, $60 million less than for 1981

Given an expected inflation rate of about 10 per cent, the result will be a significant reduction in overall effort The reductions, however, will not be shared equally, with the two major weapons laboratories, Los Alamos National Laboratory and the Lawrence Livermore National Laboratory, receiving budget increases of 11 per cent and 16 per cent respectively

Laboratories hit harder by cuts include Argonne National Laboratory near Chicago, with a budget reduction of more than 25 per cent, while a reduction of similar magnitude has been absorbed at Oak Ridge National Laboratory, Tennessee In both instances, the major decreases are in programmes of research into fossil energy, conservation technologies and "other energy supplies"

A decision last year by the Department of Energy, in light of its expected budget cuts, to decrease the energy-related programmes by 10 per cent from 1980 levels, has already markedly affected staffing Some laboratories have been able to absorb most of the technical and scientific staff who have been displaced in weapons-related projects, at Oak Ridge, for example, many have moved to nuclear-warhead production Others have not been so lucky Brookhaven National Laboratory in Long Island has already had to lay off 270 out of its total of 3,600 staff At Argonne, the reduction so far has been 600 out of about 4,400

The prospects for next year do not look much better Although precise budget proposals will not be known until they are presented to Congress by President Reagan on 8 February, it is widely expected that the Administration will suggest similar reductions for 1983, after that, the laboratories can expect level funding at best for the next three to five years

A significant change in policy direction was already indicated in a memorandum last May to laboratory directors from Acting Under-Secretary of Energy, Dr Raymond Romatowski Under this regime, Dr Romatowski said that in principle the multi-programme laboratories should be restricted to two main functions The first was to conduct basic and applied research comprising important "technology-base" activities that the private sector is ill-equipped or not motivated to pursue, the second was to undertake development work in promising areas "beyond the private sector's capability and interest"

Several review committees are now looking at how to put these two principles into practice The main review, being carried out by the Office of Science and Technology Policy, will take some time to complete In the shorter term, a panel of the Department of Energy's Energy Research Advisory Board has been asked by the Deputy Energy Secretary, Mr W Kenneth Davis, to carry out its own review of the multi-programme laboratories, and a final report is due by September

Meeting in Washington last week, the members of the advisory board panel agreed to offer various strategies as possible options for action in their interim report, due at the beginning of March

In the course of preparing its full report, the panel will be looking at the experience of other countries in running government laboratories to see if they may provide a model for new institutional arrangements in the United States

Whatever proposals are finally accepted by the Administration, attempts significantly to change the current status of the laboratories is guaranteed to meet an uphill struggle in Congress, where many have powerful political supporters

David Dickson

EEC research and development

Time for success

Brussels

Vicomte Etienne Davignon, European Commissioner for Research and Development in Brussels, set alight a rather quiet meeting on the evaluation of Community research and development on Monday with a sharp attack on previous Community policies There is a "great deal of scepticism" about Brussels-sponsored research and development, he said, and it was time for some successes

Davignon singled out the seven-year gestation of the bioengineering programme, recently agreed at the Council of Ministers, as an example "We came out with a mouse," he said. If anyone believed the Commission should go through that kind of agony again, he was mistaken, said the Commissioner. The Commission should scuttle programmes far sooner when member states do not agree.

Not that Davignon is against Community support for biotechnology — far from it. Rather, he appears to detest the national bickering which delayed the programme so long. His policy now is to set up a "framework for research", a broad structure of ministerial agreement on Brussels research and development policy. The framework would stretch over, say, five years, leaving the Commission room to develop detailed programmes within the guidelines and giving nation states the chance to see a fair return on Community investment in a much wider context.

This framework is to be thrashed out in the next two meetings of the Council of Ministers for research, one in March and the next in June. If nothing happens in 1982, the momentum will be lost, says Davignon. But the transition from the present structure to the new one will be gradual. Some heads have already rolled at the Directorate-General for Research, but Davignon's cabinet insists that the night of the long knives will not last long. The objective is to use existing staff in new ways, Davignon claims — although some Commission staff remain nervous.

And to what end? To revitalize European industry. Davignon, whose commission also covers energy and industry affairs, says Brussels research and development has a way of redirecting European economic development, to fill gaps — such as in telematics and computers — in relation to the Japanese and United States competition. To achieve this, Davignon is prepared to be surprisingly flexible, and sees a role for the Commission even in helping to set up bilateral research and development projects among member states, and in giving international promotion to national centres of excellence. Davignon hopes member states will agree to his ambitious programme because of the economic risks involved in not doing so.

Robert Walgate

Fusion decision awaited

Brussels

The next EEC research council on 8 March is now likely to approve the next five-year programme on controlled thermonuclear fusion. The fear that there might be a gap in the sliding programmes, between the last budgetary allocation and this, was further reduced with the release last week of a favourable opinion from the Consultative Committee for the Fusion Programme, which considers the planned financial envelope — 1,500 million European Currency Units (£750 million) has been allowed.

Continued membership by Sweden, one of the two non-EEC countries participating, is, however, in jeopardy. The committee observes that Sweden finds the cost excessive. One difficulty is that neither Sweden nor Switzerland participates in the EEC's annual budgetary procedure, when the amount of money devoted to a programme can be adjusted. National contributions are assessed on the basis of a percentage of gross national product, and for Sweden more money for the EEC programme means less for national research.

The Commission's thermonuclear research strategy, which is to concentrate effort on the tokamak line while retaining an interest in magnetic confinement, reverse field pinch and stellerators, wins the approval of the committee, which nevertheless recommends a periodic assessment of the relevance of these side-lines to reactor development.

The committee is, however, more cautious in its views on the step to be taken after JET, the Joint European Torus now nearing completion at Culham in Britain. It recommends that plans for the next large thermonuclear machine, called NET (for Next European Torus), should be reviewed again before a decision is made in 1984. Likewise the committee is noncommittal on the need for the proposed tritium laboratory.

Jasper Becker

US university funding

Tax act fails

Washington

Universities in the United States are complaining that so far they have benefited little from the Reagan Administration's attempts to augment spending on research by tax cuts rather than direct support.

On the one hand, the tax cuts were structured in such a way that it has been equally, if not more, tempting to a company to increase its internal research efforts rather than contract work to outside groups. On the other, there is a feeling that the new incentives will have little effect on some of the largest companies which already have relatively low tax liabilities.

Two parts of the Economic Tax Recovery Act signed by President Reagan last summer were supposed to help universities, one a tax credit designed to increase industry support for basic research at universities, the other a new deduction for industries contributing research equipment to universities.

"Neither appears to hold significant promise," Dr John C Crowley of the Association of American Universities (AAU), which follows legislative affairs for the major US research universities, told a recent meeting of the American Association for the Advancement of Science.

Dr Crowley quoted a letter from Mr B J McKelvain, an analyst with General Electric Company, which has been among the most aggressive companies seeking tax incentives to boost spending on research and development. Mr McKelvain presents the company's estimate that the research tax credit will result in an increase of less than two per cent in industry-funded research.

The difference in the incentive for increased support of university research compared with in-house work is probably "negligible", Mr McKelvain had written. And although he says that the incentive for equipment donations should result in some increased giving, "we would not expect the response to have a significant impact on the critical shortage of state-of-the-art equipment available for university research".

The principal reason for this pessimistic assessment is based on the narrow scope of the tax provisions. For example, any equipment donated by a company must have been manufactured by that company and cannot contain purchased parts accounting for more than 50 per cent of the tax costs.

"Despite these limitations, the equipment donation provision is a start in the right direction. If broadened somewhat, it could have a considerable impact on the problem", said Dr Crowley, one of the co-authors of a report prepared by AAU for the National Science Foundation two years ago. This formed the basis for the Carter Administration's proposal to provide an additional $7 million in the foundation's budget for university research equipment, but was one of the first items to be cut by the Reagan Administration when it came to power last January.

As for the broader impact of the new tax laws, Dr Crowley concludes that the 1981 Tax Act offers "only token incentives for research support and donations of research equipment by industry".

This view is confirmed by officials from several major universities. Mr Stuart H Cowen, for example, vice-president for financial arrangements at the Massachusetts Institute of Technology, said that, so far, the institute had "not seen much effect of the new tax law", although speculating that companies may be holding back until the Treasury Department publishes detailed guidelines on how the law will be interpreted.

Although disappointed, few university officials are surprised at the apparent failure of the bill. Whereas they had pushed hard for inclusion in the tax legislation of a clause allowing companies to write off all contributions to university basic research against tax, the Treasury Department was not convinced that the value of this move would outweigh the costs in terms of lost revenue, the bill as finally passed by Congress merely allows for tax relief on the amount that support for such research is increased by a company.

Several congressmen are hoping to

0028 0836/82/040274 02$01 00

introduce legislation that would reinstate the original objective.

The universities are also worried about a new bill passing through Congress which could require that up to three per cent of the federal government expenditure on research and development should go to small businesses. **David Dickson**

Telecommunications

Gear on sale at last

Users of the British telephone network can now legally buy handsets from retail shops. This is the first tangible effect of the Telecommunications Act, passed last November to liberalize part of British Telecom's business. Users may, however, be disappointed that the choice of telephones on the market has not yet increased. So far, only four types of handset have been certified for sale through general retail outlets, all of which British Telecom also markets itself. Twenty-five further requests for certification are waiting in the wings.

The aim of the act is to encourage open competition between manufacturers of equipment for connection to the public network. British Telecom will still retain control of the network but will have the right to connect only the first instrument. The liberalization is to be phased over three years, starting with handsets and discrete modems (digital analog interfaces, as they are known in the trade), followed by integral modems this spring, equipment not using call switching or loudspeakers in July, simple telex-teleprinters in October and, finally, private automatic branch exchanges (PABXs) in July 1983.

The British Standards Institution (BSI) has been charged with the task of drawing up compatibility standards for each type of equipment. Certification of individual items will be taken over by a newly-created subsidiary of the British Electrotechnical Approval Board (BEAB) later in the year.

So far, the liberalization seems to be going according to plan. But users and manufacturers have been concerned that it may be too slow. The system cannot get into full swing until BSI, which must follow lengthy procedures under its charter, has drawn up standards and BEAB has set up the machinery required for certification. Moves by BSI, however, to reorganize existing staff and appoint more and to reduce the time taken for public comment on draft standards to one month seem to have quelled some fears. First drafts for seven standards including plugs, handsets, modems, teleprinters and appliances to be connected to private circuits leased from British Telecom, are due to be published within a few months. Earlier wrangles over the terms under which BEAB would operate also seem to have been resolved. It is now hoped that an independent subsidiary will go into business in July.

Meanwhile, manufacturers have little alternative than to accept the role of British Telecom, one of their competitors, as the approval agency and that of the Department of Industry in selecting applications for consideration. These interim arrangements, however, do not seem to have been a deterrent. The department has already received applications for many types of equipment, the latest being for PABXs from Ferranti, GTE, Harris Systems, Mitel Telecommunications, ITT Business Systems, Philips Business Systems, and Plessey Office Systems. One company, International Business Machines, is planning to be use the liberalization to introduce equipment new to the British market. It is installing an Integrated Networking System, which allows separate telephone switchboards to operate as one, at the American Express International Banking Corporation.

On terminal equipment at least, there seems to be continued optimism that the liberalization will work without destroying too many manufacturers' hopes.

Judy Redfearn

Soviet biotechnology

Keeping a secret

Last month's annual general meeting of the Soviet Academy of Sciences placed a special stress on the development of Soviet biotechnology. Academician Ovchinnikov stressed especially the achievements of biotechnology. Soviet scientists, he said, were now leading the world in "a number of very important branches of biology".

Ovchinnikov's summing-up covers a major confrontation during the past year among scientists involved in biotechnology. There appears to have been a power struggle between Ovchinnikov and his supporters from the physical chemical wing and Academician Dubinin representing the biologists. After some manoeuvring, Ovchinnikov emerged victorious and Dubinin retired from active scientific life. At the same time, there was considerable criticism in the Soviet press of the management of molecular biology research which, since May 1974, has had "top priority" status.

Another and more interesting confrontation has apparently been going on between the academy's biologists and the military scientific sector. This began two years ago when Professor David Goldfarb, a Jewish biologist, applied to emigrate to Israel. Professor Goldfarb had previously been involved in work on bacterial plasmids, and therefore, according to the emigration authorities, his work could be classified as secret. Several Western scientists wrote to Academician Ovchinnikov on Professor Goldfarb's behalf, but received only noncommittal answers. According to the latest information, however, certain academicians have spoken out clearly to say that in their opinion Professor Goldfarb's work was not secret. This accords with the fact that Professor Goldfarb was never cleared by the security authorities for access to secret information. The whole matter appears to reflect not merely the usual blocking of a Jewish scientist wishing to emigrate but a genuine conflict between the academy and the security establishment over what is and is not secret information in the field of biotechnology. **Vera Rich**

Pasteur institute

Rien ne change pas

Paris

François Gros, science adviser to the prime minister of France, has thrown in his lot with politics. He has resigned as director of the Institut Pasteur in Paris, one of the most famous of laboratories. The laboratory was founded in 1888 by Louis Pasteur, and since then it has been directed by a series of well-known biologists. Gros, a Nobel laureate himself, took over from Jacques Monod. The call of the new politics in France must be great!

The new incumbent — who took up his job this month — is Raymond Dedonder, 60, previously director of the Institute of Molecular Biology of the University of Paris. Dedonder is a microbiologist with a strong inclination towards the application of his work to the economy and to medicine — something already well-established in the tradition of the Pasteur. He has worked with *Bacillus subtilis*, of interest to industrial genetic engineering, and with *Bacillus thuringiensis*, contributing to the development of a bacterial toxin against certain insects.

It is unlikely that Dedonder will much change directions at the Pasteur. He spent a large part of his early career there and so is a "Pasteur man" — and Gros himself is likely to continue to take a fatherly interest from the prime minister's office.

So plans made under Gros's directorship — and, in fact, under the previous government — will not change. A new laboratory of immunology has been established and a laboratory of biotechnology will be set up, to come into operation in 1984. The independent management of the Pasteur is likely to continue, despite the fact that half the institute's money comes from government. Dedonder believes that far from wanting to nationalize the Pasteur — as some have suggested — the government wishes to take it as a model of fruitful symbiosis between basic and applied research.

The one change that may come with the new directorship — and new government — is a greater emphasis on the overseas laboratories of the Pasteur, particularly those in Third World countries, such as the Instituts Pasteur in Tunis, Algier, Casablanca, Dakar and so on, in line with the government's foreign policy. Dedonder will be encouraging that development. **Robert Walgate**

0028-0836/82/040275-01$01 00

CORRESPONDENCE

All in The Book

SIR — Creationism is on the march again, not only in the United States, but, as the letter from the Glasgow creationists shows (*Nature* 26 November 1981, p. 302), in the United Kingdom as well. For a concept as theoretically and scientifically destitute as creationism, it is surprising to many that the idea keeps coming back. It seems to have the resilience of herpes.

It is neither easy nor much fun to argue with such grass-roots ignorance in a calm and civil manner. Consequently, lest the following comments be construed as arrogant, condescending, and supercilious, I trust that the Glasgow group will take them with good spirits. The Scots are, after all, renowned for their spirits.

Why do these people channel their vast intellectual energies against the innocuous theory of evolution? Why not against the pernicious satanic forces of quantum mechanics or particle physics? Why do they insist upon biblical literalism only in this specific case? After all, *Leviticus* **11** 19 classifies the well-known mammal, the bat, as a bird. Jesus Christ (in *Luke* **23** 43) says to his friends on the cross, "Today you will be with me in paradise," but everybody knows he did not show up in paradise himself until three days later. Why should anyone want to take *Genesis* **1** more literally?

Nineteen centuries ago, Josephus wrote that Moses "speaks some things wisely, yet enigmatically, and others allegorically" (*Antiquities of the Jews*, Preface, 4). Slightly later, the early Church father Origen wrote in his *De Principiis* (IV,i,5) "Who that has understanding will regard the statement as truthful that the first three days existed without Sun, Moon, and stars, and the first day without even a sky? And who is so ignorant as to suppose that God, as if a husbandman, planted a real tree in Eden such that anyone eating of it with bodily teeth should obtain life, and, eating of another tree, should come to the knowledge of good and evil? … No one, I think, can doubt that (these things) are related figuratively, not literally, in Scripture, and some mystical meaning may be indicated by it."

A single millennium after that (and before now) Maimonides concluded (*Guide for the Perplexed*, II, xxv) "If we accepted the Eternity of the Universe … and assumed, with Plato, that the heavens are likewise transient, we should not be in opposition to the fundamental principles of our religion." If the Bible was taken figuratively by scholars tens of centuries ago, who presumes to assert that it must now be taken at face value? What new information affirms the inerrancy of the Bible more now than in the time of Christ or Aquinas?

As a work of mythology and moral precepts, the Bible is probably as good as anybody's … except, of course, where Jael kills Sisera by nailing his head to the floor, Dinah is raped by Shechem and Lot is seduced by his own daughters. However, the Bible is neither among the most original nor imaginative of such works, as a glance through the mythology of nearly any culture on Earth will quickly reveal.

Nevertheless, those fatuous enough to require a biblical justification for everything, including evolution, might turn to *Ecclesiastes* 3 19 — "For that which befalleth the sons of men befalleth beasts … As the one dieth, so dieth the other, yea, they have all one breath, so that man hath no pre-eminence above a beast, for all is vanity. All go unto one place, all are of the dust, and all return to dust."

The creationists claim that we may come to know the Creator by deducing Him from his work on Earth. Well, we know that there are 750,000 species of insect now alive. Anyone who has ever had a conversation with an entomologist knows what a deadly dull lot those fascinated by insects can be. To envision the Creator expending his divine energy on three-quarters of a million different, meticulously crafted bugs necessitates an image of Him as a dismal, insufferable, cosmic bore!

The patterns of the history of life also argue eloquently about the Creator's revelation of himself. As Haldane put it half a century ago "Most lines of descent end in extinction, and commonly the end is reached by a number of different lines evolving in parallel. This does not suggest the work of an intelligent designer, still less of an almighty one."

Similarly, the fact that humans and chimpanzees hold more than 97 per cent of their genetic material in common should suggest that either they have evolved from a recent common progenitor, or that they were zapped into existence independently by Someone lacking a great deal of imagination.

The belief in such an Omnipotent Simpleton is certainly a matter of personal choice, but his existence (or lack thereof) is completely independent of the reality of evolution. For the natural world all but cries out for us to acknowledge phylogenetic relationships, and these relationships will be equally real to science whether or not deities exist.

Thus, evolution is not atheistic, it is agnostic. The existence of deities is not denied by evolution — it is ignored, because it is irrelevant. The study of evolution is the study of the diversity and unity of known life, the existence of God is as relevant to evolution as the existence of giant boll weevils on the planet Antares. Either things have evolved, or they are designed to appear to have evolved — either way, science leads to the conclusion of evolution, the only paths to non-evolution are fraud and obscurantism.

Finally, one need only compare the last page of the first and sixth editions of *The Origin of Species* to see that even Darwin never completely ruled God out.

Well, everybody makes mistakes.

Tucson, Arizona, USA

Safe as 2,4,5-T?

SIR — One of us (H.F.T.) reported last year on 2,4,5-T use and congenital abnormality rates in Hungary[1]. Since that report more information has become available on the herbicide used and on congenital abnormality and spontaneous abortion rates.

The Hungarian herbicide is applied either as Klorinol, the 2,4,5-T precursor, 2,4,5-trichlorphenoxyethanol (2,4,5-TE), or as Buvinol, a combination of 2,4,5-TE with *S*-triazine. Buvinol is one of the most important products of the Budapest Chemical Works, which marked its 100th anniversary by publishing a book about it entitled *The Development of a Pesticide as a Complex Scientific Task*[2]. This monograph was published "as a tribute to the skill and many years of painstaking work performed by the research team and to reflect the standard and modern conditions of Hungarian pesticide research"[2]. The editor suggests that the development of Buvinol "may be considered a real — even if not ideal — model of modern pesticide research"[2].

Development of the chlorinated phenoxy alkanols was conducted between 1962 and 1975. In 1969 contamination of 2,4,5-TE by dioxin (TCDD, 2,3,7,8-tetrachlorodibenzo-*p*-dioxin) was discovered. The level of TCDD contaminant until mid-1972 was up to 1.6 p.p.m. After that date improvements in the formulated product reduced the TCDD contaminant to levels below 0.1 p.p.m. The extensive animal testing of 2,4,5-TE and Buvinol included studies of acute toxicology, neurotoxicology, teratogenicity and carcinogenicity[2]. Chromosomal studies were also undertaken of workers manufacturing 2,4,5-TE and Buvinol[2]. The general conclusion reached on the basis of all these studies was that if proper labour safety measures were taken and the relevant regulations for residues observed, no health hazard would arise. The production and consumption of 2,4,5-TE in Hungary has therefore continued to rise. In 1976, 1977 and 1978 consumption of 2,4,5-TE (total product) was 1,278, 1,533 and 1,753 tonnes respectively[3]. Trends in congenital anomalies and stillbirths have continued as described previously[1] despite rising herbicide consumption.

Between 1970 and 1980, there has also been a consistent fall in the national spontaneous abortion rate (16.3 to 11.8 per cent of all recorded conceptions, excluding those terminated by induced abortion). The highest rates of fetal deaths occur in Budapest and the lowest in the country areas. There have been no reports in Hungary linking congenital abnormalities or spontaneous abortions with the use of 2,4,5-TE. Furthermore, a study of female agricultural workers exposed to 2,4,5-TE found no evidence that their offspring had a higher rate of congenital abnormalities[4].

NEWS AND VIEWS

Mirror-image navigational errors in migrating birds

from Jared M. Diamond

EXAMPLES of the navigational accuracy of migrating or homing birds are plentiful the Arctic Tern commutes 18,000 km between its Arctic breeding grounds and sub-Antarctic wintering grounds, the Laysan Albatross is born on Midway Atoll and wanders the ocean for about eight years before returning to Midway to breed, the first year young of New Zealand's Long-tailed Cuckoo head out over the Pacific, unaccompanied by adults, to find and winter on tiny islands up to 8,000 km away But there are also examples of navigational 'failure' These could be of special significance because they may give us some insight into how navigation normally occurs

Particularly interesting are examples[1–5] of mirror-image navigational error The phenomenon was first observed in western North America by David DeSante (Point Reyes Bird Observatory, Stinson Beach, California) He found that some out-of-place birds appearing on the California coast in autumn were following a westerly bearing which was a mirror image of their normal migration path, that is, they were taking the correct bearing with respect to the north–south axis, but choosing the wrong east-west (right–left) sense of that angle He made map comparisons of the aberrant and normal migration tracks and their timings and carried out behavioural tests which proved the captured vagrants unable to tell left from right in the test context[6–10]

The story starts in the 1960s, when growing numbers of bird-watchers on the coast of California began searching for rare birds It turned out that, in the autumn, rare individuals of almost every species of New World warbler (Parulidae) typical of eastern North America appeared on the west coast[11, 12] However, different warbler species were very differently represented among these rare vagrants, two species (Blackpoll and Palm Warblers) accounting for nearly as many records as the other 28 species These vagrants could not be just wind-blown birds, as had been previously suggested[13,14], for then warblers starting from the same breeding grounds would reach California simply in proportion to their breeding abundance Relative abundances combined with small deviations from the normal migration route can account for some of the differences among species[12] but big unexplained anomalies are left

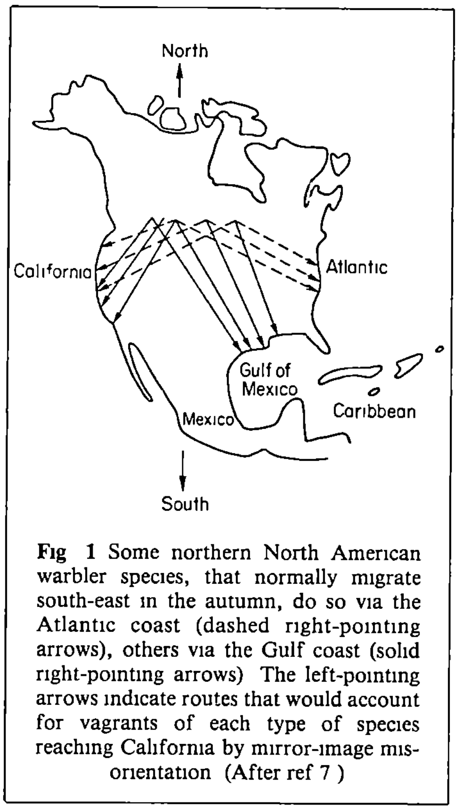

Fig 1 Some northern North American warbler species, that normally migrate south-east in the autumn, do so via the Atlantic coast (dashed right-pointing arrows), others via the Gulf coast (solid right-pointing arrows) The left-pointing arrows indicate routes that would account for vagrants of each type of species reaching California by mirror-image misorientation (After ref 7)

Parulid warblers normally set out from their breeding grounds and fly overland in a series of single night flights, covering about 300 km in a night and resting about four days between flights to feed and replenish fat reserves They then make a long overwater flight across the Gulf of Mexico, Caribbean, or west Atlantic to reach their wintering grounds in Central or South America or the West Indies During the overwater flight landmarks are absent, and it is thought that immature birds, on their first autumn flight south, follow a given (genetically specified) compass direction for a given distance or time[15] They thus need an inherited knowledge of the correct compass bearing, plus the ability to determine a compass reference point (for example, by circumpolar stars[16]) to follow the correct migration route Adults, on the other hand, have already made one round trip and are thought to have knowledge of the map coordinates of the breeding and wintering grounds plus an ability to determine their present location Over ninety per cent of the vagrant autumn parulids on the California coast are immatures, presumably dependent on 'distance-and-direction' navigation

Misorientation and disorientation

Timing of west coast arrival makes it possible to distinguish errors of *mis*orientation from errors of *dis*orientation, that is, an inability to follow *any* consistent direction For each species DeSante tabulated the mean arrival date of normal (easterly) migrants at stations on the US Atlantic or Gulf coasts and, measuring distances from the centre of the breeding range, predicted a date of west coast arrival assuming a direct great-circle flight path and one 300 km night flight every four days (see Fig 1) The predicted arrival dates for each species agreed, on average, with the observed ones to within one day, even though the arrival time of different species differed by nearly a month and the west and east coast arrivals of the same species also differed by up to a month because of the different distances from the breeding grounds The vagrants are thus not *disoriented* but *misoriented* they are covering distance at the same rate as normal migrants, but on the wrong bearing

What type of misorientation error might the vagrants be making? One simple possibility, that the birds were following a reversed (180° out) bearing that would be appropriate for the return to the breeding grounds in the spring can be ruled out by a glance at the map — the commonest vagrant species breed entirely north of California Are the vagrants following an actual mirror image of their normal orientation path or are they simply mis-

oriented in the sense of having inherited the wrong bearing or a wrong reference point?

Most of the vagrants can be assigned to two groups those that normally bear far east from their breeding grounds to the Atlantic coast, then fly over the western Atlantic to the West Indies or South America, and those that normally bear closer to south to the Gulf Coast, then across the Gulf of Mexico to Central America The two possibilities above make quite different predictions when one compares the Atlantic and the Gulf migrants with respect to their frequency and time of arrival in different parts of California Mirror-image misorientation would, for instance, cause the northern California contribution to all Californian records to be higher for Atlantic than for Gulf migrants, while simple misorientation would not

Examination of the data consistently indicated mirror-image misorientation This conclusion is consistent with the different frequencies of different species or vagrants the two most frequent vagrants are Atlantic migrants, although they are much further off-course than Gulf migrants in California

Mirror-image misorientation in the laboratory

It is no easy task to demonstrate mirror-image misorientation in the laboratory because it is, after all, rare even to *see* the vagrants in California, let alone catch them All Californian bird-watchers combined saw only about 150 individuals per year in the decade 1962-72

De Sante went to the isolated Southeast Farallon Island off the California coast, where lost overwater migrants concentrate, and succeeded in catching alive, in three years' autumn operations, 24 individuals of the commonest vagrant, the Blackpoll Warbler Under a clear moonless sky he tested them individually in an Emlen cage, an inverted paper cone with an ink pad at the bottom, such that the bird fluttering up the cone (about 80 times per hour) marks its direction with inked footprints To analyse the inkmarks, DeSante devised optical scanning techniques and new statistical methods for recognizing multiple modes in a circular distribution, these are important and deserve to be more widely known

The vagrants oriented not just in the expected mirror-image direction (WSW), but in four preferred directions (Fig 2)[1] One mode was about 125° (ESE), the angle of the normal migratory track The second was its mirror image, about 235° (WSW), the angle expected for a mirror-image misorientation flight from Canada to the California coast The other two modes were about 305° (WNW) and 55° (ENE), the 180° reverse tracks of the other two modes

The 180° reverse modes are easy to explain most autumn migrants on the Farallon Islands arrive from the south-west, having overshot the California coast and the islands in their southwesterly flight at night, and doubled back north-east on their track in the morning Orientations cage studies on normal migrants have also noted 180°-reversed modes along with normal modes A reasonable interpretation is that the best strategy for a nocturnal migrant finding itself at dawn over ocean or unsuitable habitat is to fly back up its track until it regains the coast or suitable habitat.

But why did the migrants orient ESE and WSW with equal frequency, when only a WSW track could account for their appearance in California and an alternating ESE/WSW track would have taken them in a zigzag south? In the cage experiment they could not tell left from right, whereas on migration they systematically chose right In both humans and animals, left and right reflex responses are often encoded together, and subsequent success at left/right discrimination depends on available motor and sensory cues[17] It seems likely that both normal and vagrant warblers inherit a knowledge of the correct angle with respect to the north–south axis, that the normal warbler can also use sensory cues to choose the correct east–west sense, but that the vagrant initially chooses the sense at random on the first night and then maintains that sense on subsequent nights

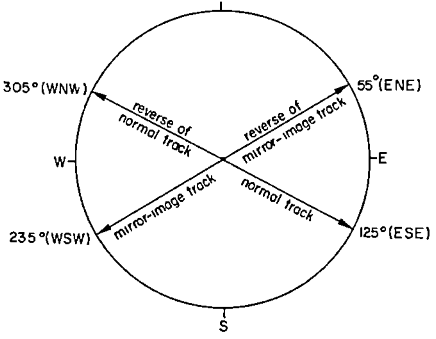

Fig. 2 The four preferred orientations of caged Blackpoll Warblers caught as autumn vagrants in California (After ref 7)

Evolutionary origins

Parulid warblers have extended their breeding ranges far to the north-west since the retreat of the Pleistocene glaciers and may still be sorting out the new navigational techiques needed, including left–right discrimination Most of the mirror-image vagrants probably end up far offshore in the Pacific and die There are, however, several cases of banded mirror-image vagrants returning to the same California location in three consecutive winters Two warbler species, the Townsend's Warbler and 'Myrtle' race of the Yellow-rumped Warbler, have regular west coast winter ranges isolated from their main winter ranges to the south and east, at locations consistent with mirror-image migration Hence mirror-image misorientation may occasionally lead to the evolution of new winter ranges

A worldwide phenomenon?

Observations suggestive of mirror-image misorientation have been described from three other parts of the world First, MacLaren[4] noted the occurrence of western warblers in eastern North America They may have taken the mirror image (NE) of their normal (NW) migration path from their Mexican wintering grounds up the axis of Mexico Second, the Old World warbler species *Phylloscopus proregulus, P inornatus, P trochiloides* and *P borealis* (Sylviidae) breed in Siberia and normally migrate due east in the autumn before heading south, but regularly appear in low numbers as autumn migrants in western Europe[1,18] Other species whose autumn vagrancies in western Europe suggest mirror-image misorientation include the pipits *Anthus novaeseelandiae* and *A gustavi*, and the warbler *Phylloscopus fascatus* Third, several races of the wagtail *Motacilla flava* that breed in Siberia and normally migrate south-west in the autumn occasionally winter in Australia and New Guinea, suggesting a mirror-image flight to the south-east[2,3] Finally, vagrants of numerous species that breed in north-east Asia and normally migrate south-west follow a mirror-image course south-east to western Alaska and the Aleutian Islands, and rarely down the North American coast as far as California[5] Systematic re-examination of off-course migrant records elsewhere in the world, especially Europe, could yield further examples of mirror-image misorientation

Finally, we might speculate that De Sante's work will be linked to the neuropsychological literature on left–right discrimination in humans and other animals Humans with impaired left–right discrimination[19-22] often prove to have lesions in particular parts of the cerebral cortex and other associated sensory and motor problems Behavioural and neuroanatomical studies of captured mirror-image migrants may indicate whether birds and humans with impaired left–right discrimination share similar defects □

Meteorite erosion and cosmic ray variations

from David W. Hughes

A METEORITE has had a chequered career before it finally ends up in a museum store room. It seems that meteorites were formed about 4.6×10^9 yr ago, but spend a great deal of their time buried in some larger body; each type is exposed to the space environment for a different length of time, although a typical value is 10^7 yr.

The length of the exposure can be estimated by looking at the damage inflicted on the meteorite by cosmic ray bombardment. Nuclear reactions are induced in the elements in the surface regions, and leave behind tracks of radiation-damaged material analogous to the tracks produced by nuclear fission. The tracks extend tens of centimetres into meteorites retrieved from the Earth's surface. If the abundance of the reaction products can be measured and their production rate in space is known, then the exposure age can be simply calculated. Measurements of the rate at which the track density varies as a function of depth can lead to an accurate estimation of the amount of material ablated from the meteorite during its passage through the atmosphere.

A problem remains, however. The exposure ages given by measuring the nuclide ^{40}K (half life 1.3×10^9 yr) are systematically 45 per cent longer than those obtained by measuring relatively short-lived nuclides such as ^{39}Ar, ^{36}Cl, ^{26}Al and ^{10}Be which have half lives of 270, 3×10^5, 7×10^5 and 1.5×10^6 yr respectively. The difference may be caused by a temporal variation of the intensity of galactic cosmic rays. If the intensity was 45 per cent higher over the last 10^6 yr than it had been over the previous 10^9 yr, then the anomaly would be resolved. A second solution is possible if variations in exposure ages are due to some mechanical process such as multiple collisions in the Solar System or the erosion of the meteorite surface. The problem has now been tackled by O.A. Schaeffer, K. Nagel, H. Fechtig and G. Neukum at the Max-Planck-Institut für Kernphysik, Heidelberg, and their findings have been published in *Planetary and Space Science* (**29**, 1109; 1981).

Multiple collisions

A specific meteorite could have spent a considerable time shielded from the cosmic ray flux below the surface of a larger body. If the larger body was then fragmented in a collision the meteorite could find itself in a less shielded position. If the less shielded exposure lasts longer than a few times the half life of the relatively short-lived nuclides (that is, longer than a few million years), the ^{10}Be, ^{36}Cl and ^{39}Ar will be in equilibrium with the high flux whereas the ^{40}K will still register the low flux. Unless the change in shielding is always the same — something that is highly unlikely — the ratio of the two exposure ages will vary from meteorite to meteorite. That ratio has been measured accurately in only twelve meteorites. Eight of them have the ^{40}K exposure age 1.45 ± 0.10 times the short-lived nuclide exposure age. The authors conclude that it is most unlikely that such a large fraction of meteorites has suffered collisions which produce the same exposure age ratio; so the cause of this discrepancy must be something other than their collision history.

Space erosion

An exposed meteorite is continually being cratered by collisions with cosmic dust particles at planetary velocities. As the surface is eroded, over time the cosmic ray intensity at a given depth inside the meteorite increases. Schaeffer, Nagel, Fechtig and Neukum calculate the expected erosion rate in some detail.

Only three meteorites, Přibram, Lost City and Innisfree, have known 'out of atmosphere' orbits. Comparing these orbits with those obtained for the meteoroids responsible for very bright fireballs seen by the camera networks gives a mean aphelion distance of 2.8 AU for the average meteorite.

Using satellite and lunar microcrater data the authors estimate how the flux of microparticles (diameters 1 μm to 1 cm) striking the meteorite surface varies as a function of particle size and distance from the Sun. The collisional velocities of these microparticles have also been calculated as a function of heliocentric distance. It is found that the impact velocity of the 1 – 10 μm particles varies between 15 and 5 km s^{-1} as the meteorite moves between points 1.25 and 3.75 AU from the Sun. Larger particles, with diameters between 100 μm and 1 cm, seem to have a relatively constant impact velocity of around 9 km s^{-1}.

From laboratory experiments, where silicate surfaces were exposed to collisions with small particles, the authors found that the volume, V, excavated by an impacting particle of diameter d is given by $V = 7.94\ d^{3.236}$. Integrating over particle sizes, the meteorite orbit produces a mean erosion rate for stoney meteorites of 650 μm per million years.

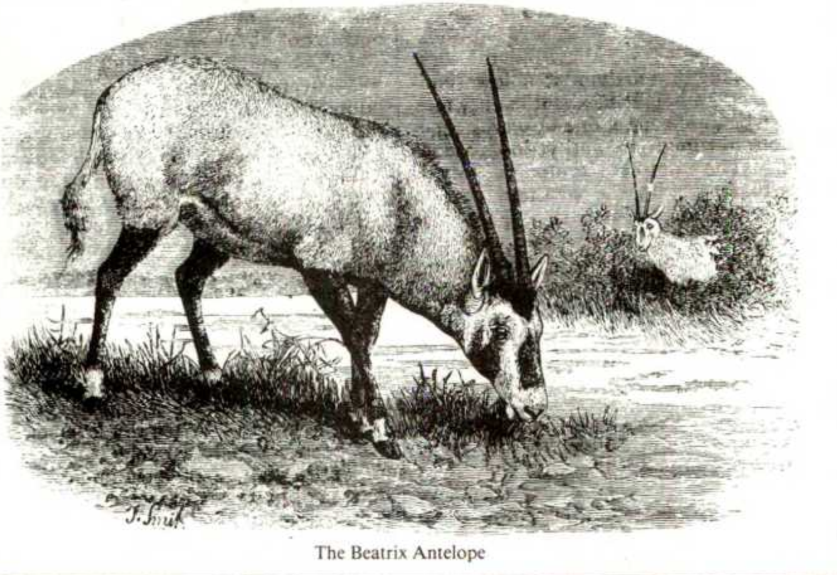
Dust particles hitting iron meteorites excavate less material, and laboratory experiments using a light gas gun to accelerate particles indicated that the eroded volume of iron was a factor of 30

100 years ago

ILLUSTRATIONS OF NEW OR RARE ANIMALS IN THE ZOOLOGICAL SOCIETY'S LIVING COLLECTION

THE Beatrix Antelope (*Oryx Beatrix*). — The antelopes of the genus *Oryx* constitute a well-defined and most beautiful group of the Bovine Family. In 1857, the late Dr. Gray described a new *Oryx* species based upon an animal received from Bombay, but supposed to have been originally brought from some port on the Red Sea. The Beatrix Antelope, as it was named by Dr. Gray after the Royal Princess of that name, remained a somewhat obscure species until 1872, when, singularly enough, a second living example was received from Colonel Pelly, H.B.M. Resident at Bushire, and deposited in the Society's collection. In 1878 a third example of the same antelope was received by the Society from Commander Burke, of the S.S. *Arcot*. This animal was obtained at Jedda, but was stated to have been originally captured in the Hedjez passes, some 150 miles in the interior of Arabia. The fourth example of this antelope, lately presented to the Society by Lord Lilford, comes from a still more definite locality, the great desert behind the mountainous district of Oman. It is now therefore abundantly evident from these four examples, which agree in all material points, that the Beatrix Antelope is a good and well-defined species, and that its native home is the interior of the Arabian peninsula, where it replaces the Beisa of the Abyssinian plateau.

From *Nature*, 26 January, 295, 1882.



The Beatrix Antelope

David W. Hughes is in the Department of Physics, University of Sheffield, Sheffield S3 7RH.

0028-0836/82/040279-02$01.00

smaller than that for silicate rocks. So the erosion rate for iron meteorites is about 22 μm per million years.

The authors investigated the possibility that the dust particle flux had varied as a function of time. Microcraters on lunar rocks indicate that the flux has remained constant within a factor of 2 for the last 20 million years. There is no information about the small particle flux before this time. As regards large craters, however, it can be concluded that the flux of objects responsible for craters with diameters between 0.01 and 100 km has remained constant to within a factor of 50 per cent for the last 850 million years. By comparing craters on Mars with those on the Moon the authors concluded that there has been no change for nearly 10^9 years in all regions of the Solar System between 1 and 4 AU from the Sun.

The discrepancy between the ^{40}K exposure ages and the ^{39}Ar, ^{10}Be and ^{36}Cl exposure ages could be explained if the erosion rate of iron meteorites was 200 μm per million years, but it has been found to be nine times less; or if the flux of small particles had increased, but it has been found to be constant for about the last 10^9 yr; or if meteorites had had the same collision history, but this is highly unlikely. So one is left with the conclusion that there has been a real change in the cosmic ray flux in the inner Solar System during the last 10^9 yr. And the meteorites indicate that the present flux, the one active over the last 10^6 yr, is about 45 per cent higher than the average flux over the previous 10^9 yr. The next problem, needless to say, is to find out why the cosmic ray flux changed. □

Prohormones for vasopressin

from B. T. Pickering

"STUDIES on the distribution and biosynthesis of neurophysin within the neurones of the [hypothalamo-neurohypophysial complex] suggest the interesting possibilities that either neurophysin and vasopressin share a common precursor or that there is a common genetic unit that controls the synthesis of the major components of the neurosecretory substance." Thus wrote Howard Sachs in 1969[1] and, during the past 12 years, more and more evidence has accumulated in favour of such a common precursor (see, for example, ref.2). The final vindication of Sachs's suggestion is reached today with the publication, by Richter and his colleagues, of the complete amino acid sequence of the bovine vasopressin–neurophysin precursor (see this issue of *Nature*, p.299).

This sequence, deduced from cDNA prepared from hypothalamic mRNA, reveals no surprises, being composed of a leader (or signal) peptide separated by a pair of basic residues from the sequence of arginine vasopressin which is followed by a glycyl residue and a further pair of basic amino acids and then the 97 residue sequence of bovine neurophysin II. The 17.3K precursor is completed with a carboxy-terminal 39 residue polypeptide which represents the glycopeptide known to coexist with vasopressin and neurophysin in the secretory granules of the neurohypophysis[3,4]. Such a sequence had already been predicted in several laboratories, both from isolation of putative precursors labelled *in vivo* and from the nature of the polypeptides synthesized in cell-free systems directed by hypothalamic mRNA. This is not to detract from the latest work of the Richter group, which has not only substantiated the size of the vasopressin precursor but established the order of the component polypeptides within the sequence. It will be interesting to see the nature of the carbohydrate side chain, the biological importance of which is unknown. Even more so because there is no evidence for such glycosylation of the oxytocin precursor which is considerably smaller than the vasopressin one. No doubt the Richter group will soon provide the cDNA, and hence the sequence, of this precursor too.

The successful elucidation of the nature of this vasopressin precursor, while concluding a chapter, does not end the story. As discussed in these columns last year[5], Paul Cohen and his group in Paris have drawn attention to the presence in bovine posterior pituitary extracts of much larger molecules (140K) containing the immunodeterminants of neurophysin and vasopressin and thus qualifying for consideration as putative precursors. This work has now been extended[6] and the 140K species has been shown to behave as one of 80K if examined under denaturing conditions. Moreover, this material appeared to consist of two components, linked by both a labile peptide bond and a disulphide linkage, which could be dissociated to give a 10K polypeptide that showed sequence homology with neurophysin and a 68K one which lacked the immunodeterminant for neurophysin. Rosenior *et al.*[7] also have evidence for immunoreactive vasopressin and neurophysin species of about 80K and 40K in rat hypothalamic extracts, and consider them to be putative precursors.

Arguments against such precursors come from the failure of extracted mRNA to direct the synthesis of products larger than 20–25K and, now, from the apparent completeness of this message with start and stop codons. The French group has argued that the 80K molecule might be directed by a different mRNA than the one preferentially extracted. However, in none of the *in vivo* studies has there been indications of incorporation of tracer amino acid into immunoreactive neurophysin or vasopressin species larger than 25K so that such a message would necessarily be present in minute amounts — much smaller than would be suggested from the relative proportions of larger vasopressin components found by Rosenior *et al.*

Very recently the 80K vasopressin/neurophysin putative precursor has taken on even more significance. Cohen and his colleagues have shown[8] that its 68K fragment contains immunoreactive sequences for both ACTH and β-endorphin, and that biologically active ACTH can be released from it by limited proteolysis. They interpret their data to suggest the existence of a pluripotent molecule which is a common precursor for all, or many, of the neuropeptides found in the posterior pituitary and which they term neurohypophysial coenophorin.

Quite apart from the rigorous criteria necessary to ascertain that large molecules, especially those rich in disulphides, do not arise from self-association of smaller ones (criteria which have been applied by Cohen and his associates), it should perhaps be questioned whether a large polypeptide containing within it the sequence of a smaller one is necessarily a precursor of the latter rather than vice versa. As part of the secretory process a newly synthesized polypeptide is packaged into secretory granules and, in every system which has been studied, there is evidence for a proportion of the secretory product being bound to the granule membrane. Could the large molecules discussed above represent such membrane-bound components which are in fact covalently linked to membrane proteins? Certainly a membrane-associated component from the ACTH system might share many of the properties of a similar component from the neurohypophysial system. Its presence in neurohypophysial extracts might arise from the close association of the pars intermedia and the pars nervosa in the pituitary gland.

Whatever their origin, these large molecules do present a fascinating problem, the solution of which will tell us much more about the nature of the secretory process in the polypeptide-producing cell. □

Is phosphatidylinositol now out of the calcium gate?

from J.N. Hawthorne

PHOSPHATIDYLINOSITOL (PI) is a minor phospholipid constituent of most mammalian cell membranes and has attracted attention because of its response to the activation of a wide variety of surface receptors. Most of the receptors concerned mobilize calcium as a second messenger and Michell[1] suggested in 1975 that PI hydrolysis opened cell surface Ca^{2+} channels. His hypothesis has been particularly fruitful but recent results make it untenable as a general explanation of the PI response.

The original observation of Hokin and Hokin[2] illustrates the PI response. When treated with acetylcholine, slices of pigeon pancreas secreted amylase. If the incubation medium contained ^{32}P-labelled inorganic phosphate, secretion was accompanied by increased labelling of phospholipids which were later identified as PI and its precursor, phosphatidic acid. It is now generally believed that receptor activation causes hydrolysis of PI to diacylglycerol and inositol phosphates and that the labelling seen in the Hokin experiment reflects subsequent resynthesis of PI. The proposed cycle of events and Michell's suggested link with calcium gating are outlined in the figure.

As a mechanism for controlling Ca^{2+} influx, breakdown and resynthesis of PI seems rather cumbersome. The initial hydrolysis is presumed to be at the plasma membrane, though there is little clear evidence of this. A kinase producing phosphatidate from the resulting diacylglycerol may occur in the same membrane, but the remaining enzymes for PI resynthesis are located on endoplasmic reticulum, so that there are transport problems. Another difficulty is that the phospholipase hydrolysing PI in response to receptor activation is located in the cytoplasm, rather than in the plasma membrane as required. Resynthesis is also costly to the cell, because it involves the loss of three high-energy phosphate bonds. This seems an expensive way to move calcium ions down a concentration gradient.

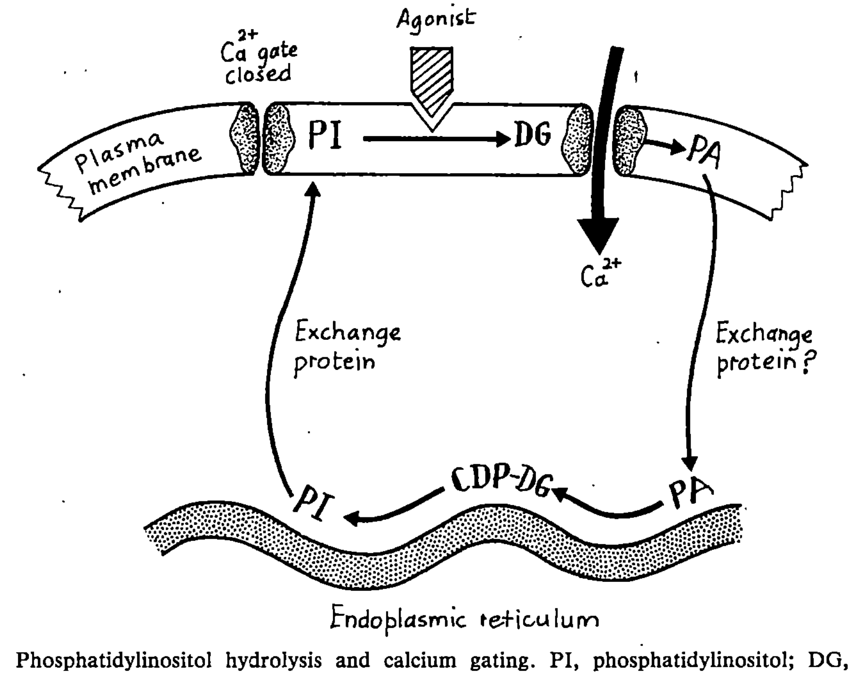
The cytoplasmic phospholipase just mentioned is activated by Ca^{2+}, suggesting that PI breakdown might be a consequence rather than a cause of Ca^{2+} mobilization. However, the PI effect usually seemed to be independent of extracellular Ca^{2+} and this provided an important argument in favour of the calcium gating theory[1,3]. Further support came from the fact that in several systems calcium entry in response to an ionophore did not cause hydrolysis of cellular PI. However in a number of tissues studied more recently, PI hydrolysis appears to depend on external Ca^{2+}. Some of these results, and their implications, have been reviewed by Cockroft[4]. Furthermore, reinvestigations of pancreas and adrenal medulla, which originally provided support for the gating theory, now provide results contrary to it.

Farese *et al.*[5] repeated the original Hokin experiment, showing that cholinergic release of amylase from rat pancreatic fragments was accompanied by a chemically measured loss of PI. Removal of calcium abolished both effects and the calcium ionophore A23187 itself caused PI breakdown in a medium containing 2.5 mM Ca^{2+}. This implies that the PI loss follows calcium mobilization. Work with rabbit neutrophils led to a similar conclusion[6]. Stimulation of these cells with the peptide fMet-Leu-Phe in the presence of cytochalasin B caused secretion of lysosomal enzymes and breakdown of PI. Extracellular Ca^{2+} was essential for the PI breakdown, which could be produced in response to the calcium-carrying ionophore ionomycin, as well as to the peptide agonist. In platelets also, hydrolysis of PI can be promoted by either thrombin activation or a calcium ionophore[7].

Bovine adrenal medulla presents a different picture. The PI response is to muscarinic but not nicotinic activation, and it is certainly independent of external Ca^{2+}. However, the physiological response, catecholamine secretion, is mediated by nicotinic receptors and associated with an influx of Ca^{2+}. Muscarinic receptors probably modulate the secretory process and their activation[8] causes no measurable entry of Ca^{2+}. Cholinergic muscarinic receptors present a more general difficulty in understanding the PI effect. The post-synaptic ones produce secretory effects by opening calcium gates but the pre-synaptic muscarinic receptors usually inhibit secretion. The mechanism by which they act is not understood, but it is likely that they decrease calcium availability. Yet activation of both pre- and post-synaptic receptors produces breakdown of PI.

Results from some tissues in which receptors control Ca^{2+} mobilization still provide support for Michell's hypothesis. One of the most impressive comes from the blowfly salivary gland[9]. This gland secretes iso-osmotic KCl when stimulated by 5-hydroxytryptamine, a process involving PI breakdown and entry of calcium into the epithelial cells. Continued treatment with the agonist causes loss of a small pool of PI and a fall in Ca^{2+} transport. Incubation of the washed glands with inositol restores both PI sensitivity to 5-hydroxytryptamine and transport, indicating close links between receptor activation, PI hydrolysis and calcium influx. In spite of this, there are so many systems in which the receptor-linked PI loss requires external calcium that a universal role for PI in Ca^{2+} mobilization cannot be upheld.

Michell's insistence on a link with Ca^{2+} should not be lightly set aside and in this respect triphosphoinositide and diphosphoinositide, the phosphorylated derivatives of PI, are of interest. They are highly labile, have considerable affinity for



Phosphatidylinositol hydrolysis and calcium gating. PI, phosphatidylinositol; DG, diacylglycerol; PA, phosphatidate.

J.N. Hawthorne is Professor in the Department of Biochemistry, University Hospital and Medical School, Clifton Boulevard, Nottingham NG7 2UH.

0028-0836/82/040281-02$01.00

Ca^{2+} and are usually found in plasma membranes. Both adrenergic and cholinergic stimuli cause breakdown of these lipids[10,11] which would be followed by a loss of PI for their resynthesis. Whether this could explain the PI response generally remains to be seen, since the polyphosphoinositides occur in such low concentrations in most tissues. Polyphosphoinositides are unlikely to replace PI in a calcium gating theory, because their hydrolysis seems to require calcium[11,12]. Nevertheless, on the basis that there is a less obvious calcium requirement for the vasopressin-induced breakdown of triphosphoinositide in hepatocytes[13], Michell now seems prepared to shift his ground from PI to this lipid.

What are PI and polyphosphoinositides doing if not Ca^{2+} gating? There is no shortage of suggestions but none provides a convincing general explanation. Conversion of PI to diacylglycerol, for example, could produce a localized increase in membrane fluidity. This in turn could facilitate exocytosis or protein–protein interactions in a membrane. Recent work suggests that polyphosphoinositides and PI may control protein kinases[14,15]. Activation of some receptors leads to protein phosphorylation, so the possible involvement of inositol lipids deserves further study.

The inositol lipids are rich in arachidonic acid and another theory of the PI response is that receptor-linked hydrolysis supplies this fatty acid for prostaglandin synthesis[16]. Since many systems showing the PI effect do not require prostaglandins for the physiological response, this theory cannot apply generally.

It would be tedious to continue the list of inadequate answers to the puzzle of PI. If this is goodbye to the calcium gating theory, we shall miss it, at least until we have a better explanation. □

A new model for giant H II shells

from J.C. Raymond

SEVERAL years ago it was realized that the energy injected by supernovae can determine the overall structure of the interstellar medium[1,2]. When it is considered that the energy flux of the wind of an early-type star is roughly one per cent of the stellar luminosity it is also apparent that over its short lifetime of a few million years, an O star transfers more energy to the interstellar gas through its powerful wind than it does in its supernova demise. (O stars are massive and very hot blue objects often associated with dust clouds.) Theoretical models of the bubble created by such a wind in the surrounding H II region have been available for more than a decade[3,4] and nebulae having very low densities near the centre, such as the Rosette Nebula, have been considered examples of the phenomenon. Since O stars are generally formed in groups, it is expected that the winds of the stars in a group, together with any supernovae resulting from the rapid evolution of these massive stars, will act together to produce a larger bubble[5]. It is only quite recently that observations of young star clusters and the associated shells have become sufficiently precise for a detailed comparison with the theories.

One such investigation has found excellent agreement between observations of the Cygnus Superbubble and the expanding bubble model[6], but a second, by M. Dopita and colleagues, argues against the straightforward expansion model for an object in the Large Magellanic Cloud[7]. The latter group favours a model in which the stellar winds balance the collapse of the neutral hydrogen cloud from which the stars were formed[8]. In this model, the star cluster is offset from the centre of the collapsing cloud with the result that the standing shock wave created in the stellar wind is oblique. The normal component of the wind velocity is thermalized, providing the pressure to balance the collapsing cloud, while the tangential component becomes a flow along the inner surface of the shell. This flow produces velocity shifts which are largest close to two opposite sides of the bubble, with a band of nearly zero doppler shift (purely tangential velocity) across the middle. The model is similar to one recently proposed for the origin of Herbig-Haro objects from the winds of T Tauri stars[9].

Dopita *et al.* have made a wide variety of observations of N70, a giant filamentary shell in the Large Magellanic Cloud. It is a hollow shell 110 pc in diameter containing the O association Lucke 114. Spectra of nine stars in the cluster and spectra and surface photometry of the shell itself, along with radio observations, demonstrate that photoionization by the stars accounts for the observed emission in the optical lines. Neither radio nor optical evidence supports the earlier suggestions that the shell is an old supernova remnant.

There are two arguments against the model of the standard expanding bubble created by the stellar winds — the age of the cluster, about 6×10^6 years based on the stellar spectra, and the pattern of velocities in the shell, with doppler splittings up to 90 km s^{-1}. While the inferred mass loss rates of the cluster stars are adequate to produce a bubble of the observed size with an expansion velocity of 40–50 km s^{-1}, its age would be less than one million years. Unless something like the effect of mass loss on the evolution of the cluster stars caused an order of magnitude overestimate of the age of the cluster, the observed doppler velocities of the shell are not due to overall expansion.

The second argument against the expansion picture is the pattern of velocity splittings. A nice correlation is found between the observed velocity splittings and those predicted by a model which fits the slightly non-circular shape of the nebula. The primary evidence against expansion comes from several points close to the centre of the nebula which show very little velocity splitting, though the splitting should be largest near the nebula centre if the shell is expanding. In the model of flow along the bubble surface, this is the region where the flow is almost entirely transverse to our line of sight. To rescue the expansion hypothesis it is necessary to place a high density cloud in this section of the shell to inhibit the acceleration. Such a cloud might be consistent with the high surface brightness observed in that region.

If the new model of flow along the inner boundary of the shell is correct, a reinterpretation of observations of many giant and supergiant shells in the Large Magellanic Cloud and other galaxies will be required. □

Fluorescence photobleaching in cell biology

from Ken Jacobson, Elliot Elson, Dennis Koppel and Watt Webb

In the past few years, new techniques have emerged to measure the translational mobility of fluorescence-labelled molecules within microscopic specimens, including living cells. The methods are based on the photobleaching of discrete regions of the samples bearing fluorescent molecules, thereby destroying their emission, and the subsequent observation of the recovery of fluorescence due to the diffusion or flow of unbleached fluorophores from the surrounding region into the irradiated area. The speed of recovery is directly related to the diffusion coefficient or flow velocity of the labelled molecule while the degree to which the fluorescence regains the prebleach value gives the mobile fraction of the measured population of probe molecules.

The techniques have become known as fluorescence recovery (or redistribution) after photobleaching (FRAP), fluorescence photobleaching recovery (FPR), or fluorescence microphotolysis (FM). In most instruments a continuous wave laser is focused by the microscope objective on either a micron-sized spot or lined pattern on the specimen. The simplicity of the techniques has promoted their rapid application to measurements of translational diffusion in natural and artificial membranes, the diffusion of biopolymers in solution and, most recently, molecular diffusion in the cytoplasm of living cells.

The potential importance of such measurements is twofold: first, the measured molecular mobility rates may be related to cell physiological functions; second, by characterizing the structural interactions which limit the translational mobility of the labelled components, a dynamic view of the molecular environment immediately surrounding the diffusant should be obtained. At this juncture, no other methods give comparable information about the translational mobility of molecules in defined regions of individual living cells and their organelles. Advances that have been made using the photobleaching techniques were discussed at a recent meeting*.

Valuable structural information concerning cell surface membranes is beginning to emerge from comparative studies largely based on the well characterized red blood cell membrane and artificial lipid bilayers. In the latter membrane model, photobleaching and magnetic resonance techniques have yielded diffusion coefficients for lipids, peptides and proteins ranging from 10^{-8} to 10^{-7} cm^2 s^{-1}; this range of diffusion coefficients means that the molecules can wander from their starting point a net average of several microns in one second. In sharp contrast to the protein mobility values in artificial bilayers, cell surface (glyco-) proteins, in general, diffuse much more slowly, with some fraction of each population not being observed to move at all on the time scale of the measurement.

Now, experiments on the red cell and tissue culture cells are beginning to resolve this difference. Groups at the University of Connecticut and Harvard have shown that agents (for example, polyphosphates) and conditions (for example, low ionic strength and high temperature) which destabilize the submembranous spectrin–actin protein matrix of normal erythrocytes also increase the lateral mobility of the band 3 integral membrane proteins, while the lateral diffusion rates of membrane lipids remains largely unchanged. Moreover, band 3 diffusion rates are some 50 times higher in spectrin-deficient spherocytic mouse erythrocytes than in normal mouse red cells. In the red cell, therefore, the spectrin network on the cytoplasmic aspect of the plasma membrane is definitely implicated in the control of band 3 lateral mobility. A remaining question is whether the mobility constraints are provided by specific binding interactions of the band 3 proteins' cytoplasmic domain with the spectrin network or whether diffusion is simply hindered by the projection of the cytoplasmic domain of the membrane protein into a subjacent polymer matrix. In a separate attempt to determine constraints on lateral mobility, workers at Cornell University have studied induced membrane blebs on lymphocytes, fibroblasts and myoblasts. Protein diffusion in these blebs is greatly increased compared with mobility in the unperturbed cell surface membranes. As actin-specific fluorescent labels show that the blebs are largely devoid of membrane-associated cytoskeletal elements, structures peripheral to the plasma membrane are again implicated in determining the rates of lateral diffusion of surface membrane glycoproteins.

So far, however, it has not been easy to relate the lateral diffusion coefficients of membrane molecules to biological function. These rates, while undoubtedly obligatory in many reactions, have not been demonstrated to be limiting except perhaps in a few cases where metabolic reactions occur within intracellular membranes, such as the inner membrane of the mitochondrion or the endoplasmic reticulum. In the future, it seems likely that precise relationships between lateral diffusion and function will be characterized in such intracellular membranes.

The validity of the photobleaching techniques has been questioned because of the possible harmful effects of the photobleaching light pulse (M.S. Bretscher *Trends biochem. Sci.* **5**, 6; 1980). The potential for membrane photodamage (that is, protein cross-linking) has been demonstrated in conventional photochemical experiments carried out under conditions different from the photobleaching measurements. Several important experiments suggesting there is no appreciable photodamage artefact in the measurement of lateral mobility have been performed at The Johns Hopkins University. When two spectrally distinguishable fluorescent labels were directed towards the same cell surface determinant, extensive photobleaching of one of the surface labels over the entire cell did not alter lateral diffusion coefficients subsequently determined by spot photobleaching of the second label. Also, measurements of the membrane diffusion coefficient of rhodopsin in the visual receptor membrane both by fluorescence photobleaching and by a photobleaching method which uses the natural photochemistry of rhodopsin yield the same values within experimental error. Finally, a careful comparison shows that lateral diffusion coefficients inferred from rates of antigen intermixing on heterokaryons and obtained independently by photobleaching are consistent.

This latter point has been elegantly extended by workers at the University of Connecticut who have shown that diffusion coefficients derived from membrane protein intermixing following red cell–red cell fusion agree with those obtained by subsequently photobleaching the identical fused cell pair. However, at least one puzzling discrepancy remains to be resolved.

In this issue of *Nature* (see p.332), M-m. Poo gives an estimate of the rate of acetylcholine receptor lateral diffusion in the plasma membrane of embryonic muscle cells from observations of the recovery of sensitivity to acetylcholine following local inactivation of receptors by α-bungarotoxin. Poo finds that the recovery kinetics are consistent with a receptor lateral diffusion coefficient of $\sim 3\times10^{-9}$ cm^2 s^{-1}. This is 50-fold faster than that determined by Axelrod *et al.* (*Proc. natn. Acad. Sci. U.S.A.* **12**, 4594; 1976) using the spot photobleaching technique, which requires that the receptor be labelled with fluorescent α-bungarotoxin. Furthermore, according

*The 'International Workshop on the Biological Applications of Photobleaching Techniques' was held by the Department of Anatomy and the Laboratories for Cell Biology at the University of North Carolina, Chapel Hill from 25 to 28 October 1981. Abstracts of the talks and a full list of speakers can be obtained from K. Jacobson.

0028-0836/82/040283-02$01.00

to the photobleaching measurements, some 25 per cent of the bungarotoxin–acetylcholine receptor complexes were immobile on the time scale of the measurement, another finding not confirmed by Poo's new experiments. These discordant results raise the possibility that the macromolecular ligand, α-bungarotoxin, has retarded the lateral mobility of the native receptor either by direct interaction with other cell surface components or, indirectly, by enhancing the ability of the receptor to interact with other cellular components. Alternatively, the rate of diffusion might be reduced by a photochemical process unique to this labelled ligand–receptor combination in the muscle cell membrane.

While photobleaching techniques have so far been largely directed towards problems in membrane biology, an exciting development has been their application to the study of macromolecules in solution and within the cytoplasm of living cells. At Syracuse University, photobleaching techniques are being used to study the polymerization of actin monomers in solution by monitoring the growth of the immobile fraction with time and should provide a useful alternative to conventional viscometric techniques. Further, the association of fluorescently derivitized actin with existing fibres in live cells is being examined at the Weizmann Institute using a combination of microinjection and photobleaching techniques. In another novel application, investigators at the University of North Carolina and Penn State University have shown that the diffusion of macromolecules, such as IgG and bovine serum albumin, microinjected into the cytoplasm of living fibroblasts is retarded 70-fold compared with aqueous buffer values; these results suggest that the cytoplasmic matrix hinders the free diffusion of such molecules sterically and/or through binding interactions between the diffusant and the matrix.

These emerging applications of the photobleaching techniques to the study of molecular movement both within cell membranes and within the cytoplasm suggest a great potential for this approach to provide unique dynamic information on cellular structures, particularly when these measurements can be interpreted in the context of available biochemical and ultrastructural data. □

Gravitational lenses

from Charles Alcock

ONE of the most exciting recent developments in astronomy has been the discovery of multiple imaging of quasars. There are three confirmed examples[1-3] of this phenomenon, and in one case, the gravitational lens responsible for the multiple imaging has been detected[4]. It is a large elliptical galaxy near the centre of a cluster of galaxies.

The great virtue of the phenomenon is that, by the standards of extragalactic astronomy, it can be fairly unambiguously interpreted. In each case the optical emission line spectra of the different images are essentially the same and have identical redshifts.

The general properties of gravitational lenses are easy to understand. A galaxy or cluster of galaxies will bend light rays through small angles, producing (in general) an odd number of images of a background quasar. Usually there will be only one image, but fortuitous projection of a quasar behind a galaxy can result in three or more images. The image brightnesses differ from the brightnesses that would be observed if the lens was absent because the beams are focused.

Three papers in a recent issue of the *Astrophysical Journal* explore some more speculative suggestions involving gravitational lenses. In the first, Tyson[5] revives an old suggestion of Barnothy and Barnothy that quasars may be the nuclei of Seyfert galaxies and appear very luminous because an intervening gravitational lens has amplified the flux from the nucleus. The apparent increase in the density of quasars with increasing redshift can then be accounted for by the larger probability that amplification will occur if the Seyfert galaxy is at a greater distance. What is new in Tyson's approach is that he uses his own data (obtained using automated pattern recognition techniques) on the number density of galaxies on the surface of the celestial sphere as a function of measured flux to calculate the logarithmic slope of the number density of quasars as a function of measured flux. The answer, d log $N_{\mathrm{Q}}/\mathrm{d}m_{\mathrm{Q}} = 0.9$ (where $m_{\mathrm{Q}} = 2.5 \log \mathrm{flux}$) is within the range of observed slopes (0.86–0.95).

The primary difficulty with this model is that the large (>15 times) amplification required is difficult to obtain with gravitational lenses. Furthermore, high amplification should be accompanied by multiple imaging but multiple images have only been detected in three cases out of the nearly 1,000 known quasars. In addition there would need to be a large number of distant galaxies, at present undetected, capable of producing amplification to explain the observed surface density of quasars. Since only a minority of the galaxies we see locally appear capable of producing large amplifications, the mean density of the Universe has to be very high if the model is to work. Success in predicting d log $N_{\mathrm{Q}}/\mathrm{d}m_{\mathrm{Q}}$ is not sufficient to remove these doubts.

In the second of the papers Avni[6] addresses a closely related point. He discusses Turner's suggestion that amplification by gravitational lenses may significantly perturb the measured statistics of quasars, perhaps accounting for the apparent increase in the number density of quasars with increasing redshift. Quasar analyses are customarily performed on flux-limited samples, which will preferentially include quasars whose flux has been amplified by an intervening gravitational lens. Avni's improvement on Turner's model is to require average flux conservation, which implies that the mean amplification has to be unity. This is an important, obvious requirement which considerably reduces the effect of lenses on the quasar statistics below that computed by Turner. Avni correctly concludes that it is unlikely that the gravitational lens effect can account for the apparent evolution of the density of quasar with redshift.

The third paper takes a different direction. Paczyński and Górski[7] suggest that a cluster of quasars[8] at redshift 2.05 may be another example of multiple imaging by a gravitational lens. However, there are some difficulties — the objects have a large separation (minutes, rather than seconds, of arc) and their redshifts are different (by about 10^3 km s^{-1}). The authors produce model lenses consisting of two large clusters of galaxies which can account for the large angular separations. The model cannot account for the redshift differences but the time delays between the three images are 10^2–10^3 years, and it is suggested that the quasar's redshift might change during this time interval.

The velocity dispersions of the two clusters of galaxies in the models of Paczyński and Górski are large (>1,500 km s^{-1}). They point out that if there is a positive cosmological constant the necessary velocity dispersion decreases. This suggests that, should the clusters be discovered and their velocity dispersion measured, one could then estimate the cosmological constant.

It is clear that gravitational lenses can in principle do many remarkable things. The studies described here are very speculative, and definitive answers await further work.

Crater densities and geological histories of Rhea, Dione, Mimas and Tethys

J. B. Plescia

J. M. Boyce

Planetary Geology Program, Office of Solar System Exploration, National Aeronautics and Space Administration, Washington DC 20546, USA

Crater density determinations for parts of the surfaces of several of Saturn's icy satellites including Rhea, Dione, Mimas, Tethys and 1980S3 reveal significant variations. These data, combined with observations of surface morphology, indicate that each satellite has undergone extensive post heavy bombardment geological evolution.

THE Voyager 1 encounter with the Saturn system provided the first close view of icy satellites intermediate in size between asteroids and the large icy galilean satellites[1]. The saturnian satellites have surfaces much more diverse than had been anticipated for bodies of such a small mass and low density.

Several of the satellites (Rhea, Dione, Mimas and Tethys) were imaged by Voyager 1 with resolution sufficient to allow crater counts on at least part of their surfaces. These counts were made to determine the character and magnitude of crater density variations and the relative ages of the different terrain types. Enceladus and Hyperion have been viewed at high resolution by Voyager 2 (ref. 2) and will be discussed elsewhere.

Our data indicate that the surfaces of the saturnian satellites are not uniformly cratered and hence not of uniform age. Significant variations in density occur at all diameters but are most noticeably in the distribution of large diameter (>50 km) craters. The differing surface ages and tectonic features argues that these satellites have evolved significantly beyond their post-accretional state. The range in surface age suggests that the duration and degree of evolution varies between satellites. Such extensive post-accretional activity seems remarkable in view of the small size and mass of the saturnian satellites[3].

Rhea

Rhea, the largest of Saturn's airless satellites, is heavily cratered, with bright whispy planetary scale markings. Rhea's surface shows areas of significantly different crater density. Two of the clearest examples occur in the north polar region and in the equatorial region near 30° longitude.

The north polar region (Fig. 22 in ref. 1) can be divided into two zones based on crater size distributions[1], with the boundary occurring at ~0° long. Westward from 0° longitude numerous craters in the diameter range 40–130 km occur, while to the east of that line craters are generally <20 km and all are <30 km diameter. Smith *et al.*[1] suggested that this difference in crater size distribution was correlated with albedo variations observed in far encounter images of Rhea (Fig. 20 in ref. 1)—that the region of low albedo correlated with the area in which the large craters were present while the brighter area correlated with the area in which they were absent. This conclusion, however, is not supported by our analysis.

The crater size boundary, at ~0° long., is sharp compared with the more diffuse albedo boundary lying ~45° to the east, at 315° long. As the two areas do not coincide, it argues against a common origin. The albedo patterns observed in far encounter images of both Rhea and Dione have been attributed to the uneven distribution of micrometeor impacts[1]. The cumulative size–frequency distribution for areas of the north pole shown in Fig. 1 reveal that while the two areas differ markedly at large diameters, they are statistically indistinguishable at small diameters. The distributions have a 10-km crater density of 1,300±300 at 315° long. and 950±150 at 45° long.

The absence of large craters in parts of the polar regions suggests a major resurfacing event[1]. Large craters are generally lacking in the equatorial areas, but are again found at the south pole. Such a distribution could be explained by an internally generated thermal pulse that lowered the viscosity of some parts of the crust and hence preferentially removed the larger craters. This viscous relaxation would have been less effective near the poles perhaps because of the lower surface temperature.

If the crater size frequency distribution for the polar area near 315° is extrapolated from large to small diameters, it indicates a density far in excess of that observed. While a thermal event might be capable of removing large craters it cannot account for the deficiency of small craters. The low density of small craters might best be explained by a blanketting or flooding event that

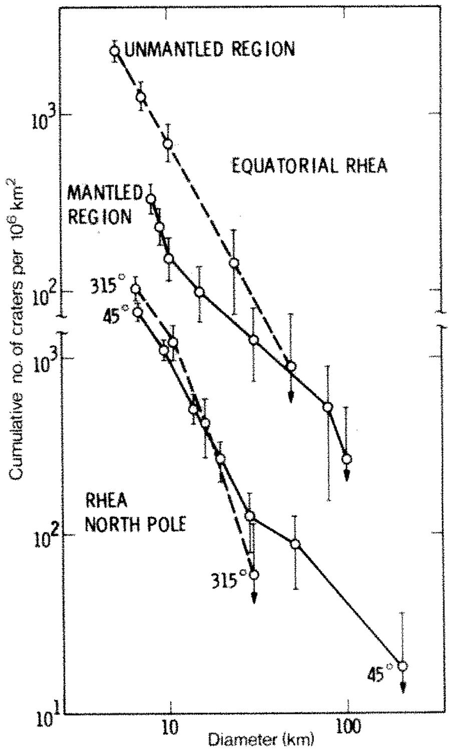

Fig. 1 Cumulative size–frequency distribution for Rhea. Upper distributions indicate crater for the mantled and unmantled equatorial areas. Lower curves illustrate the densities for the north pole.

0028–0836/82/040285—06$01.00

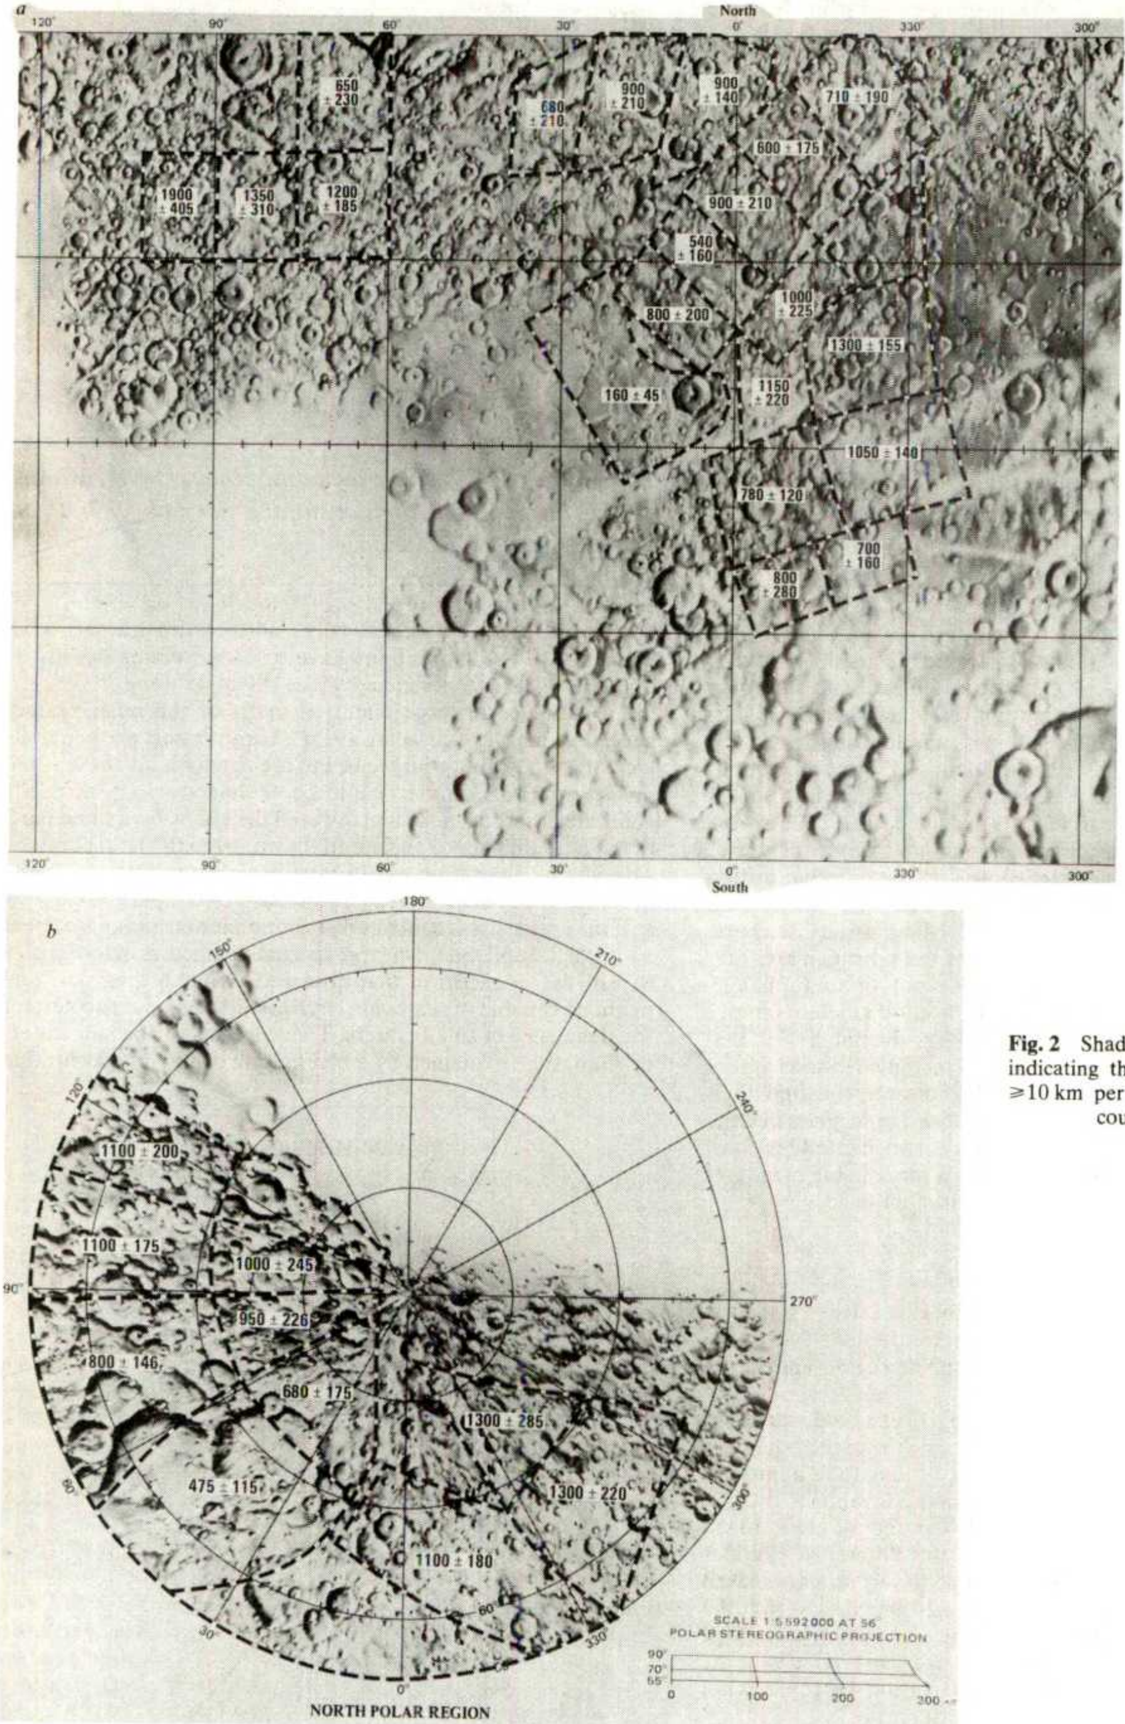

Fig. 2 Shaded relief map of Rhea indicating the number of craters ⩾10 km per 10^6 km^2 for various counting areas.

buried the small craters, and subdued the larger ones. Such an event would also be consistent with the shape of the cumulative size–frequency distribution for the eastern polar area.

Regions near the equator exhibit subdued surface texture when compared with other areas and an absence of small craters suggesting that the area has been mantled (Fig. 21 in ref. 1). This region was imaged only at high Sun angle which may account for some muting of the topography, however, the sharp and irregular shape of the boundary indicates that the mantle is real and not simply a lighting effect. Cumulative size–frequency distributions of craters for the mantled area is shown in Fig. 1. The shape of this curve is suggestive of complete burial of small craters and only partial burial of larger ones. The slope of the curve for the mantled area decreases at diameters <10 km, suggesting that the thickness of the blanket is sufficient to bury 10-km craters or ~2 km deep. A curve for the adjacent unmantled region is also shown and has a 10-km density of 700 ± 150, consistent with the density observed over a large part of the equatorial area. The mantled region has close to a factor of 5 fewer 10-km craters, at 160 ± 45, than does the unmantled region.

Figure 2 shows the extent of the variation of 10-km crater densities observed on Rhea's surface. The most densely cratered regions occur in the mid-northern latitudes west of 60° long. and in the north polar area between long. 300° and 330°. A zone of lower crater density extends from the north pole along the 30° meridian. The area east of 0° long. is heavily cratered but with some variation. Near the equator and extending westward for ~15° is the mantled area. The lack of a clear global crater density pattern suggests that local rather than global processes produced the observed differences. The variations in density and distribution of 10-km and larger craters suggest that Rhea has undergone extensive crustal resurfacing. Processes, most probably endogenic, have operated that are capable of complete erasure of large craters over vast areas of the surface. The absence of large craters suggests that this internal activity extended past the time of post-accretional heavy bombardment when large impacts accumulate.

Mimas

Mimas, the innermost of the major saturnian satellites, is heavily cratered on all areas viewed by Voyager 1. Mimas is heavily, though not uniformly, cratered and has areas of significantly different crater density. On the leading hemisphere (Fig. 14 in ref. 1), west of the crater Herschel, the surface is covered with numerous craters >40 km. The south polar and adjacent areas (Fig. 14 in ref. 1), by comparison, generally lack craters >20 km and are devoid of craters >30 km.

Figure 3 illustrates the cumulative size–frequency distribution for the two areas. Curve E is the distribution for the equatorial area near Herschel (a projected 10-km density in excess of 7,500). Curve SP is the distribution for the south pole (a 10-km crater density of 1,250 ± 490). The density of small craters in the equatorial region could not be determined because of the low resolution of the images. The roughness, at the limit of resolution, caused by 10-km craters seems far less than indicated by the extrapolation, with the surface fairly smooth even near the terminator where subtle relief should be enhanced. Hence the density at 10 km could be the same in both areas. The region 180°–240°, which lies between the equatorial and polar areas, appears to be transitional in terms of size–frequency distribution of craters (curve TC in Fig. 3). An inflection between 15 and 40 km suggests a mixing of two populations of craters, perhaps the result of resurfacing. The small diameter segment is similar to the density for the south pole, while the large diameter segment is comparable to the density in the heavily cratered equatorial area.

The surface of Mimas has apparently been affected by some process which has removed all of the large craters from the south polar region. It had been suggested that numerous impacts of small bodies might have caused destruction of larger craters but there is no evidence that the flux of impacting debris was higher at the south pole than at the equator[1]. The process seems to have been gradational in that progressively smaller craters were spared removal at progressively larger distances from the pole. The distribution of small craters appears to have been reduced over the entire surface of Mimas. This rather uniform and low density of small craters and the absence of large craters at the south pole may reflect at least two episodes of resurfacing.

Dione

Dione exhibits terrain types of distinctly different morphology, ranging from rough heavily cratered areas to smooth lightly cratered plains (Fig. 18 in ref. 1). Planetary scale patterns of bright whispy material stretch across the trailing hemisphere and appear superimposed on the various terrain types and surface features.

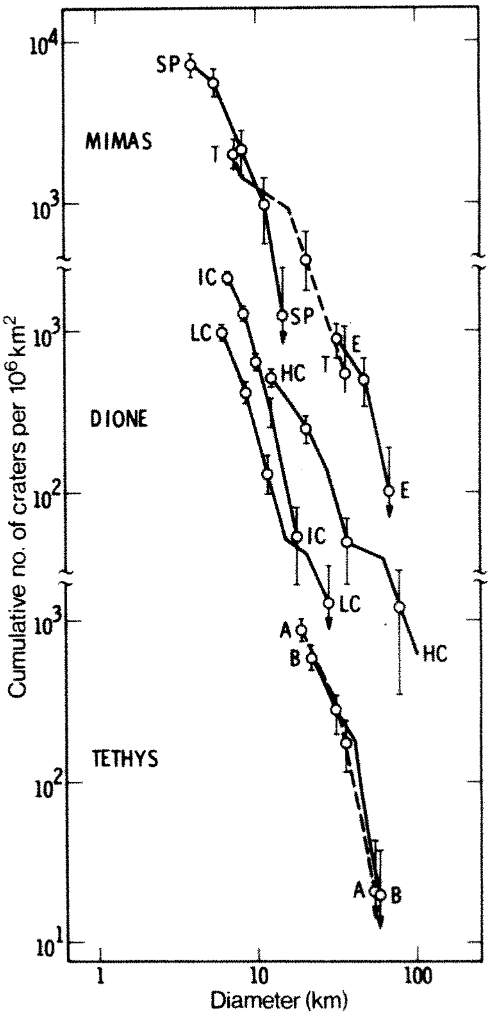

Fig. 3 Cumulative size–frequency distributions for Mimas, Dione and Tethys. Letters refer to locations on the satellites discussed in text.

Three terrain types observed in the highest resolution frames were singled out for preliminary analysis of crater densities: (1) a rough terrain with numerous large craters, centred at ~15° S, 20° long.; (2) a plains unit with intermediate crater density which is elongate in the north–south direction and centred on the equator at 50° long., and (3) a smooth plains unit with low crater density centred on the equator and 65° long. Cumulative size–frequency distributions for these terrains are shown in Fig. 3.

Crater densities for the plains units are considerably less than that for the heavily cratered terrain, indicating a younger age for the plains. At 20 km the heavily cratered area (curve HC) has a crater density of 270 ± 50, compared with ~45 ± 25 for the plains (curves IC and LC). The least cratered plains unit (LC) has a 10-km density of 260 ± 50 compared with 750 ± 100 for the intermediately cratered plains (IC). Figure 3 shows that the heavily cratered distribution has a slope of −2.0, while the younger units have a slope closer to −4.0. This difference in slope, coupled with the apparent age difference, suggests that the two surfaces may reflect different populations of impacting bodies.

These plains units and the structure of the cumulative frequency distribution for the heavily cratered terrain suggest extensive post-accretional alteration of the surface of Dione. It has been suggested that the material responsible for resurfacing parts of the satellite was extruded from the branching trough which extends from the north pole through the plains units. E. Shoemaker (personal communication) and Owen[4] suggested methane snow eruptions from these troughs which would bury surrounding areas and form a smooth young surface. However, the sharp boundary between terrain types suggests a process that totally obliterated all topography up to the boundary which is inconsistent with a snow hypothesis. In such a case topography farther from the vent would receive a thinner blanket of snow than nearer the vent. While the exact nature of the mechanism remains speculative, Dione has clearly undergone some type of endogenic process which has reshaped its surface. The distinct variations in crater density suggests that the process has acted repeatedly beyond the cessation of heavy bombardment.

Tethys

Only one image of Tethys obtained by Voyager 1 in far encounter sequences had resolution sufficient to allow detailed crater density determinations (Fig. 12 in ref. 1). This permitted counting of three regions within a band along the west side of the terminator, between 30° and 60° long.: the cumulative frequency distributions for two regions are shown in Fig. 3. These are statistically indistinguishable from each other (the third region is omitted for simplicity). The size-frequency distributions indicate that this area of Tethys is relatively uniformly and heavily cratered at all diameters investigated. Resolution of $\sim$10 km per line pair prevented determination of densities of smaller size craters. The distributions indicate a 30-km crater density of $\sim 280 \pm 70$ and, by extrapolation, a 10-km density of $2{,}800 \pm 300$.

Voyager 1 images of Tethys' trailing hemisphere show circular features suggestive of large (50–100 km) craters, which would indicate that the trailing hemisphere, like the leading, is heavily cratered. Tethys clearly has undergone post-accretional evolution as reflected in surficial albedo variations and the large canyon-like feature on the sub-Saturn hemisphere. Whether these features were induced by endogenic or exogenic processes and their effect on crater densities is uncertain.

Discussion

Shoemaker and Wolfe[5] have suggested that each saturnian satellite, like the galilean satellites[6], should record a gradient in the cratering rate across their surfaces. The rate should be highest at the apex of motion on the leading hemisphere (equator and 0° long.) and decrease sinusoidally in all directions until the low point is reached at the antapex of motion (equator and 270° long.). Such gradients should occur for impacts generated by extra-saturnian bodies as a result of the high orbital velocity of the satellite compared with the velocity of the impacting body. The ratio of the cratering rate between the apex and antapex for long period comets and Saturn family comets is 6 and 35 respectively for Rhea and 18 and 35 respectively for Mimas[5]. While such a gradient seems to explain the distribution of surfical albedo markings on Rhea and Dione[1] it does not explain the observed distributions of 10-km and larger diameter craters on Rhea, Mimas and Dione.

Figure 4 plots the 10-km crater densities for several counting areas on Rhea as a function of their angular distance from the apex of motion. The data do not follow the predictions of Shoemaker and Wolfe[5]. Crater density determinations for Rhea cover an angular distance of 30°–120° and hence the gradient, if present, should be observable.

A similar analysis for Mimas indicates that the crater densities do not follow the expected distribution, while significant variations occur they are not correlated with distance from the apex. This presents a serious problem in that images of the leading hemisphere have low resolution and hence small diameter (<20–30 km) craters are not observed, while in the southern hemisphere there are no craters larger than 30 km to use for such a comparison. Within the southern hemisphere an angular distance of 80°–140° was observed with no significant variation in density of 10- and 20-km craters.

For such a gradient in crater density to be fully developed the satellite must have remained tidally locked to its parent body during its history, particularly during the period of heavy bombardment. Also comparison between surfaces of the same absolute age must be made to observe the effect.

McKinnon[7] has examined the energy requirements for unlocking Ganymede and Callisto without reorienting the pole of rotation and found that appropriately oriented large impacts, could spin up those satellites. Similar analysis of the saturnian satellites indicates that because of their relatively small size and mass, small and hence frequent impacts could supply sufficient energy for reorientation. Impacts of $\sim 2 \times 10^{27}$ erg for Rhea and 5×10^{25} erg for Mimas would be sufficient to break their tidal lock. Those energies correspond to the formation of a 40-km crater on Rhea and a 15-km crater on Mimas. Because the momentum required must be tangentially oriented, these are minimum crater sizes. Impacts oriented closer to normal would have a smaller tangential component. Thus relatively small impacts, if appropriately oriented, could impart sufficient energy to unlock the satellite. As such craters are relatively abundant, we conclude that each saturnian satellite has been repeatedly unlocked with a frequency that is proportional to the cratering history. This process would effectively prevent the recording of the gradient.

To compare the crater densities between satellites a cumulative frequency distribution for each body is shown in Fig. 5. One of the co-orbital satellites, 1980S3, has a 10-km crater density of $1{,}450 \pm 610$ for the small region which was countable (see Fig. 29 in ref. 1). Except for 1980S3, the curves in Fig. 5 approximate the size-frequency distribution of craters on the sub-saturnian hemisphere at 0° long. to remove any effects which might result from gradients in crater density.

The distributions indicate that the satellites are dominated by two populations of craters. These two groups correlate with populations I and II of Smith *et al.*[1]. The first group, the large diameter craters, represents population I which is exposed on the more densely cratered surfaces of Rhea, Dione, Tethys and Mimas. Population II would correspond to the small diameter segments of the distributions. Craters of population II are found on the younger parts of all of the satellites. The cumulative size-frequency distributions observed on the saturnian satellites are steeper than those observed on the dark terrain of Ganymede and also indicate higher crater densities. At 10 km the densities are at least a factor of 4 higher for the saturnian satellites than for Ganymede's dark terrain. Differences in the slope of the size-frequency distributions suggests that the two systems may have been bombarded by different populations of objects. This difference in density between the two systems may not be a direct function of age in view of the possibly different

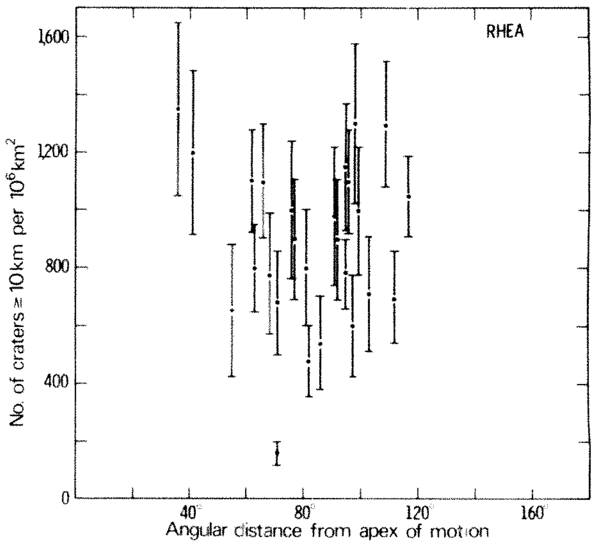

Fig. 4 Plot of crater density at 10 km as a function of angular distance in degrees from the apex of motion of Rhea.

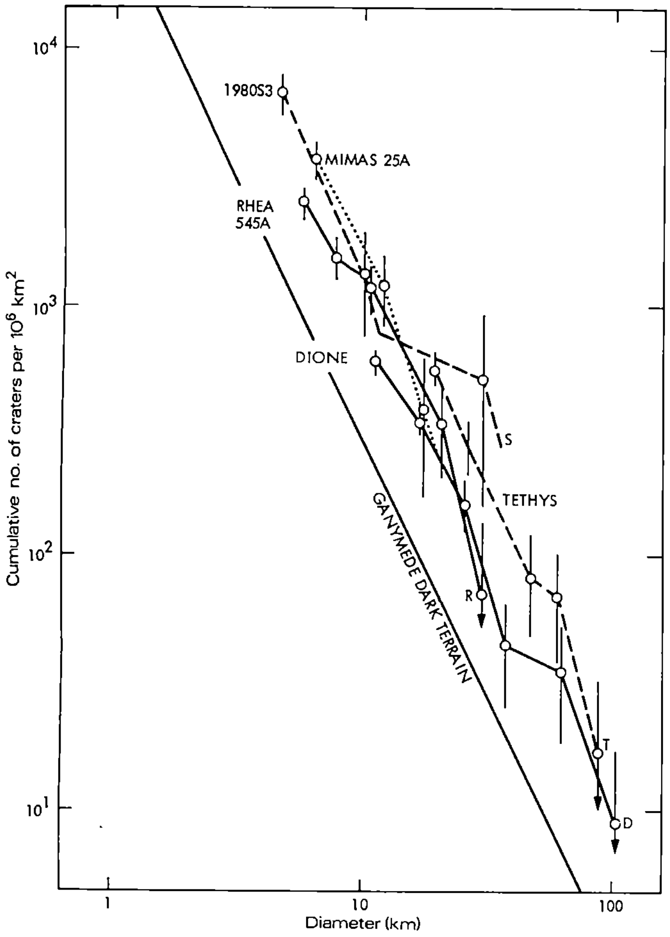

Fig. 5 Cumulative size-frequency distribution for Rhea, Dione, Tethys, Mimas and 1980S3. Average distribution for the dark terrain of Ganymede included for comparison.

impact histories. Alternatively, the steepness in slope of the small crater segment of the distribution may result from numerous secondary impacts produced by projectiles originally lost during larger impacts on these bodies. These secondary materials which would subsequently be swept up and enhance the small crater population have been termed population III (ref. 1).

The crater densities in Fig. 5 can be interpreted as representing two major geological events, which may record several episodes, in the history of the satellites. The higher-density large-diameter distribution reflects the period of late heavy bombardment, characterized by the population I distribution of many large (>50 km) diameter craters, many of which are now subdued and degraded. The second, lower-density population II occurred at a time to record episodes of resurfacing, plains formation and tectonic activity. This has occurred on all the satellites, and may date back to the end of the post-accretion heavy bombardment. The nonuniformity of crater densities on the satellites indicates that modification of their surfaces has been variable in terms of both duration and areal extent. Rhea, Dione and Mimas all exhibit distinctly different crater densities indicative of multiple resurfacing episodes.

The geological history of the saturnian satellites can be deduced from their crater densities. The areas of Dione, Rhea and Tethys, characterized by the presence of population I craters, being the most densely cratered surfaces, are the oldest regions, thought to date from the period of heavy bombardment. Regions of Dione and the leading hemisphere of Mimas which are characterized by high crater densities, combinations of populations I and II craters, suggest partial resurfacing of these areas and represent the next youngest surfaces. These surfaces probably formed during the later part of the heavy bombardment and were subsequently modified. Thereafter, episodes of more localized resurfacing occurred during which the southern hemisphere of Mimas and the north pole and equatorial areas of Rhea were altered. Larger population I craters were obliterated in these areas, and greatly subdued in others. Resurfacing continued on Rhea in more localized areas reducing crater densities. The most recent activity on the satellites discussed here seems to have been the formation of the smooth lightly cratered plains of Dione and the blanketing of parts of Rhea's equator.

The vast range of surfaces observed indicates that surface forming processes were active beyond the period of heavy bombardment. The tectonic features such as lineaments, troughs and great canyons, and the removal of large craters over vast areas indicate prolonged post-accretional activity, all reflecting the operation of internal process. Large impacts, the only major exogenic event likely to occur after the formation of the satellite, might cause extensive local morphological changes, but such events could not cause all of the diversity of ages and surface morphology. This is similar to the general conclusion drawn for the galilean satellites and the terrestrial planets.

Whether generated by core formation or decay of radioactive nuclides, heat is the basic driving mechanism for the internal dynamics of most bodies. Tidal heating seems to be important in only a few cases. Peale *et al.*[8] showed that tidal heating could have contributed only small amounts of energy to the saturnian satellites. Models[3] of the thermal evolution of small icy satellites indicate that such bodies would experience little internal activity after formation. Based on chondritic abundances of radionuclides and a 40% rock and 60% water-ice mixture, no melting would have occurred in the smaller satellites. In the slightly larger bodies such as Rhea and Iapetus a small liquid core might have formed early, however, 90% of the satellite would still have remained frozen. The addition of 10% ammonia as a hydrate would enhance additional limited melting and differentiation which could have had important consequences for the larger icy satellites, but not for those with radii <700 km. An additional mechanism, solid-state convection of ice I, might prove to be important in causing changes in the surface of the small icy satellites where that ice would be the dominant phase[3]. Such a mechanism would transmit heat to the surface allowing the largest craters to be removed by viscous relaxation[9]. Additionally the convective activity may have tectonically disturbed the surface and obliterated craters. However, formation of plains units as on Dione and blanketting on Rhea or giant tectonic features of Tethys would require a more energetic process.

The problem then is the source of the energy responsible for evolutionary processes. One possibility might be inhomogeneous accretion. Smith *et al.*[1] suggested that the saturnian satellites might be of the size where the stochastic nature of accreting compositionally different planetesimals might produce noticeable effects on the satellites' history. Perhaps concentrations of the rocky component exist beneath areas where internal activity seems to have occurred. Such local concentrations might supply sufficient radiogenic heat over a limited area to drive surface modifications. Additional energy could be provided if the local concentration 'melted' its way to the core of the satellite and hence released gravitational energy or by structural disruptions caused by the migration of the concentration.

The small icy satellites of Saturn are therefore a diverse group of bodies with a variety of surface ages and morphologies. These satellites, despite their small size and mass and low density, have evolved beyond their original accretionary state. The alteration processes seem to have been active beyond the period of heavy bombardment as reflected in the crater density determinations. The energy source for the evolution of these bodies remains unknown.

The tectonics of Ganymede

E. M. Parmentier*, S. W. Squyres†‡, J. W. Head* & M. L. Allison*‡

The surface of Ganymede, the largest icy jovian satellite, is composed of two distinct terrain types showing abundant evidence of global-scale tectonics. There is geological evidence consistent with the formation of younger bright terrain by the emplacement of relatively clean ice into rift zones developed in the more silicate-rich dark terrain.

GANYMEDE, Jupiter's largest moon, is the largest known icy object in the Solar System. Voyager images of its surface show a complex and unique geology with widespread evidence for tectonic activity[1,2]. For silicate bodies on which significant lateral motion of the lithosphere does not occur, global volume change is an important cause of surface tectonism[3,4]. As a result of internal phase changes, large icy bodies can undergo a substantial volume increase. The transition of dense ice polymorphs in the deep interior to less dense polymorphs or liquid water at shallow depths as internal differentiation and formation of a silicate core occurs could increase Ganymede's surface area by as much as 7% (ref. 5). A temperature increase of several thousand degrees centigrade would be required for a silicate body to undergo an equivalent amount of volume change due to thermal expansion. We examine here evidence concerning the nature of the tectonic processes that have operated on Ganymede. We conclude that a variety of geological evidence is consistent with the progressive rifting of Ganymede's lithosphere possibly in response to planetary expansion.

Style of global tectonics

The two principal geological units present on Ganymede are most simply termed 'dark' terrain and 'bright' terrain. Each unit covers approximately half of the surface. The density of impact craters is substantially higher in the dark terrain, indicating that it is older than the bright terrain[1,2]. The dark terrain is generally present in polygonal regions that are separated by bright terrain (Fig. 1). The bright terrain forms both broad curvilinear bands that separate the dark polygons, and narrow wedge-shaped regions that penetrate and partially divide dark polygons. In some areas bands and wedges of bright terrain appear to coalesce forming broad, irregularly shaped bright regions. Small blocks of dark terrain are frequently interspersed through such regions. The dark terrain is composed of an ice–silicate mixture, and the bright terrain is composed of relatively silicate-free ice. Bright terrain contains many linear topographical depressions called grooves[1,2]. Where it is free of grooves and impact craters, the bright terrain appears smooth at the highest Voyager resolution (600 m per picture element).

The emplacement of the bright terrain by the extrusion of a relatively water-rich magma in regions of lithospheric extension is geologically reasonable and is supported by various geological data. We examine three different styles of extensional tectonics that could be associated with the emplacement of bands of bright terrain between polygons of dark terrain. As shown in Fig. 2, lithospheric spreading (*a*) may be analogous to the formation of new ocean floor at terrestrial mid-oceanic ridges; finite lithospheric extension (*b*) may be analogous to terrestrial rift zones such as the Basin and Range Province of North America or the East African rifts; and finally, flooding of older dark terrain (*c*) may occur by the extrusion of silicate-poor material through fissures or extension fractures. These models clearly involve significantly different amounts of relative lateral motion between adjacent blocks of dark terrain. Lithospheric spreading implies lateral movement of coherent blocks of dark terrain over distances comparable to the width of areas of bright terrain. At the opposite exteme, tension fracturing and flooding would only require small lateral movements of the dark terrain sufficient to provide bright material access to the surface. The simple models provide a conceptual framework within which to interpret various geological data.

The nature of boundaries between the two terrain types provides a basis for determining whether the two surface units have a tectonic or a stratigraphical relationship. Contacts between bright and dark terrain are usually gently curving and

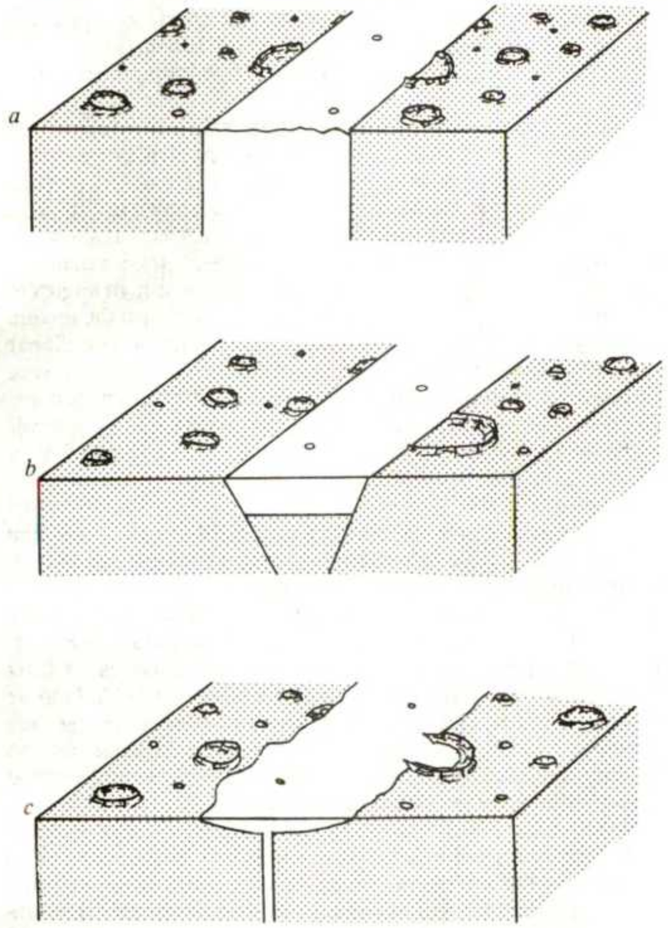

Fig. 2 Three schematic models of extensional deformation associated with the emplacement of the bright terrain: *a*, lithospheric spreading; *b*, rifting due to finite lithospheric extension; and *c*, flooding of older, dark terrain.

sharply defined. Craters and other topographical features in the dark terrain are sharply truncated at such contacts. These characteristics argue for the structural confinement of bright material at many bright terrain–dark terrain boundaries. In irregular areas of bright terrain, the contacts between bright and dark terrain are diffuse, and truncated craters occasionally appear to be filled with bright material. In some areas the bright terrain has a distinctive dark mottling suggestive of a thin layer of bright material overlying dark material. In such areas, bright material appears to have flooded dark terrain. In most cases, however, the bright material was structurally confined, arguing against flooding of dark terrain (*c*) as the main mechanism for the emplacement of the bright terrain.

Several types of observations distinguish between lithospheric spreading (*a*) and finite lithospheric extension (*b*). If lithospheric spreading has occurred, the two parts of a crater transected by a band of bright terrain should appear on opposite sides of the band. This is not observed. Another basis for distinguishing between these two tectonic styles is the degree to which adjacent dark polygons can be fit back together. The boundaries of some adjacent polygons are roughly parallel, creating the superficial impression that they were once joined, and have since drifted apart. Detailed examination shows, however, that this parallelism is only approximate, and that they cannot be fit together[6,7].

Lithospheric spreading would require relative lateral motion between adjacent regions of dark terrain comparable with the width of regions of bright terrain. Although there is evidence that crustal shear has occurred on Ganymede[8], large lateral displacements have not yet been demonstrated. The clearest evidence of shear displacement is provided by a few crater rims that are offset across linear features. The largest offset recognized in these cases is several kilometres[8]. Some bands of bright terrain also appear to be offset across transecting linear features. If these bands were offset after their formation, as much as 100 km of strike-slip dispacement would be indicated[8]. There is no evidence, however, that such bands did not form with an offset across a pre-existing fault. Therefore, post-formation strike-slip displacement is not required to explain their offset appearance. The non-concentricity of arcuate furrows in the dark terrain has also been cited as evidence for large lateral displacement between adjacent regions of dark terrain[8]. These furrows, which are 5–10 km wide flat-floored depressions predating almost all craters in the dark terrain, are thought to be ring graben formed during the viscous collapse of an early impact basin[9]. If the forrows are assumed to have formed an initially circular pattern, their present pattern suggests a lateral displacement between adjacent regions of dark terrain; however, no detailed study of this hypothesis has been reported. There is no evidence that furrows did form an initially circular pattern.

Because bright terrain covers about half of the surface of Ganymede, the formation of this terrain by the complete separation of older blocks of dark terrain cannot be explained by planetary expansion alone. Lithospheric spreading would require large-scale destruction of crustal materials and possible associated compressional deformation. Tectonic features that can be related to compressional deformation have not yet been recognized in the dark terrain. If all the bright terrain were emplaced by lithospheric spreading, it is difficult to reconcile the large area of this terrain with the absence of compressional features in the dark terrain.

All the above observations are consistent with the formation of the bright terrain by the flooding of rift zones formed due to finite lithospheric extension. Although individual tectonic features in the dark terrain, described later, strongly suggest that normal faulting has occurred on Ganymede, the structure of rift zones is not yet clearly defined. Dark terrain may have subsided along normal faults forming graben, as in terrestrial rift zones, or may have stoped[10] or foundered[4] into the deeper interior. The occurrence of small, isolated regions of dark terrain in irregular areas of bright terrain argues against stoping. A piecemeal style of stoping is difficult to reconcile with the continuity and linearity of the contact between bright and dark terrain at the edges of the bright bands.

The thickness of bright deposits place important constraints on the structure of rift zones and, if they are formed by normal faulting, on the amount of lithospheric extension. The burial of pre-existing topography on underlying dark terrain may be one indicator of this thickness. Crater rims, which are the highest topographical features in the dark terrain, are never clearly evident through the bright deposits, even where craters are truncated at a bright terrain–dark terrain boundary. Impact

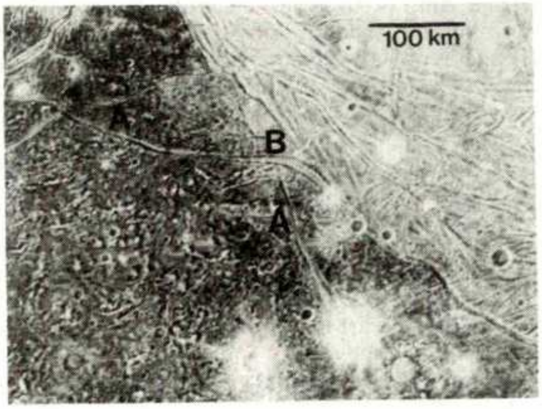

Fig. 3 Single grooves (A) and a groove pair (B) in the dark terrain. The groove pair merges along strike to form a single groove. For part of its length the groove pair forms a bright terrain–dark terrain boundary. Voyager image 382J2-001.

craters excavate crustal material at depth and therefore may be useful indicators of subsurface composition. Craters on the dark terrain with a diameter of <50 km exhibit no bright rim deposits. Larger craters, now highly degraded due to viscous flow, are brighter than the surface on which they formed. If the bright material is not solely impact melt, then the larger craters may have excavated silicate-free material from depth while the smaller craters did not. Although more detailed study is required, this suggests that relatively silicate-free ice occurs below a depth of ~ 10 km beneath the dark terrain[10]. Craters with a diameter $\geqslant 50$ km are virtually absent on the younger bright terrain. However, the floors of smaller craters have an albedo similar to that of the surrounding bright terrain suggesting that they did not excavate silicate-rich material. Thus the thickness of the icy material in some areas of bright terrain may be at least 10 km (ref. 10). Also, craters with bright ray systems are preferentially concentrated in the bright terrain[10,11]. Because there should be no significant difference in retention time of rays on the two terrains[11], this may also indicate the presence of a thick icy layer in the bright terrain. If bands of bright terrain were rift zones bounded by normal faults dipping 60° and containing a 10 km thickness of bright material, a relatively modest volume increase of 1% would produce about five such rift zones perpendicular to any great circle on the planet.

The above observations suggest the bright terrain was formed by extension of an ice-silicate crust which led to normal faulting and creation of broad rift zones[6]. Due to the presence of silicates, the crust could be slightly more dense than liquid water or relatively clean ice, causing this underlying material to be extruded[4] into the structurally defined depressions and in some areas overflowing onto surrounding dark terrain. Solidification of the water-rich magma would form bright curvilinear bands of relatively clean ice. The boundaries of the bands would be sharp where the bright material was confined within a rift zone, but would be diffuse where it overflowed onto adjacent dark terrain. The intersection and coalescence of bright bands could form the complex, irregularly shaped areas of bright terrain. Bright terrain emplacement may thus be analogous to terrestrial rifting and the flooding of rift zones with basaltic magma.

Tectonic features

Further evidence for distinguishing the style of tectonism on Ganymede is provided by structural features. The dominant topographical features on Ganymede, other than impact craters, are long, narrow depressions collectively called grooves[1,2] which we assume are the topographical expression of structural features. Although strongly concentrated in the bright terrain, grooves occur in both types of terrain. There are numerous smooth, groove-free regions of bright terrain, and many grooves in the dark terrain.

Some of the simplest examples of grooves are found in the dark terrain. They occur as single curvilinear depressions or as nearly parallel pairs of depressions with lengths of several tens to several hundreds of kilometers, and widths from a few kilometres down to the resolution limit of Voyager images. Examples of single grooves and groove pairs in the dark terrain are shown in Fig. 3. Groove pairs occur with up to ~ 10 km spacing between the individual grooves. Grooves in a groove pair commonly merge along strike to form what appears to be a single groove. In some cases single grooves or groove pairs in the dark terrain merge with dark terrain–bright terrain boundaries.

Grooves are more abundant in the bright terrain, where they occur as single grooves, groove pairs and groove sets. Single grooves and groove pairs in the bright terrain resemble those in the dark terrain. Groove sets contain many nearly parallel grooves. These sets may be up to several hundred kilometres wide and hundreds of kilometres long. The spacing between parallel grooves in a set is typically in the range of 3–10 km, but often appears more nearly constant within any particular set. Individual grooves within a given set merge or bifurcate along strike, but seldom cross. Topographical relief of grooves in groove sets, as determined by photoclinometric analysis[12], is typically 300–400 m, but does not exceed 700 m. The groove sets show no pronounced or consistent topographical asymmetry.

The pattern of grooves in the bright terrain is most regular in narrow bands of this terrain, either those that divide or partially divide dark polygons. In these areas grooves are nearly parallel to the edges of the bands of bright terrain as shown in Fig. 1. In irregularly shaped areas of bright terrain, such as that shown in Fig. 4, groove sets commonly form irregular, intersecting patterns. Some groove sets in such areas strike at high angles to dark terrain–bright terrain boundaries terminating at the terrain boundary. Grooves crosscut and are crosscut by curvilinear regions of smooth bright terrain indicating that grooves were forming concurrently with the emplacement of bright terrain. Relatively few examples of impact craters disrupted by grooves have been observed which indicates that grooves formed at or very near the time of emplacement of the bright terrain on which they occur.

In considering possible tectonic origins of grooves, it is first important to decide whether they may be of extensional or compressional origin. The topographical symmetry of most grooves argues against their being thrust fault scarps. Folds are not likely to form single grooves in which the surface is consistently depressed below surrounding terrain. Grooves, at least where they occur singly or as groove pairs, are more likely to be extensional features, either tension fractures or graben developed in a brittle surface layer. In the dark terrain, no tectonic features that can be associated with compressional deformation have yet been recognized.

Because the interpretation of the tectonic origin of grooves rests largely on their present morphology, it is important to understand the effects of processes that could have modified their topography. Although various processes can degrade topography, viscous relaxation is important in the modification of impact craters on icy surfaces[13,14]. Unlike the grooves, impact craters provide topography of known initial form. On Ganymede, impact craters are frequently shallower than those on silicate bodies and typically have domical floors. Both of these characteristics can be explained by viscous relaxation of topography on a layer of icy crustal material in which the viscosity is uniform or decreases with depth[13].

To examine the effect of viscous relaxation on tectonically produced topography, experiments have been carried out in

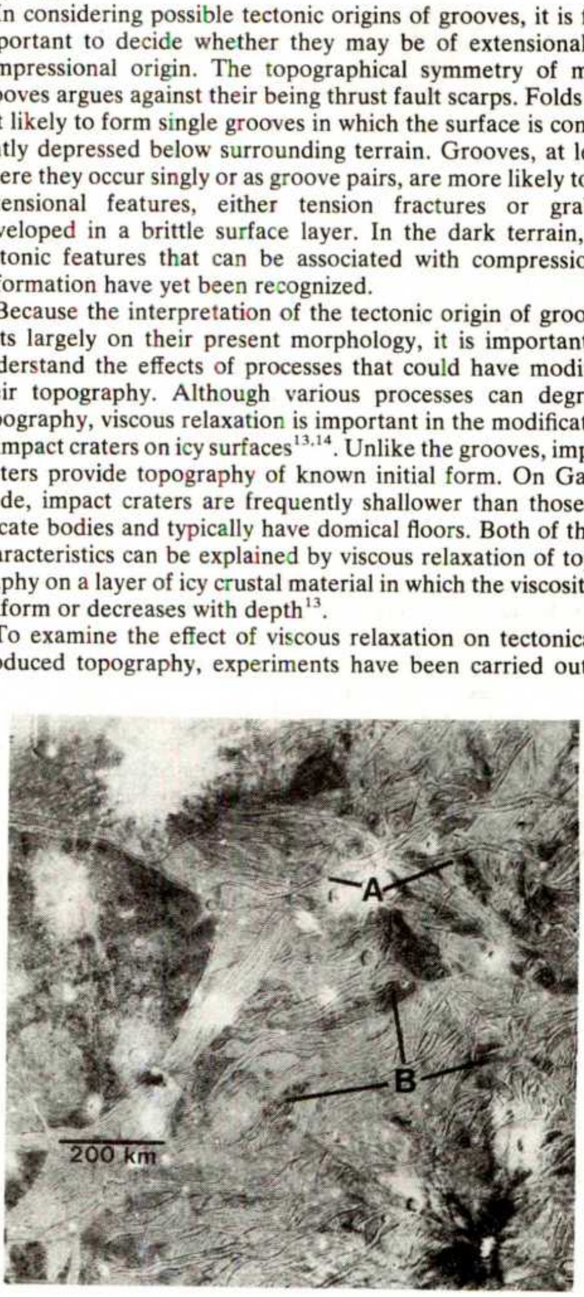

Fig. 4 Complex sets of subparallel grooves in a broad region of bright terrain. Note several well developed groove pairs (A) in the bright terrain, and some small, isolated blocks of dark terrain (B) interspersed through the bright terrain. Voyager image 955J1—000.

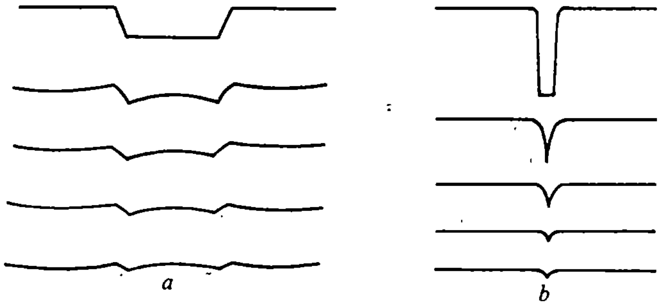

Fig. 5 Experimental relaxation of a graben (*a*) and an extension fracture (*b*) in a thick viscous layer.

which topography is impressed on the surface of a layer of viscous material and allowed to relax. The material used was polyisobutylene, a straight-chain hydrocarbon polymer with a viscosity of about 7×10^5 P at 25 °C. Relaxation was thus slow and could be easily monitored. The form of the relaxing topography at various times was measured with a contour gauge. The relaxation of both graben and tension fractures was studied in this way: typical results are shown in Fig. 5. The form of graben relaxing on a viscous layer with a thickness about twice the graben width is shown in Fig. 5*a*. The relaxing graben develop raised rims and domed floors, much like the morphology of relaxing impact craters. Graben relax to two parallel depressions which appear morphologically similar to groove pairs observed on Ganymede.

Tension cracks relax, as shown in Fig. 5*b*, to form single linear depressions with a width that gradually decreases relative to the initial width of the crack. Because deviatoric stresses are highest near the bottom, the crack closes progressively upwards resulting in a sharp-bottomed depression that shallows with time. The detailed morphology of single grooves on Ganymede cannot be determined, even at the best resolution of available images. These features could be either tension cracks or narrow graben. Relatively low lithostatic stresses on Ganymede would favour the formation of tension cracks in a thin brittle surface layer. However, the recognition of groove pairs as relaxed graben suggests that normal faults have formed. Because many groove pairs, particularly in the dark terrain, narrow along strike to form single grooves, at least some single grooves may be graben.

Another process that could modify the initial topography of grooves is impact erosion and mass-wasting. The steep walls of open extension fractures and fresh graben fault scarps would be especially susceptible to this process. Its general effect would be to widen and partially to fill initially narrow and deep topographical features. This process may thus be important in modifying steep-sided, narrow extension fractures to the broader, more gently sloping features observed. While mass-wasting is expected, Voyager images are of insufficient resolution to identify possible mass-wasting deposits within grooves. We thus cannot yet quantify the degree to which mass-wasting has altered groove topography.

Groove sets in the bright terrain are more complex than single grooves or groove pairs and are therefore more difficult to interpret. They may be a direct consequence of surface fracturing and faulting, or an expression of continuing movement on faults in underlying dark terrain. Alternatively, if the viscosity decreases with depth as indicated by impact crater morphology[13], groove sets may be formed by the folding or boudinage of a high viscocity, near-surface layer. As such, they could reflect either extensional or compressional deformation.

Photoclinometric analysis[12] indicates that in some cases the topography of groove sets is roughly sinusoidal, with groove widths nearly equal to their spacing. In other cases grooves are narrow relative to their spacing and are separated by broad, flat divides. Given the apparent diversity in groove set morphology, a variety of tectonic forms may occur. However, many groove sets could be constructed by placing simple extensional tectonic elements, single grooves or groove pairs, side by side. Given this continuity in form from single grooves and groove pairs to groove sets, it is possible that even in these complex sets the grooves are extensional. This argument is strengthened by the observation that groove sets both crosscut and are crosscut by bands of smooth, ungrooved bright terrain, indicating that the resurfacing and the groove formation must have taken place concurrently in at least some areas. If the resurfacing is a consequence of extensional tectonics, the creation of most groove sets may also be simply explained by this mechanism.

Discussion

At the resolution of available images, the association of extensional deformation with the formation of the bright terrain and the pattern of this terrain on the surface provide a basis for distinguishing the style of global tectonic evolution on Ganymede. As discussed earlier and as shown in Fig. 1, some regions of dark terrain are disrupted by wedge-shaped regions of bright terrain extending inwards from surrounding bright terrain. This pattern of failure would be expected due to membrane stresses[15] in an isolated portion of the lithospheric shell on an expanding planetary body. The continued growth of such wedge-shaped regions of bright terrain would divide a dark region into smaller regions separated by bands of bright terrain. The intersection of bands would form complex, irregular regions of bright terrain. The present pattern of bright terrain could thus be produced by the progressive fragmentation of the lithosphere.

The membrane stress in any unbroken segment of lithospheric shell will depend on its size and the stress acting on its boundary. The boundary stress would arise due to the stress transmitted across areas of bright terrain between adjacent unbroken regions of dark terrain. If the boundary stresses are small or relatively uniform, larger unbroken areas of dark terrain should experience larger membrane stresses for a given amount of planetary expansion. Progressive fragmentation of an initially uniform lithosphere should thus produce unbroken dark areas of roughly comparable size at any stage of fragmentation. This seems to be contradicted by the observation that large regions of dark terrain remain unbroken while smaller regions have undergone fragmentation. Thus, if the tectonic evolution of Ganymede is to be described by progressive fragmentation of an initially uniform lithosphere in response to planetary expansion, the stress transmitted across different areas of bright terrain must differ significantly. Alternatively, lithospheric thickness variations or other mechanisms such as tidal distortion or stresses due to convection beneath the lithosphere may have been important. Additional mapping and analysis based on Voyager images should help resolve many remaining questions about the tectonic evolution of Ganymede.

This research was supported by NASA grant NSG-7605. We thank E.M. Shoemaker for a helpful review of an earlier version of this manuscript and for a preprint describing work on Ganymede geology, and W. B. McKinnon for helpful comments.

The molecular structure of d(^{I}CpCpGpG), a fragment of right-handed double helical A-DNA

The DNA tetramer d(^{I}CpCpGpG) or ^{I}CCGG crystallizes as a double-stranded 4-base pair (bp) segment of an A helix. Two such tetramer helices are packed together in the crystal with local helix axes nearly coincident, simulating an 8-bp helix, and four such octamers make up the tetragonal unit cell. Restrained energy and reciprocal space refinement has led to an R factor of 20.5% at 2.1 Å resolution. The ^{I}CCGG helix has a twist corresponding to 10.7 bp per turn, a 19° base tilt and a 2.3 Å rise per base pair along the helix axis. The mean propeller twist of 18° is comparable with, and has the same rotational sense as that observed in the B-DNA dodecamer CGCGAATTCGCG at similarly high alcohol concentration. Backbone phosphate groups in A-DNA are extensively hydrated, including a network across the opening of the major groove, whereas base edge N and O groups in major and minor grooves are less hydrated than in B-DNA. The minor groove spine of hydration observed in B-DNA is totally absent. These observations of relative hydration confirm and extend the model for the B-to-A helix transition proposed earlier on the basis of the B helix structure.

THE first double-helical DNA structures were proposed on the evidence of X-ray diffraction data from drawn fibres obtained from natural sources, supplemented by spectroscopic and chemical information, and model building from the known stereochemistry of component parts[1-7]. Two major families of helix were proposed, A and B, differentiated by sugar puckering, base tilt relative to the helix axis, rise per residue along the axis, distance of base pairs from the centre of the helix and relative dimensions of major and minor grooves (Table 1). A-DNA is characterized by a deep and narrow major groove, a shallow minor groove and base pairs tilted by roughly 19° to the helix axis. In various members of the B family, the bases are more nearly perpendicular to the helix axis and the grooves are of comparable depth, although the major groove is wider.

Fibre diffraction patterns can give the overall average helix parameters for DNA of known composition or repeating sequence, but cannot reveal local variations in helix structure that might be produced by that sequence. This kind of information can only come from single-crystal structure analyses of discrete, homogeneous DNA oligomers. The development of triester and related methods has made the synthesis of such oligomers possible[8]. Structure analyses have been carried out for both a 12-base pair (bp) B helix[9,10] and a totally unexpected new family, the left-handed Z helix[11-13]. We describe here the first single-crystal structure analysis of a member of the A-DNA family, the self-complementary tetramer d(iodo-CpCpGpG) or ^{I}CCGG. It is also the first example of a nucleic acid structure analysis carried out without isomorphous heavy atom derivatives, using initial phasing derived from anomalous scattering as was done for the proteins haemerythrin and crambin (ref. 14 and W. A. Hendrickson and J. Smith, personal communication). (In another structure analysis of an RNA dimer, r(ApU), complexed with 9-aminoacridine, anomalous scattering was used to locate positions of phosphorus atoms, which then became the starting point for non-anomalous phase analysis[15].)

Structure analysis

To find an isomorphous pair of crystal forms, the native CCGG tetramer and four variants with 5-bromocytosine or 5-idocytosine in the first or second position along the chain were synthesized independently by the triester method. Four of these compounds were crystallized, but no two adopted the same space group. Having discussed with W. Hendrickson his experiences with haemerythrin and crambin, we decided to try to solve the better crystal form of the two iodo derivatives, ^{I}CCGG, using anomalous scattering from iodine atoms.

Crystals of the 1-iodo derivative were grown at 2 °C by vapour diffusion against isopropanol, from concentrated aqueous solution of ^{I}CCGG containing spermine hydrochloride buffered at pH 7.5 with sodium cacodylate. The cacodylate buffer was later found to be unnecessary for crystal growth. Crystals began appearing at around 40% isopropanol, and crystal growth was continued to 80% alcohol. The space group of ^{I}CCGG crystals is $P4_32_12$, with cell dimensions $a = b = 41.1$ Å, $c = 26.7$ Å and two tetramer strands (one double helix) per asymmetric unit. A measured density of 1.50 g cm^{-3} and a calculated molecular weight of 1,298 per strand indicate that the crystals are 51.0% DNA by weight.

Data were collected on a Syntex $P\bar{1}$ automatic diffractometer with graphite monochromator, and corrected for X-ray decay and absorption[16]. The pattern was quite strong to 3.5 Å resolution, but declined rapidly beyond that point. One anomalous data set to 2.1 Å resolution contained 1,486 Friedel pairs. Multiple data sets were collected on different crystals for accuracy, so that each reflection within the 3.0 Å sphere was measured at least three times. Mean R factors between independent data sets were ~5% in F.

Patterson and anomalous difference Patterson maps[17] were employed to locate the two iodine positions per asymmetric unit (16 per cell), using the 472 pairs of reflections above the 2σ confidence level within the 3.0 Å sphere. Approximately 36% of these reflections were centric and hence gave no anomalous contribution, but the iodine anomalous scattering factor of $\Delta f'' = 7.2$ electrons for CuKα radiation produced an average difference between Friedel pairs of 11% in F among acentric reflections. The location of iodine atoms was complicated by two factors: the iodine of cytosine C1 was accidentally situated

Groove width is the perpendicular separation of ideal helix strands drawn through the phosphate groups, decreased by 5.8 Å to represent van der Waals radii of two phosphate groups. Groove depth is defined precisely in ref. 4, but again is based on van der Waals radii, as though measured from a space-filling model.

directly above a 2-fold axis, with coordinates close to $(\frac{1}{4}, \frac{1}{4}, \frac{1}{4})$, and that on cytosine C5 of the other strand of the double helix was nearly just one-quarter of the cell away from it along the *a* axis. Each of these two coincidences introduced false centrosymmetry that decreased the iodine anomalous contribution to many of the acentric reflections. Thus the simple $(\Delta F_{\text{ano}})^2 = (F_{hkl} - F_{\bar{h}\bar{k}\bar{l}})^2$ anomalous difference Patterson map was not interpretable. Iodine positions were ultimately found by comparing F^2 Patterson maps using both centric and acentric reflections, with F^2 Patterson maps using only acentric data. As we suspected that our difficulties arose because the iodines sat on or near symmetry elements, those Patterson peaks which were deleted by the removal of centric data were reinforced in the simple anomalous difference Patterson map, and the composite map was then interpretable in terms of a self-consistent set of iodine–iodine vectors.

Once the iodines were located, electron density maps were calculated using Sim-weighted heavy atom phases[18] for centric reflections, and Sim-weighted anomalous phases[19,20] for acentric reflections. Of the two possible enantiomorphic maps, one was uninterpretable, while the other gave a clear and clean image of the tetramer double helix. The helix obtained from this map was subjected to 28 cycles of simultaneous energy and reciprocal space refinement[21], using the same energy constraints as for the B-DNA dodecamer[10]. Refinement progress was monitored periodically by Fourier and difference Fourier electron density maps. During this process, the *R* factor fell from 39% at 3.0 Å resolution (2σ data) to the current 20.5% at 2.1 Å. The model contains 29 solvent molecules at present and refinement is continuing.

Tetramer structure

The complete unit cell contains eight identical double-helical tetramers, one of which is shown in Fig. 1. The tetramer is a fragment of an A-DNA double helix. A helix-generating program provided by J. Rosenberg enabled us to use the relationships between base pairs within one tetramer to define the parameters of an ideal continuous helix (see Fig. 1). The helix twist angle is 33.6° per base, corresponding to 10.7 bp per turn, and the rise per base pair along the the axis is 2.3 Å. Bases are tilted by 19° from perpendicularity to the helix axis. Sugar rings are all in the C-3′-*endo* conformation with the exception of the 3′-terminal sugar of guanine G4, which is C-2′-*endo*. (See upper left of Fig. 1*b*, or lower left of Fig. 1*c*.) However, as the G4 sugar has no chain continuation to force it into a regular geometry, it is not surprising that it adopts an anomalous conformation. Table 1 compares observed CCGG helix parameters with idealized A-DNA values derived from fibre data and with those of other types of helix.

The base pairs have large propeller twists: 19°, 18°, 18° and 23° for C1–G8, C2–G7, G3–C6 and G4–C5 respectively. The large propeller twist was visible early in the analysis of the anomalously phased electron density map, and hence is not a consequence of the refinement process. The last value is perturbed by the same intermolecular crystal packing that produces the tilted C5 plane visible in Fig. 1, but the other three values are quite consistent. They are larger than the 13° average propeller twist observed for B-DNA in the low-alcohol crystals (35% methylpentanediol, MPD) of CGCGAATTCGCG[10], and more like the 19° observed in the higher alcohol (60% MPD) crystals of CGCGAATT$^{\text{Br}}$CGCG (M. L. Kopka, A. V. Fratini, H. R. Drew and R.E.D., in preparation). The sense of the propeller rotation in A-helical CCGG is the same as that in these B helices: clockwise rotation of the nearer base plane when the base pair is viewed along its long axis, defined here as the positive rotational sense for propeller twist. In contrast, the published coordinates for a model A-DNA structure derived from fibre diffraction data[22] yield an opposite rotation, with a propeller twist angle of −12°. (A recent unpublished set of new fibre-derived A-DNA coordinates supplied by S. Arnott has positive propeller twist angles of +7.5°.) Two RNA dimers are known which are fragments of an A helix: r(ApU) and r(GpC)[23,24]. In these molecules the propeller twist is smaller and of variable sign: +12.5° (average) for r(ApU) and −7.2° for r(GpC). It seems likely that a substantial propeller twist is a consequence of efficient base stacking at successive steps along one strand of a continuous double helix, and hence reasonable that the full twist typical of an infinite helix would not be generated in helices shorter than 3 or 4 bp. Indeed, one unexpected feature apparent from the single-crystal analyses of oligomers of A- and B-DNA has been the large propeller twist angles, which were not anticipated from fibre and dimer studies.

A-helical octamers in the crystal

The most apparent distortion of the tetramer in Fig. 1 is the pushing of the iodine on cytosine C5 towards the centre of the molecule, with a resultant bending of the C5 plane away from that of G4. This is simply explained in terms of the way in which tetramers are packed within the crystal. Two tetramers are stacked with their C1–G8 base planes in contact, their helix axes nearly coincident and a rotation between tetramers that closely approximates a continuous 8-bp A helix (Fig. 2). Four of these octamers are then packed around the 4-fold screw axes of the

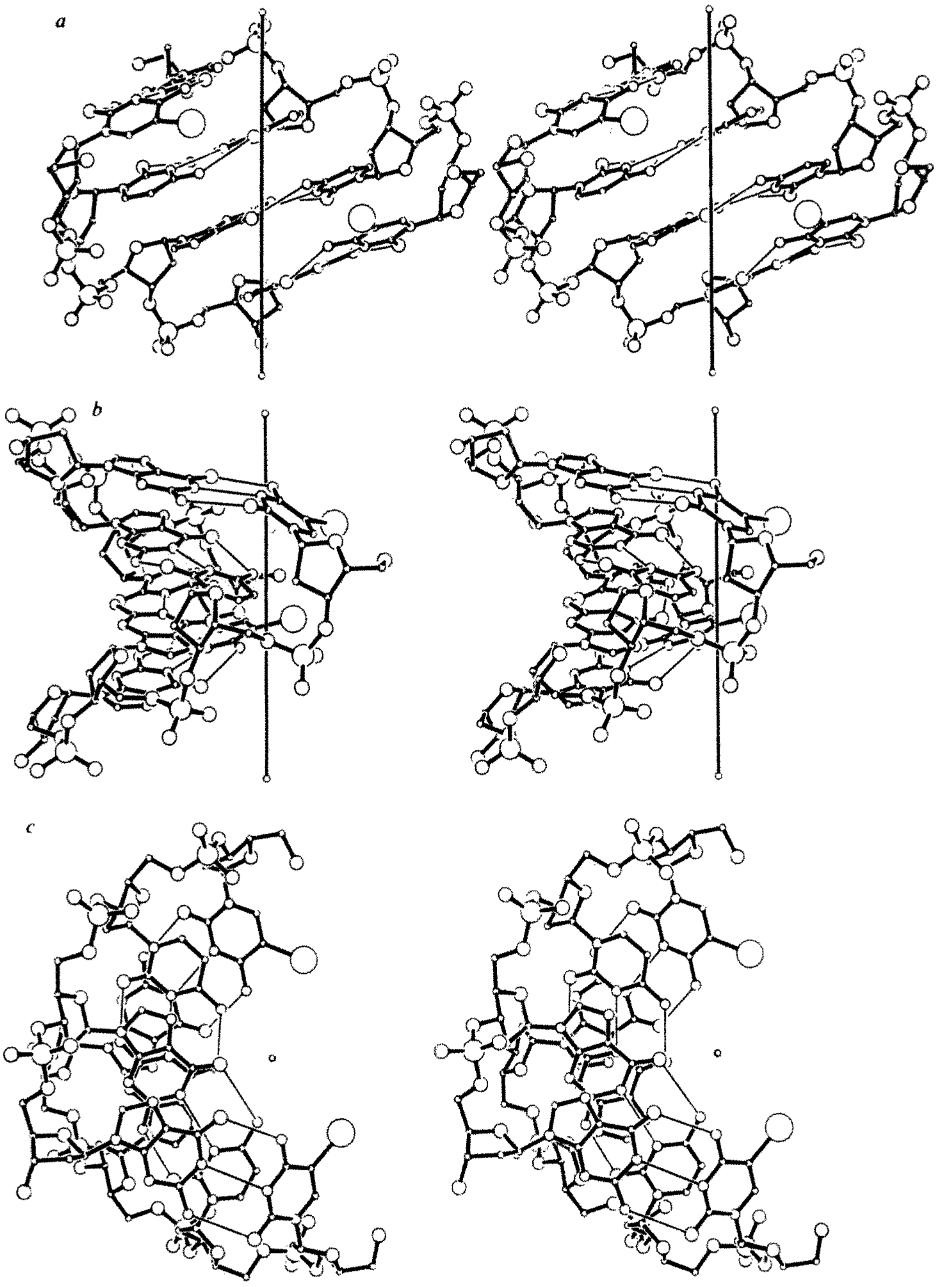

Fig. 1 Stereo views of the ^{I}CCGG double-helical A-DNA molecule. *a*, View into the major groove with helix axis vertical. Bases are numbered: 5′-C1-C2-G3-G4-3′ in one strand and 5′-C5-C6-G7-G8-3′ along the other. The two largest atoms are iodines on cytosines C1 (lower right) and C5 (upper left), and other atoms in order of decreasing size are P, O, N and C. Hydrogen bonds between base pairs are shown as thin lines. Base pair C1–G8 is at the bottom and G4–C5 at the top. *b*, View 90° to the left of *a*, showing the shallow minor groove in profile at left, and the large propeller twist of base planes. *c*, Top view looking directly down the helix axis onto base pair G4–C5. The iodocytosine base planes are tilted away from the planes of their hydrogen-bonded partners, C5 more so than C1, because of intermolecular contacts within the crystal.

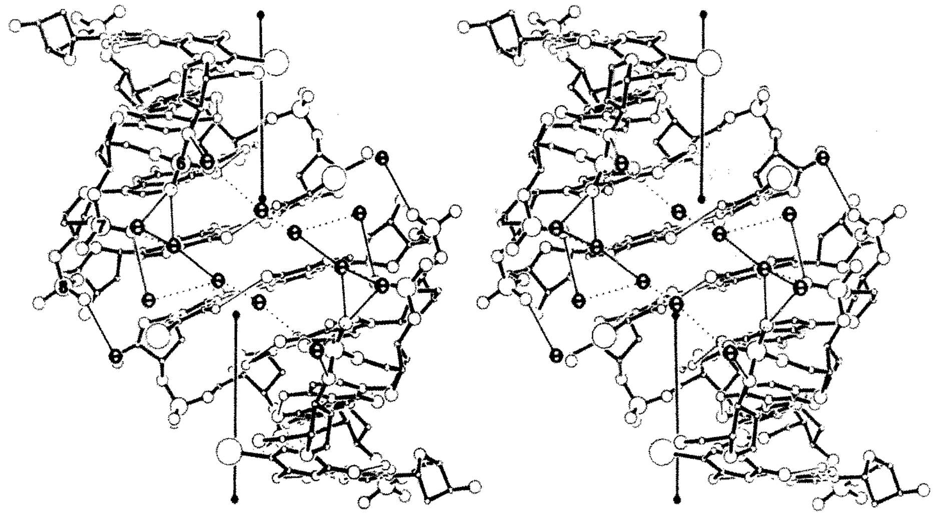

Fig. 2 Two ^{I}CCGG tetramers stacked around a 2-fold axis (normal to the page through the centre of the drawing) as they are observed in the crystal. Their C1–G8 base pairs are in contact, and have very nearly the correct displacement to continue the A helix for 8 bp. Local helix axes, as determined independently for the two tetramers, are shown by vertical lines, and are almost coincident. This view is directly into the major groove, lined by phosphates 6, 7 and 8 (numbered on one strand). After the missing phosphate between tetramers, a continuous helix would use phosphates 2, 3 and 4 around the back of the drawing on the other tetramer. Seven water molecules and their symmetry-related partners are shown spanning the major groove (⊖). Distances of ≤ 3.4 Å are shown by thin solid lines, and distances up to 3.8 Å by dotted lines. As discussed in the text, in a continuous A-DNA helix the major groove would be narrower than shown here, and the bridging network of hydration would be different in detail although similar in character.

$P4_32_12$ cell. The iodocytosine ring C5 at each end of an octamer (top and bottom of Fig. 2) is packed against the minor groove of a neighbouring octamer, between bases C2 and G3. Although the C5 iodine atom is pushed back towards the centre of the octamer, it still is in tight van der Waals contact with the C-2′ sugar atom of cytosine C2 and the C-5′ atom of guanine G3 on a neighbouring octamer.

At the centre of each octamer (deep inside the major groove in Fig. 2), the iodine of cytosine C1 on one tetramer is displaced slightly because of a close contact with the five-membered ring of G8 on the other tetramer (the next base step along the helix), but the effect on its cytosine orientation is small. The two local helix axes as viewed in Fig. 2 are displaced sideways by 1.5 Å, which serves to lessen the overlap between each iodine and its facing G8 ring. The extreme top and bottom of the two axes in Fig. 2 are tipped down into the plane of the page so the axes make an angle of 8° to one another, which also lessens the iodine/guanine clash. The absence of phosphate groups to connect the tetramers allows a degree of adjustment that might not be present in a true double-stranded octamer.

Four octamers as shown are packed into the tetragonal unit cell of the crystal in helical arrays around water channels with elliptical cross-sections, parallel to the *z* axis. Each octamer uses its relatively flat minor groove side to define a long side of one elliptical channel, and its more concave major groove to make the sharp bend at the short side of a different elliptical channel. The individual octamers are hydrated as described below, and networks of localized solvent molecules extend across the channels.

The idealized extended A helix

The octamer in Fig. 2 does not provide a true impression of a continuous A-DNA helix with this helix geometry. Figure 3 shows two views of a full turn of helix, constructed by stacking three identical tetramers on top of one another with their local helix axes coincident. The very deep major groove is particularly striking in stereo (Fig. 3*a*). The groove is narrower in the continuous helix (Fig. 3) than in the crystal structure octamer (Fig. 2) because of the 8° angle between local helix axes in the octamer. If this angle were straightened out to 0°, then the major groove in the octamer would appear as in Fig. 3*a*, with phosphorus–phosphorus separations across the groove of 7.8 Å rather than 10.9 Å, the P6–P6 separation in Fig. 2. This factor will become important in the following discussion of hydration.

The shallow minor groove is hardly a groove at all in comparison with its structure in B-DNA. Figure 3*b* shows the hollow channel down the centre of the helix, a feature peculiar to A-DNA. In a sense the A helix is more a twisted, double-edged ribbon than a cylinder of stacked base pairs. The major groove is only one-quarter as wide as the minor one, but is four times as deep (Table 1).

Hydration and contrast with B-DNA

The A-DNA structure itself has been completely refined;

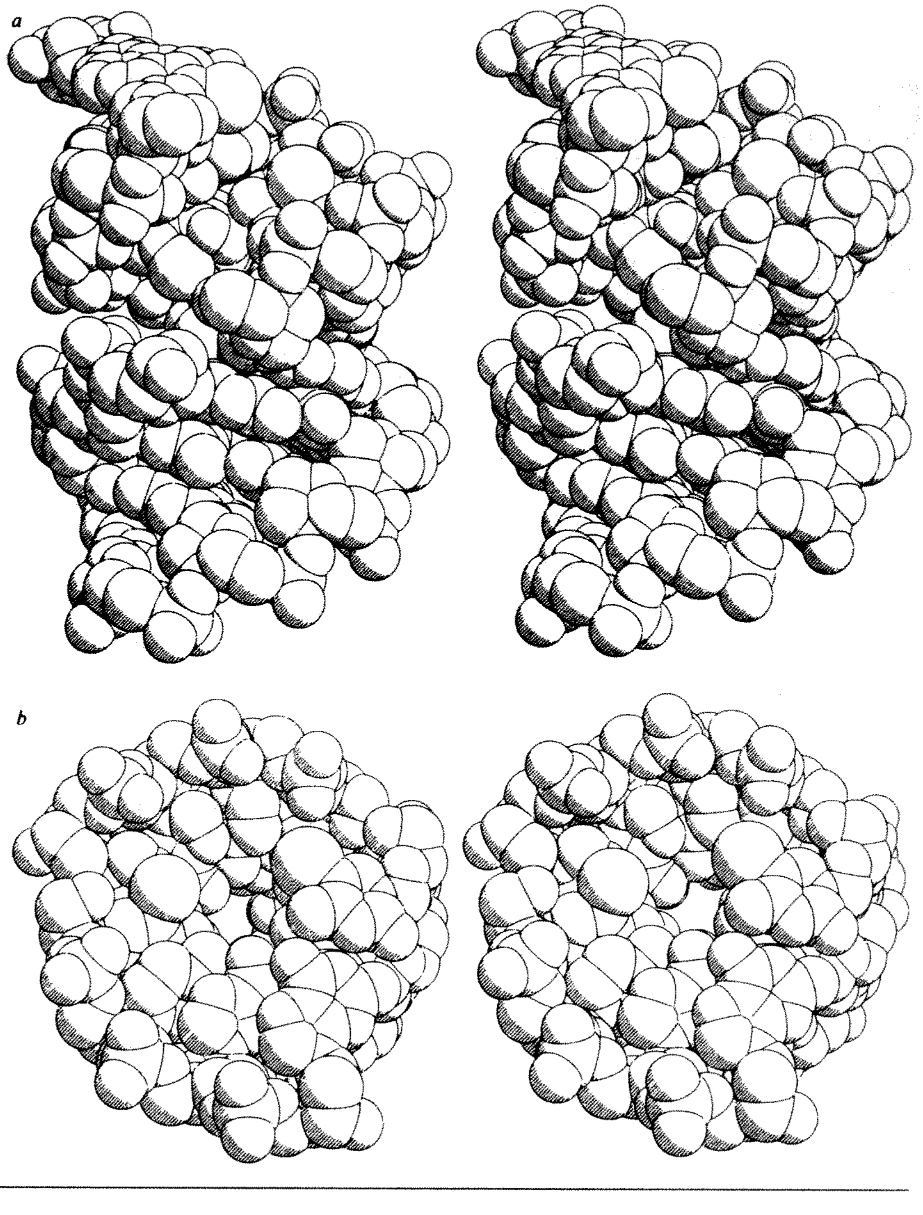

Fig. 3 PLUTO space-filling drawings of three $^{\mathrm{I}}$CCGG tetramers stacked atop one another along their helix axes to form a complete turn of A-DNA helix. In the actual octamer found in the crystal (Fig. 2), one tetramer is inverted before being stacked on the other, with equivalent base pairs in contact. In contrast, in this simulation of a complete turn of helix, all three tetramers are stacked upright in the sense of Fig. 1, with base pair G4–C5 at the top and C1–G8 at the bottom. No attempt has been made to idealize or regularize individual molecules, or to fill in the missing phosphate groups that would connect tetramers in a continuous helix; each tetramer is exactly as observed in the crystal. *a*, Side view looking into the cavernous major groove at the top, with the shallow minor groove in profile at right. *b*, Top view down the helix axis, showing the 'spiral staircase' arrangement of base pairs and the hollow centre.

remaining refinement will be concerned principally with adding more solvent peaks until the difference electron density map has no significant residual features. The 29 solvent peaks added so far give a good impression of the hydration state of the A helix, since most of the peaks that have yet to be incorporated lie in the open solvent channels between molecules. A detailed analysis of intermolecular water networks, and comparison with other results (refs 25, 26 and M. L. Kopka, A. V. Fratini, H. R. Drew and R.E.D., in preparation) will be described elsewhere (B.N.C. and R.E.D., in preparation). The helical octamers are long enough to establish true major and minor groove solvent environments, even though the chemically unique unit is only four bases long.

The hydration state of A-DNA in CCGG is significantly different from that of B-DNA in CGCGAATTCGCG. In the 35% MPD crystals of B-DNA[26], all the N and O groups on the edges of base pairs in the major groove are hydrated by a monolayer of solvent molecules, but the bulk water within the major groove appears disordered. Similarly, except for three examples where a water molecule is trapped in a clathrate-like manner between a phosphate group and a thymine methyl, hydration of B-DNA along the phosphate backbone also is unlocalized, without clearly defined peaks. But taking the B-DNA dodecamer to the higher alcohol concentration of 60% MPD produces a more extensive second- and third-shell hydration within the major groove, and a more extensive and ordered hydration along the phosphate backbone (M. L. Kopka, A. V. Fratini, H. R. Drew and R.E.D., in preparation). Almost every free phosphate oxygen has a solvent ligand, and another solvent molecule frequently bridges the two oxygens. The most striking and unvarying aspect of B-DNA hydration, however, is a zigzag spine of water molecules running down the narrow minor groove, bridging purine N-3 and pyrimidine O-2 atoms on adjacent base pair steps, where not interrupted by N-2 amino groups on guanines. This feature is identical in low and high MPD crystals, though slightly more extensive in the latter. It has been proposed that the breakup of this minor groove spine of hydration is the crucial first step in the cooperative transition from the B to the A form[26,27].

With respect to the phosphate backbone, CCGG in 80% isopropanol resembles CGCGAATT$^{\mathrm{Br}}$CGCG in 60% MPD: a chain of localized water molecules follows each tetramer backbone strand, bonding to the two unesterified oxygens on each phosphorus. Eighteen well defined solvent peaks are associated with the phosphate backbone, and many of these first hydration shell ligands are themselves bridged by other solvent molecules (see Fig. 4). In the view of the octamer in Fig. 2, a network of six solvent molecules (and their six symmetry-related partners) arches across the opening of the major groove, connecting phosphates P-6 and P-7 on opposite sides. This octamer is so short that the two edges of the major groove are in opposition only at P-6 and P-7. In a continuous A helix, such as in Fig. 3, one would expect the opening of the major groove to be crossed by a continuous network of solvent molecules, especially as the actual A-DNA groove would be 3 Å narrower than that in the octamer of the crystal structure. This network of solvent molecules stitching together the two edges of the major groove may be a distinctive feature of the A helix.

In contrast, fewer ordered water molecules seem to be located deep in the major groove of A-DNA, or in the very shallow minor groove, even though the major groove is more accessible in this crystal structure analysis than it would be in continuous A-DNA. Only one-third of the N and O atoms on base edges have clearly defined full-occupancy ligands, five in the major groove and three in the minor one. Another one-quarter has small nearby peaks that may represent partial occupancy sites (three each in major and minor), but hydration within the grooves is less impressive than in either of the grooves of B-DNA, even at comparable alcohol concentrations.

Water structure and the B-to-A transition

In summary, in A-DNA there is no trace of the minor groove spine of hydration that is so prominent in B-DNA, nor does there appear to be as uniform a monolayer of ordered solvent lining the major groove. The extensive solvation of phosphate backbone observed in B-DNA at 60% MPD reappears in A-DNA, where it seems to lace together the two edges of the major groove.

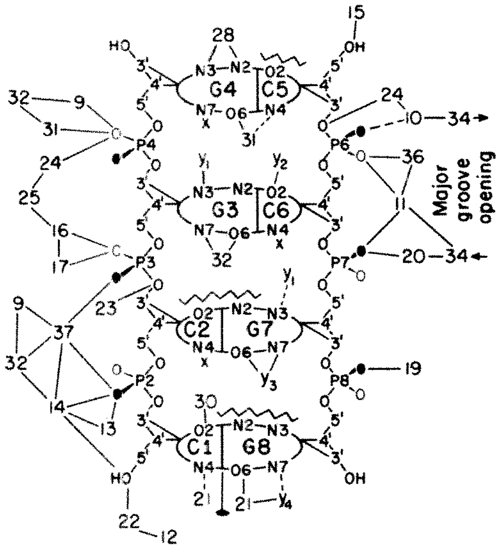

Fig. 4 Schematic drawing of hydration in the immediate vicinity of the CCGG double helix in the crystal. The four central ovals represent purine–pyrimidine base pairs identified by base numbers, as 'G4/C5' at the top. Base ring nitrogen and oxygen atoms are shown by N3, N2, O2 and so on around the perimeter of each oval. The upper edge of each oval faces the minor groove, and the lower edge faces the major. The two sugar–phosphate chains run vertically at either side of the base pair ovals, with C-3', C-4' and C-5' atoms indicated merely by 3', 4' and 5'. (Atoms C-1', C-2' and O-1' are omitted for clarity.) Phosphates are numbered P2–P4 and P6–P8 according to the base to which they are linked via C-5' atoms. Solid black oxygen atoms on phosphates are those facing the major groove. Large numbers identify the most prominent solvent molecules in the immediate vicinity of the double helix. x Indicates that a peak was specifically looked for in the electron density map but not found. y_1–y_4 Are lesser peaks not included in the original hydration search, but found in the map when specifically examined for base edge coordination. ⁓ Indicates that base edge atoms are blocked by neighbouring DNA substituents, and hence unavailable for hydration. The region of the major groove opening depicted in Fig. 2 appears at the upper right edge. A chain of five solvent molecules (24-10-34-11-36) runs diagonally downwards to the right from phosphate P-6 in Fig. 2, with the parallel symmetry-related chain (36-11-34-10-24) just below it. Solvent molecules 19 and 20 in two symmetry-related pairs lie just below and above these two strands in Fig. 2. The solvent network shown at the left of the diagram is necessarily incomplete and distorted because a three-dimensional network cannot easily be flattened into a planar diagram. Solvent atom 32 at the lower left, for example, is part of a network connecting phosphate P-2 with phosphate P-4 on a different double helix (upper left). It also is coordinated directly to major groove atoms N-7 and O-6 on base G3 of the same helix. However, the figure does provide an accurate depiction of the first hydration shell of the helix.

These observations permit the ideas proposed in ref. 26 on the B-to-A helix transition to be carried one step further. The backbone phosphate groups are more polar, and have a greater attraction for water molecules, than do the N and O groups on the edges of base pairs within the grooves. In conditions where the activity coefficient of water is high (conditions favouring B-DNA), all these polar groups should be solvated; but when the water activity is decreased, either by dehydration or by addition of alcohol, then the groove N and O groups should lose their solvation shells before the phosphates do. When the spine of hydration in the minor groove is disrupted, the integrity of the B structure is destroyed and the helix slips into the A form, in which the still hydrated phosphate groups participate in a network of solvation that laces together the two edges of the now quite narrow major groove. The phosphate-associated lacing across the major groove in A-DNA may have a stabilizing role comparable with that of the base-associated spine within the minor groove in B-DNA. When the water activity around an A helix is increased again, rehydration of base edge N and O groups, including re-establishment of the minor groove spine, shifts the equilibrium in favour of B-DNA, because the number of molecules solvating the phosphate backbone is not altered, but only their disposition.

Since submission of this manuscript, O. Kennard and co-workers at Cambridge have solved the structure of another A-DNA helix, of sequence: GGTATACC (personal communication).

We thank Al Fratini, Mary Kopka and Horace Drew for permission to quote their dodecamer results in 60% MPD before publication, and Lillian Casler for assistance with the figures. This work was supported by NIH grant GM-12121 and NSF grant PCM79-13959. B.N.C. was the recipient of an NIH predoctoral traineeship. This is contribution no. 6482 from the Division of Chemistry and Chemical Engineering.

The sequence of a cDNA encoding the nonapeptide arginine vasopressin (AVP) and its carrier protein, neurophysin II (NpII) from bovine hypothalamus, proves that the 166-amino acid precursor molecule contains a signal peptide of 19 amino acids followed directly by AVP connected to NpII by a Gly-Lys-Arg sequence. The carboxy-terminal region of the precursor contains a naturally occurring glycopolypeptide of 39 amino acids which is separated from NpII by a single arginine residue.

THE nonapeptide hormones arginine vasopressin and oxytocin are synthesized in the supraoptic and paraventricular nuclei of the hypothalamus together with their respective 'carrier' proteins, the neurophysins (for reviews see refs 1–4). Arginine vasopressin and oxytocin are produced by separate populations of magnocellular neurones in both nuclei[5,6]. Together with the neurophysins they are packaged into neurosecretory vesicles and transported axonally to the nerve endings located in the neurohypophysis, where they are either stored or secreted into the bloodstream. More than a decade ago, Sachs and co-workers[7,8] suggested that arginine vasopressin and its corresponding neurophysin (molecular weight M_r) 10,000 are synthesized in the form of a common precursor which is cleaved by proteolysis to yield the biologically functional peptides. This hypothesis is supported by the finding that rats with hereditary diabetes insipidus are deficient in synthesis of arginine vasopressin[9] and one species of neurophysin[10–13]. Further evidence in support of this model of a cellular polyprotein[14] was obtained by the isolation from the hypothalamus of rats[15,16] and mice[17] of precursor polypeptides with apparent M_r of 20,000 and 17,000, respectively. These polypeptides cross-reacted with antibodies directed against neurophysin[17,18] and were found to be processed *in vivo* to polypeptides of neurophysin size[15]. One of the precursors gave rise to an arginine vasopressin-like peptide after trypsinization[16]. Neurophysin precursors were also demonstrated after *in vitro* translation of hypothalamic mRNA[19–21]. Recently, an *in vitro* synthesized common precursor to arginine vasopressin and bovine neurophysin II (AVP-NpII) has been identified both immunologically[22,23] and by tryptic fingerprint analysis[24]. The latter showed that authentic AVP$_{1-8}$ and the expected oligopeptides specific for NpII can be released from the *in vitro* synthesized precursor[24]. Furthermore, comparison of the tryptic peptides obtained from the pre-proform, the glycosylated proform and a 14,000-M_r intermediate of the AVP-NpII precursor indicated that AVP should be directly connected to the signal peptide and that AVP and NpII should be close neighbours within the precursor[24]. However, proof of the intramolecular organization of the AVP–NpII precursor awaits elucidation of its amino acid sequence.

The construction of bacterial plasmids containing the mRNA sequence for the AVP–NpII precursor is a direct approach to analysing the amino acid sequence, the mRNA and the gene for the hypothalamic polyprotein. Here we present the nucleotide sequence of the mRNA which allows us to predict the primary structure of the AVP–NpII precursor synthesized in the bovine hypothalamus.

Cloning of cDNA encoding the AVP–NpII precursor

Poly(A)-containing RNA from bovine hypothalamus was isolated as described in Fig. 1 legend. To estimate the relative proportion of mRNA coding for the AVP–NpII precursor, the RNA was translated *in vitro* using a rabbit reticulocyte lysate in

Fig. 1 Cloning of cDNA specific for bovine hypothalamic mRNA and selection of plasmids carrying sequences encoding the AVP–NpII precursor. Membrane-bound polysomes were isolated from bovine hypothalami and the RNA extracted with SDS/phenol/chloroform[27]. Polyadenylated RNA was purified by oligo (dT)-cellulose affinity chromatography. The yield was 0.4–0.5 μg poly(A)-containing RNA per g of tissue[27]; 1.2 μg of single-stranded cDNA was constructed from 10 μg poly(A)-containing RNA with AMV reverse transcriptase[26]. To generate double-stranded cDNA (ds cDNA), the cDNA was dC-tailed at its 3′ end with terminal deoxyribonucleotidyl transferase (TdT). The synthesis of the second cDNA strand was primed by oligo(dG) hybridized to the 3′ tail[26]. The cDNA was extracted with chloroform/isoamylalcohol and ethanol-precipitated twice, then hybridized to oligo(dG). Reverse transcriptase (60 units) was added to the incubation mixture to catalyse synthesis of the complementary cDNA strand. The reaction was stopped as described above. Ds cDNA (0.8 μg) was run on a 2% agarose gel in Tris-acetate buffer *p*H 8.0 and molecules in the range 500–1,500 bp were recovered from the gel by the glass binding method[62], with a yield of 0.2 μg. Ds cDNA was tailed, and ~10 dC residues were added to each 3′ end[63]. The dC-tailed ds cDNA was then annealed to an equimolar amount of *Pst*I-cut (Renner) dG-tailed pBR322. Ten microlitres of annealing solution (2.5 ng vector) were taken for 100 μl of competent cells. Transformation of *E. coli* 5K (ref. 64) was carried out as described elsewhere[65] in L3/B1 conditions as specified by the Zentrale Kommission für Biologische Sicherheit of the FRG. Screening for tetracycline-resistant cells yielded ~200 colonies per ng of ds cDNA with a background of 10% ampicillin-resistant clones. To screen the recombinant colonies, plasmid DNAs from 550 clones were individually prepared according to a minipreparation protocol[66] and spotted on to nitrocellulose filters[67]. The filters were hybridized to a ^{32}P-labelled poly(A)$^+$ RNA probe[68] which was enriched for mRNA coding for the common AVP–NpII precursor by two subsequent separations on isokinetic sucrose gradients[27]. Desired fractions were selected by an *in vitro* translation assay[27]. Plasmid DNAs from 55 colonies giving a hybridization signal markedly above background were collected into 11 groups, RNase A-treated, restricted with *Sau*961 (BLR) and labelled at their 3′ ends with *Escherichia coli* DNA polymerase I Klenow fragment (BRL). Unincorporated radioactivity was removed by centrifuging the reaction mixture through a syringe packed with Sephadex LH-60 (Pharmacia). The excluded material was ethanol-precipitated and run on a 15% polyacrylamide gel (*b*, lanes 2–12). DNA M_r standards: Lane 1, pBR322 was digested with *Hpa*II and the 3′ ends were labelled with [α-^{32}P]dCTP as described above. Lane 13, molecular *Cla*I linkers (Collaborative Research) were phosphorylated with [γ-^{32}P]ATP and ligated. Numbers indicate the size of the DNA marker bands in base pairs (bp). The gel was dried and autoradiographed. *a*, *Sau*961 cleavage sites predicted from the amino acid sequence of neurophysin. Definite sites are framed by solid lines, possible sites by broken lines (for further explanation see text).

the presence of five ^{3}H-labelled amino acids. About 1% of the trichloroacetic acid-precipitable radioactivity was found in material that was immunoprecipitated with antibodies against bovine neurophysin II[25].

Double-stranded cDNA was synthesized from the poly(A)-containing RNA by a method that reduces the loss of the 5′-terminal mRNA sequences in the steps following cDNA synthesis[26]. This approach avoids the self-priming step for generation of double-stranded cDNA. Therefore, no S_1-nuclease digestion step is required. Instead, the cDNA is tailed with dC residues at its 3′ end using terminal deoxynucleotidyl transferase. The synthesis of the second strand was primed by oligo(dG) hybridized to the 3′ tail. dC-tailed double-stranded cDNA was then annealed to the plasmid pBR322 that had been previously linearized by restriction endonuclease *Pst*I and dG-tailed. Tetracycline-resistant transformants were screened for ampicillin sensitivity (for details see Fig. 1 legend).

To identify plasmids carrying the more frequent mRNA sequences, plasmid DNAs from 550 colonies were hybridized to *in vitro* ^{32}P-labelled poly(A)-containing RNA from bovine hypothalamus that was ~10-fold enriched for AVP–NpII mRNA by fractionation after passage through two consecutive sucrose gradients[27]; 55 plasmids gave a positive hybridization signal. Because the yields of mRNA isolated from bovine hypothalami were very low, the RNA-consuming positive hydrid selection assay[28] could not be used for clone identification. To identify clones specific for AVP–NpII precursor sequences, we adopted a strategy whereby restriction endonuclease cleavage sites in an unknown DNA sequence can be predicted unambiguously from a known amino acid sequence. Only a few restriction endonucleases have recognition sequences that fulfil the necessary requirements. *Fnu*4HI (GCNGC)[29] cuts the DNA at any position corresponding to the amino acid sequence Ala-Ala (GCNGCN), *Sau*96I (GGNCC)[30] cuts at all positions coding for Gly-Pro (GGNCCN). The neurophysins exhibit Gly-Pro sequences at positions 14–15 and 23–24. If a DNA sequence coding for neurophysin is digested with *Sau*96I, a 27-base pair (bp) fragment should be generated by cuts at the predicted cleavage sites. Computer analysis revealed the possible existence of an additional restriction site for *Sau*96I within this 27-bp fragment which, if it were present, would lead to cleavage of the 27-bp fragment into fragments of 14 and 13 bp (Fig. 1*a*). To detect clones carrying the 27-bp fragment, the 55 positively hybridizing plasmid DNAs were pooled into 11 groups, cut with *Sau*96I, ^{32}P-labelled at their 3′ ends and run on a polyacrylamide gel (Fig. 1*b*, lanes 2–12). Plasmids revealing fragments of between 25 and 30 bp were identified individually and a partial nucleotide sequence of the inserted cDNA was determined[31]. Neurophysin and arginine vasopressin amino acid sequences were compared with the cDNA sequences using a suitable computer program[32]. Of the eight plasmids giving rise to a *Sau*96I fragment 25–30 bp long, three were found to carry cDNA sequences corresponding to NpII amino acid sequences. The 27-bp fragments in lanes 6, 10 and 11 of Fig. 1 (arrows) represent this type of cDNA sequence. The bands in lanes 6 and 10 are clearly visible on longer exposures.

Rescreening of the 550 recombinant plasmids by hybridization with ^{32}P-labelled cloned cDNA for the AVP–NpII pre-

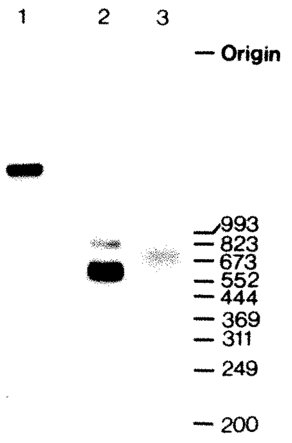

Fig. 2 Size determination of the mRNA encoding the common bovine AVP–NpII precursor. Bovine hypothalamic poly(A)-containing RNA which previously had been separated on a 2% agarose formaldehyde gel and transferred to a nitrocellulose filter[69] was hybridized to ^{32}P-labelled pVNpII-1 DNA. After washing, the dried filter was autoradiographed at −70 °C using an X-ray intensifying screen. Lane 3, bovine hypothalamic poly(A)-containing RNA (~1 μg) hybridized to ^{32}P-labelled pVNpII-1 DNA. Lane 1, chick oviduct poly(A)$^+$ RNA (120 ng) hybridized to ^{32}P-labelled poa-1210 DNA, an ovalbumin cDNA-carrying plasmid (H.L., unpublished results). Lane 2, hybridization of chick oviduct poly(A)$^+$ RNA (1.2 μg) to ^{32}P-labelled pom-48 DNA[70] and pls-1 DNA[71]; pom-48 carries ovomucoid cDNA sequences, pls-1 carries chicken lysozyme cDNA sequences. Assuming a length for the poly(A) tail of ~40 residues, the bands corresponding to the mRNAs represent sizes of 1,900[72], 860[73] and 630[74] nucleotides, respectively. Numbers indicate the lengths of ^{32}P-labelled DNA fragments obtained after *Hin*fI cleavage of SV40 DNA.

cursor identified seven positive clones, all of which were present in the 55 preselected clones; five carried sequences homologous to the bovine AVP–NpII precursor, and two had sequences specific for the oxytocin–nurophysin I precursor. Both cDNAs cross-hybridized because of the high degree of sequence conservation between NpII and NpI.

To correlate the sizes of the inserted cDNAs with the length of the mRNA for the bovine AVP–NpII precursor, poly(A)-containing RNA from bovine hypothalamus was run on a denaturing agarose gel, blotted on to a nitrocellulose filter and hybridized to ^{32}P-labelled cloned cDNA for the AVP–NpII precursor (Fig. 2, lane 3). One band was observed corresponding to a length for the mRNA of 700–750 nucleotides. Because of the sequence homology and the different size (M_r 16,500)[22] of the oxytocin–neurophysin I precursor one might expect to find an additional faster migrating band corresponding to the oxytocin–neurophysin I precursor mRNA. Both mRNAs may be of similar molecular size and may therefore not be separated in this gel system.

The plasmid pVNpII-1, which carries the largest cDNA insert specific for bovine AVP–NpII precursor (~750 bp) was selected for further studies. Its nucleotide sequence was determined using the strategy shown in Fig. 3.

cDNA sequence defines primary structure of AVP–NpII precursor

Figure 4 shows the nucleotide sequence of the bovine AVP–NpII precursor mRNA. AVP is encoded by nucleotides 1–27. Nucleotides 37–321 correspond precisely to the amino acid sequence determined for bovine neurophysin II; nucleotides 301–303 code for valine, a position known to be heterogeneous (Ile/Val) in bovine NpII[33]. The polypeptide carrying the carbohydrate moiety of the precursor[16,17,21,22,34] can be deduced from nucleotides 325–441 and is followed by a stop codon. The predicted sequence is completely homologous to the amino acid sequence previously reported for a glycoprotein of 39 amino acids isolated from bovine pituitary[35].

An open reading frame is found in the cDNA sequence upstream from nucleotide +1. Assuming that the methionine codon AUG at positions −55 to −57 is the location of the translational initiation site, the following 19 mainly hydrophobic amino acid residues would represent the leader or signal peptide similar to that of other secreted proteins[36]. This is in close agreement with the *in vitro* identified prepro- and proforms to AVP–NpII which differ in size by ~15–20 amino acids[23]. The bovine AVP–NpII precursor consists of 166 amino acid residues, with a calculated molecular weight of 17,310, which is smaller than that estimated for the non-glycosylated preproform (M_r ~21,000)[19,21,22] synthesized *in vitro*. This may, however, be explained in a way similar to that of the mature neurophysins, the molecular weights of which are overestimated by SDS-polyacrylamide gel electrophoresis[37]. There is no evidence for the existence of a larger AVP–NpII precursor[38].

The cDNA sequence cloned in pVNpII-1 terminates nine nucleotides upstream from the AUG codon. To determine the sequence of the 5′-terminal portion of the AVP–NpII precursor mRNA which is missing in the cDNA clone, primer extension sequencing experiments[39] were done. The results are shown in Fig. 4: nucleotides −106 to −67 (in parentheses). As this sequence has been obtained for one strand only, it is not yet firmly established; however, these experiments map the 5′ end of the mRNA sequence 40 nucleotides upstream from position −66 (not shown). This implies a length of ~610 nucleotides for the mRNA body. Taking into account the long poly(A) tails cloned in pVNpII-1 and pVNp-2 (~150 A residues), this estimate corresponds well with the size of the AVP–NpII precursor mRNA determined by Northern blotting (Fig. 2).

The codon usage is non-random and very similar to that in other eukaryotic mRNAs (not shown)[40–43]. Particularly, it reflects a high preference for C or G in the third position of the codons: 93 codons (56%) terminate in C, 61 (36%) in G, 7 (4%) in A and 6 (4%) in T. Thus, as in the adrenocorticotropic

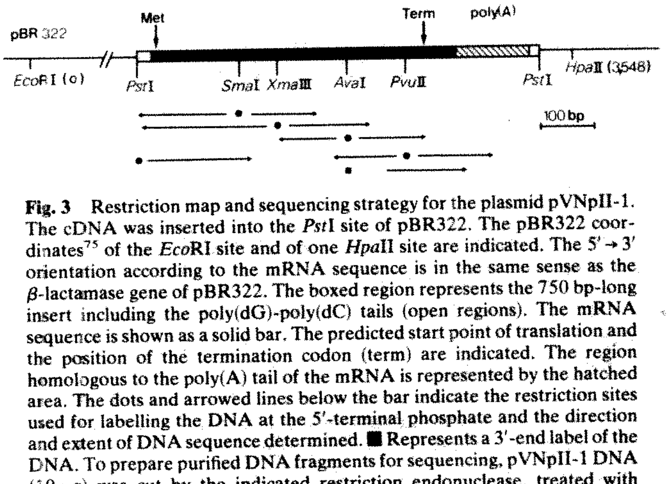

Fig. 3 Restriction map and sequencing strategy for the plasmid pVNpII-1. The cDNA was inserted into the *Pst*I site of pBR322. The pBR322 coordinates[75] of the *Eco*RI site and of one *Hpa*II site are indicated. The 5′→3′ orientation according to the mRNA sequence is in the same sense as the β-lactamase gene of pBR322. The boxed region represents the 750 bp-long insert including the poly(dG)-poly(dC) tails (open regions). The mRNA sequence is shown as a solid bar. The predicted start point of translation and the position of the termination codon (term) are indicated. The region homologous to the poly(A) tail of the mRNA is represented by the hatched area. The dots and arrowed lines below the bar indicate the restriction sites used for labelling the DNA at the 5′-terminal phosphate and the direction and extent of DNA sequence determined. ■ Represents a 3′-end label of the DNA. To prepare purified DNA fragments for sequencing, pVNpII-1 DNA (10 μg) was cut by the indicated restriction endonuclease, treated with alkaline phosphatase from calf intestine (Boehringer) at 37 °C for 30 min in 50 mM Tris-HCl *p*H 8, heated at 70 °C for 10 min in the presence of 6 mM EGTA and then phenol-extracted. DNA was labelled with 10 units of T4 polynucleotide (BRL) at 37 °C for 30 min in a 10 μl volume of 50 mM Tris-HCl *p*H 7.5, 10 mM $MgCl_2$, 5 mM dithiothreitol (DTT), 0.1 mM spermidine, and 50 μCi [γ-^{32}P]ATP (>5,000 Ci mmol^{-1}; Amersham). 3′ Labelling was performed with T4 DNA polymerase (BRL) in 10 μM of 20 mM Tris-HCl *p*H 7.5, 10 mM $MgCl_2$, 1 mM DTT and 50 μCi [α-^{32}P]dTTP (2,000–3,000 Ci mmol^{-1}; Amersham). The labelled DNA was subsequently cut with *Pst*I (BRL), then separated by gel electrophoresis through 5% polyacrylamide in 50 mM Tris-borate *p*H 8.1, 1 mM EDTA. The appropriate fragments were eluted, purified on DE52 (Whatman) and ethanol-precipitated. The *Sma*I$^+$–*Ava*I$^+$ fragment was purified by gel electrophoresis before cutting with *Xma*III. The crosses represent the position of the [γ-^{32}P] label. Sequence reactions were carried out as described elsewhere[31].

Fig. 4 Nucleotide sequence of AVP–NpII precursor mRNA from bovine hypothalamus, and deduced amino acid sequence. The nucleotide numbers are shown above the sequence. Nucleotide residues are numbered in the direction $5' \rightarrow 3'$ in the mRNA strand, beginning with the first residue in the coding region for arginine vasopressin. The nucleotides upstream from residue 1 are indicated by negative numbers. The predicted amino acid sequence is numbered by designating as 1 the first residue (Cys) of arginine vasopressin. The amino acids constituting the putative signal peptide are indicated by negative numbers, those towards the carboxy terminus of the precursor have positive numbers. The untranslated sequence at the 5′ terminus, shown in parentheses is derived from primer extension sequencing of the mRNA[39] and has not been confirmed by sequencing of cloned DNA. The ^{32}P-labelled DNA fragments *Bst*NI(−58)–*Sau* 96I(+39)$^+$ and *Dde*I(−23)–*Sau*96I(+39)$^+$ were used as primers. Asterisks indicate the position of the [γ-^{32}P] label.

hormone (ACTH) β-lipotropin hormone (β-LPH) precursor mRNA[43], the AVP–NpII precursor mRNA has a high G+C content (70%) markedly exceeding that of total bovine DNA (39%)[44]. The occurrence of 48 C–G dinucleotides within 610 nucleotides is in contrast to the relatively low abundance of this dinucleotide in other eukaryotic mRNAs[40–42] as well as in total bovine DNA[45]. The sequence AAUAAA commonly found near the 3′ end of eukaryotic mRNAs[40–43] is present in the AVP–NpII precursor mRNA 12 nucleotides upstream from the poly(A) tail.

Structural and functional implications of AVP–NpII precursor

The mRNA sequence presented here proves conclusively that the hypothalamic peptide hormone arginine vasopressin and its carrier protein neurophysin II are synthesized via a common precursor. This precursor is one of the class of cellular polyproteins which have the uncommon feature of being processed into several functionally distinct oligo- or polypeptides[14]. Members of this class include the hypophyseal precursor to corticotropin, melanotropic hormones and endorphins[43] and the precursor containing the Met- as well as the Leu-enkephalins from the adrenal medulla[46]. The precursors to somatostatin[47] and calcitonin[48] may also contain biologically active peptides in addition to the hormones but this has not been proved. Compared with these polypeptides, the AVP–NpII precursor seems to be the only example where the sequence information is entirely represented within the *in vivo* identified cleavage products (Fig. 5). AVP immediately follows the assumed signal peptide, and as indicated by the nucleotide sequence, has a glycine residue (amino acid 10) adjacent to its carboxy-terminus. As with other polypeptide precursors[43,49–52], the gly-

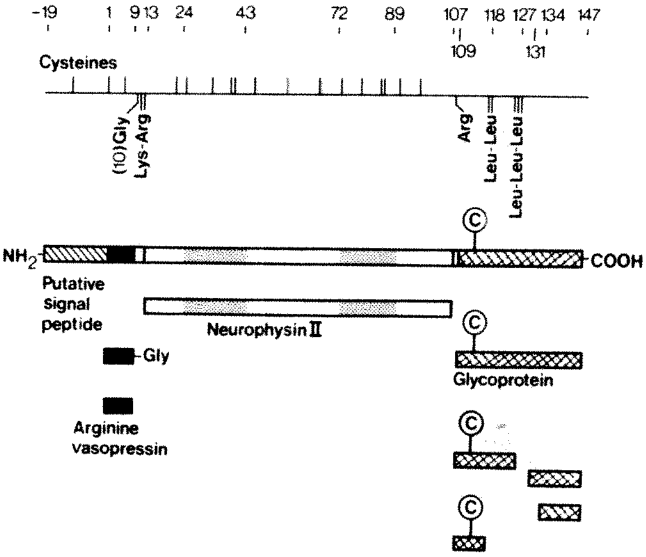

Fig. 5 Schematic representation of the structure of bovine AVP–NpII precursor. Characteristic amino acids are shown: the arrangement of cysteines (marks above the line), and glycine (residue 10) necessary for amidation of AVP and amino acid signals for proteolysis. Numbering of the amino acid residues is as in Fig. 4. The putative signal peptide (−19 to −1) is represented by the hatched bar. Vasopressin (closed bar) extends from amino acid residue 1 to 9. Neurophysin II (13–107), shown as a shaded bar, exhibits areas of internal homology (dark shading) located between amino acid residues 24–43 and 72–89 (ref. 57). The glycoprotein part of the precursor (109–147; cross-hatched bar) carrying a carbohydrate chain (C) at position 114 is further cleaved into several peptides of 10 (109–118), 18 (109–127), 17 (131–147) and 14 (134–147) amino acid residues[35].

cine residue may serve as a signal and amino donor to the preceding amino acid at the C-terminus of AVP. The glycine residue is followed by a pair of basic amino acids suggesting a trypsin- and carboxypeptidase-like cleavage site. For cleavage between neurophysin II and the glycopolypeptide, only one arginine residue (amino acid 108) seems sufficient, whereas the neighbouring arginyl-arginine dipeptide (amino acids 105–106) remains uncut.

A glycoprotein of 39 amino acid residues (109–147) is located at the carboxy terminus of the precursor and contains a typical glycosylation site, Asn-X-Thr (114–116)[53]. This glycopolypeptide has also been isolated from the pituitaries of several species[35,54] and contains a glucosamine-rich side chain at the corresponding asparagine residues[35,54,55]. Microinjection of *Xenopus laevis* oocytes with bovine hypothalamic mRNA gives rise to a glycosylated AVP–NpII precursor containing glucosamine as well as fucose and mannose residues[34]. Smyth and Massey[35] isolated four different naturally occurring subfragments of the glycopolypeptide (see Fig. 5). Two fragments, comprising amino acids 109–118 and 109–127, may be evidence for the existence of an alternative processing activity which cleaves at the carboxyl side of consecutive leucine residues; a similar fragment has been described by Holwerda[55]. The two other fragments extend from residues 131 and 134, respectively, to the carboxy-terminal tyrosine (amino acid 147).

There have been no studies made of the subcellular localization of the glycoprotein and its fragments, nor is anything known about a possible biological function which may be inferred from its remarkable sequence conservation during evolution[54]. However, it is of interest that six consecutive residues (131–136) of the glycopolypeptide show close homology to the amino-terminal region of procine β-LPH (amino acids 1–6, Glu-Leu-Ala-Gly-Ala-Pro)[35,56].

The internal amino acid sequence homology described for neurophysin II between residues 24–43 and 72–89 may represent directly duplicated segments of an ancestral gene[57] as reflected by the repeated arrangement of cysteine residues (Fig. 5). The sequence of the entire precursor does not reveal any additional homologies as observed for the melanotropic hormones in proopiocortin[43].

It is unknown whether the neurophysins have any biological role other than their carrier function. Proteins immunologically related to the neurophysins have been found in the target organs (kidney, uterus and mammary gland) of vasopressin and oxytocin, and it has been suggested that these proteins may act as receptors for the nonapeptides[58]. A cDNA clone encoding lactoglandin, a neurophysin-like protein, has recently been isolated from a lactating mouse mammary gland specific cDNA library. The relationship of this protein to the neurophysins is reflected by a similar pattern of cysteine residues[59].

The functional significance of the components of the AVP–NpII precursor remains to be determined. Although various factors are known to regulate the metabolism of AVP or oxytocin and their corresponding neurophysins[8,60,61], the nature of the control of its synthesis is poorly understood. The cloned cDNA provides the basis for a detailed study of the regulation of arginine vasopressin and neurophysin biosynthesis in the peptidergic neurone.

We thank C. Schmidt and C. M. Strange for technical assistance; Dr J. W. Beard for providing reverse transcriptase; Drs G. Osterburg and J. Collins for help in computer analysis; L. Henninghausen for stimulating discussion; Drs R. Ivell, W. Keller, M. Grez, G. Scherer and A. Scott for critical comments on the manuscript; and U. Joa for secretarial assistance. This work was supported by the Deutsche Forschungsgemeinschaft 192/14 to D.R.

Creation of open universes from de Sitter space

J. Richard Gott III

Department of Astrophysical Sciences, Princeton University,
Peyton Hall, Princeton, New Jersey 08544, USA

Hawking[1,2] has shown that event horizons produce thermal radiation. I propose here a new cosmological model which has an early event horizon and in which the observed[3] cosmic microwave background radiation is Hawking radiation. The model starts with de Sitter space—a space-time of constant curvature which is a solution to Einstein's vacuum field equations with a positive cosmological constant. Associated with an event E in de Sitter space there is a quantum barrier penetration tunnelling which leads to an open, negatively curved ($k=-1$) cosmology. This has an early exponential expansion phase but turns into a standard big-bang solution at late times. The geometry and quantum mechanical treatment within the future light cone of E are similar to that found in the Brout, Englert and Spindel (BES) theory[4,5]. This model has the following advantages: (1) It has no singularities. (2) The observed isotropy of the cosmic microwave background is explained because the different regions we observe have all been in causal contact. (3) The temperature at early epochs ($T_0 \sim 10^{19}$ GeV) is high enough to allow grand unified theories (GUTs) to produce the observed baryon excess from an initial thermal distribution through CP violations[6,7]. (4) T_0 is correct to make the BES scenario work. (5) The early exponential expansion phase can naturally account for the observed large number $n_0 \sim 10^{88}$ of particles within a volume a^3 (where a is the radius of curvature) and the Guth[8] flatness problem. (6) It predicts that our Universe is an open $k=-1, \Omega<1$ cosmology consistent with the amount of mass detected in the universe so far[9-11]. (7) The existence of the event horizon makes it possible to create from the original de Sitter space other $k=-1$ universes (perhaps an infinite number) which are entirely disjoint from our own and from each other.

The BES model starts with Minkowski space. At an event E there occurs a spontaneous phase transition from an $m=0$ vacuum (Minkowski space) to an $m \neq 0$ vacuum, the appearance of mass being the signature of a broken symmetry. The metric inside the future light cone of E may be written as

$$ds^2 = -d\tau^2 + a^2(\tau)[d\chi'^2 + \sinh^2 \chi'(d\theta^2 + \sin^2 \theta \, d\phi^2)]$$

(Planck units $G=\hbar=c=k=1$ are used throughout). This is a $k=-1$ cosmological metric. There is a brief transition phase $0 \leq \tau \leq \tau_0$, $\tau_0 \sim 0(1/m)$, $a(\tau) \sim \tau$, followed by a particle creation phase $\tau_0 < \tau < \tau_1$ during which the matter being produced approaches a constant energy density $\rho = \lambda/8\pi$, $P=-\lambda/8\pi$, $\lambda=$ constant. During this period $a(\tau) \propto \exp(\tau/\tau_\lambda)$, $\tau_\lambda = (3/\lambda)^{1/2}$, $T_{\mu\nu} = -\lambda \, g_{\mu\nu}/8\pi$ and the space approximates a piece of de Sitter space. After a time τ_1, incoherence develops, particle production stops and the model enters the conventional radiation dominated regime of a standard $k=-1$ big-bang model. A detailed quantum-mechanical treatment[4] shows that a self-consistent exponential expansion phase is possible only if the mass of the created particles (and anti-particles) is of the order of the Planck mass ($m \sim 0(1)$. τ_λ could be as short as $1/m \sim 0(1)$. τ_1 will be of the order of a relaxation time which is expected to be comparable with the decay time of the particles (say $\sim 10^2 \text{ m}^{-1}$). The BES model has no singularity, and all the regions we see today have been in causal contact (with the event E) explaining the observed isotropy of the cosmic microwave background radiation.

While the BES model has attractive features its overall spacetime can be conformally mapped onto Minkowski space and has no event horizons. In the model proposed here the 'future of E' part of the BES model will be essentially transplanted from its original Minkowski space to a complete de Sitter space with $T_{\mu\nu} = -\lambda g_{\mu\nu}/8\pi$ equal to that found in the exponentially expanding part of the BES solution.

If $T_{\mu\nu} = -\lambda g_{\mu\nu}/8\pi$ and the cosmological constant $\Lambda = 0$, then the solution to Einstein's field equations $G_{\mu\nu} = R_{\mu\nu} - 1/2 \, g_{\mu\nu}R + \Lambda g_{\mu\nu} = 8\pi T_{\mu\nu}$ is de Sitter space. (Note that one usually encounters de Sitter space as the solution to the vacuum field equation with positive cosmological constant: $T_{\mu\nu} = 0$ and $\Lambda = \lambda$). De Sitter space may be embedded as a hyperboloid[12].

$$-V^2 + W^2 + X^2 + Y^2 + Z^2 = r_o^2 = 3/\lambda \tag{2}$$

in a flat five-dimensional space R^5 with a metric

$$ds^2 = -dV^2 + dW^2 + dX^2 + dY^2 + dZ^2 \tag{3}$$

Introduce coordinates $(\eta, \chi, \theta, \phi)$ where $\eta = 2\tan^{-1}[\exp(t/r_0)]$ and $r_0 \sinh(t/r_0) = V$, $r_0 \cosh(t/r_0) \cos\chi = W$, $r_0 \cosh(t/r_0) \sin\chi \cos\theta = X$, $r_0 \cosh(t/r_0) \sin\chi \sin\theta \cos\phi = Y$, $r_0 \cosh(t/r_0) \sin\chi \sin\theta \sin\phi = Z$, then the metric is

$$ds^2 = r_o^2 \cosh^2(t/r_0)[-d\eta^2 + d\chi^2 + \sin^2\chi(d\theta^2 + \sin^2\theta \, d\phi^2)] \tag{4}$$

This can be mapped conformally onto the Einstein static universe $S^3 \times R$ (a static three-sphere existing in time) with $0 < \eta < \pi$.

The event horizon of a black hole in an asymptotically flat space time is usually defined[12] as the boundary of the causal past of future null infinity $\mathscr{I}^+$. Alternatively it can be defined as the boundary of the past of a timelike world-line which has a future endpoint at future timelike infinity i^+. (In an asymptotically flat region $\mathscr{I}^+$ and i^+ are the places where photons and matter particles respectively go as $t \to \infty$). De Sitter space has event horizons satisfying this second definition[13]. An observer whose world-line is $\chi = 0$, $0 < \eta < \pi$, has an event horizon at $\chi = \pi - \eta$. Every timelike geodesic world-line has an event horizon of radius $r_0 = (3/\lambda)^{1/2}$. Gibbons and Hawking[13] have shown that each geodesic observer in de Sitter space detects Hawking radiation from these event horizons with a temperature

$$T = (12)^{-1/2} \pi^{-1} \lambda^{1/2} \tag{5}$$

A thermal radiation field with temperature T equal to the observed Hawking temperature has a classical energy density:

$$\rho_{\text{HAW}} = \frac{\pi^2}{30} N(T) T^4 = \frac{N(T)\lambda^2}{4{,}320\pi^2} \tag{6}$$

where $N(T)$ is equal to the number of helicity states of all particle species ($\times 7/8$ for fermions) with mass less than T. For standard GUTs $N(T) \sim 10^2$ in the high temperature limit[6]. Each geodesic observer observes a total energy density $\rho_{\text{obs}} = \lambda/8\pi$.

In de Sitter space different geodesic observers have different event horizons so the Hawking radiation is observer dependent. This prompted Gibbons and Hawking to argue that it should not contribute to the observed $T_{\mu\nu}$. Press[14] on the other hand has argued that the Hawking radiation should contribute to $T_{\mu\nu}$. Thus the question of whether the Hawking radiation contributes to $T_{\mu\nu}$ is controversial. However, if the Hawking radiation does contribute to $T_{\mu\nu}$ then the symmetries of de Sitter space seem to demand that its contribution be of the de Sitter invariant form $(T_{\mu\nu})_{\text{HAW}} = -\lambda' g_{\mu\nu}/8\pi$ where λ' is a constant. If the Hawking radiation is the only source of $T_{\mu\nu}$ then $\lambda = \lambda'$ and $\rho_{\text{obs}} = \rho_{\text{HAW}}$. The required $P = -\rho$ equation of state for the thermal Hawking radiation may be a natural result of trace anomalies produced by

0028-0836/82/040304—04$01.00

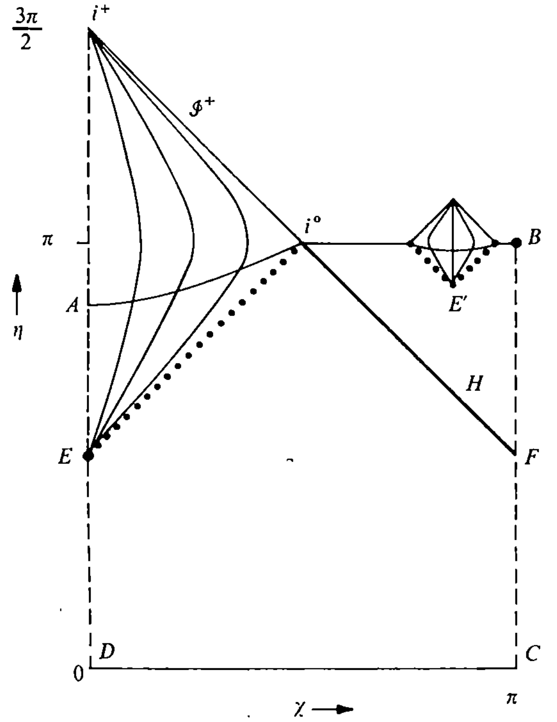

Fig. 1 Penrose diagram of the proposed cosmological model. η is a timelike coordinate and χ is a radial spacelike coordinate. This is a conformal map in which light travels always at ±45° to the vertical. The region $EAi^\circ E'BCD$ has the metric of de Sitter space. At the spacelike hypersurface Ai° there is a phase transition from $P=-\rho$ to $P=\rho/3$. The region $Ai^\circ i^+$ is a standard $k=-1$ Robertson Walker big-bang cosmology from the Planck time onwards. The curved lines connecting E and i^+ are world-lines of co-moving observers in the big-bang universe. This big-bang universe has $\Omega<1$ and expands forever, the fact that the curved lines coverage at i^+ is an artefact of the conformal mapping. There is an event horizon H. Observers in the Robertson-Walker big-bang cosmology never see any photons from events inside the region $Fi^\circ B$. At E' another $k=-1$ universe is created which is entirely disjoint from the E universe. Note, $\eta(A)=2\tan^{-1}[\exp(\tau_1/\tau_\lambda)]$, see text.

the space-time curvature of de Sitter space itself. For example, classically, a massless conformally invariant scalar field ϕ is traceless ($P=\rho/3$). However, DeWitt[15] has shown that in de Sitter space with radius r_0, quantum mechanical effects in the one-loop approximation produce for this field a renormalized $\langle T_{\text{ren}\,\mu\nu}\rangle=-g_{\mu\nu}/960\pi^2r_0^4$ which is de Sitter invariant and has $P=-\rho$. If $\langle T_{\text{ren}\,\mu\nu}\rangle$ is to be the source term producing the de Sitter solution then $\langle T_{\text{ren}\,\mu\nu}\rangle=-3g_{\mu\nu}/8\pi r_0^2$, so $r_0=(360\pi)^{1/2}$ and $\rho=135$ for the self consistent false vacuum state. This density is just a factor of 2 larger than we would obtain from setting $\rho_{\text{obs}}=\rho_{\text{HAW}}$ with $N(T)=1$ for a single scalar field (compare with equation (9)). Trace anomalies become significant when the radius of curvature becomes comparable with the wavelength of the thermal radiation (at the Planck epoch). De Witt's work supports the contention that a self consistent de Sitter false vacuum occurs at an epoch when $\rho_{\text{HAW}}\sim\rho_{\text{obs}}\sim 0(1)$ and $T\sim 0(1)\sim 10^{19}$ GeV rather than at 10^{14-15}GeV as proposed by Guth[8]. There is another reason for equating $\rho_{\text{obs}}=\rho_{\text{HAW}}$ which is independent of whether or not the Hawking radiation contributes to the de Sitter $T_{\mu\nu}$. If the de Sitter false vacuum decays, dumping its energy density ρ_{obs} in the form of thermal radiation there will be no instantaneous change in temperature across the phase transition if $\rho_{\text{obs}}=\rho_{\text{HAW}}$. Such a phase transition (see Fig. 1) leads to formation of an observer-independent event horizon (boundary of the past of $\mathscr{I}^+$). As in the black hole case we expect this to lead to observer-independent Hawking radiation. Setting $\rho_{\text{obs}}=\rho_{\text{HAW}}$ ensures a smooth transition from the observer-dependent Hawking radiation to the observer-independent ($P=\rho/3$) Hawking radiation.

For the above reasons, I adopt $\rho_{\text{obs}}=\rho_{\text{HAW}}$. This gives:

$$T_0=\left[\frac{45}{\pi N(T_0)}\right]^{1/2} \tag{7}$$

$$\lambda=540\pi/N(T_0) \tag{8}$$

$$\rho=135/2N(T_0) \tag{9}$$

Thus, T_0, λ and ρ are all of the order of unity in Planck units.

The BES model with $\lambda=540\pi/N(T_0)$ is now transplanted into this space. Pick an event E in the de Sitter space and choose coordinates so that $\eta(E)=\pi/2$, $\chi(E)=0$ ($W=r_0$, $V=X=Y=Z=0$). Adopt coordinates (τ, χ', θ, ϕ): $W=r_0.\cosh(\tau/r_0)$, $V=r_0\sinh(\tau/r_0)\cosh\chi'$, $X=r_0\sinh(\tau/r_0)\sinh\chi'\cos\theta$, $Y=r_0\sinh(\tau/r_0)\sinh\chi'\sin\theta\cos\phi$; $z=r_0\sinh(\tau/r_0)\sinh\chi'\sin\theta\sin\phi$; then the metric for the future of E, ($W>r_0$, $V>0$) $\tau>0$ is that of equation (1) with $a(\tau)=\tau_\lambda\sinh(\tau/\tau_\lambda)$ and $\tau_\lambda=r_0=(3/\lambda)^{1/2}$. This is a $k=-1$ cosmology. This is equivalent to the BES solution particle production phase and the need for the transition period $0<\tau<\tau_0$ is eliminated. The de Sitter metric applies then for $0<\tau<\tau_1$. As in the BES theory we require that the particle creation halts by the epoch τ_1, causing a transition in the equation of state from $P=-\rho$ to $P=\rho/3$ in the Robertson–Walker frame. At τ_1 each observer with world-line χ', θ, $\phi=$ constant sees Hawking radiation with $T\sim[45/\pi N(T)]^{1/2}$. After τ_1, $P=\rho/3$ with the Hawking radiation observed at τ_1 providing the observed energy density and redshifting in the usual way. Equation (7) gives $T_0\sim 0(1)$. The BES model requires that the created particles in the de Sitter phase have $m\sim 0(1)$ and these particles will be produced in a thermal distribution only if $T_0\sim 0(1)$.

If currently $\Omega_0\sim 0.1$, $H_0\sim 50\text{ km s}^{-1}\text{ Mpc}^{-1}$, $T=2.7$ K, and $N(T_0)\sim 10^2$, the standard big bang model implies $\Omega_1\sim 1-2.5\times 10^{-60}$ at the epoch when ρ is that given by equation (9). This nearness of the initial Ω to unity is the Guth[8] flatness problem. Now for $0<\tau<\tau_1$, $\Omega=8\pi\rho/3H^2=8\pi\rho a^2/3\dot{a}^2=1-[\cosh(\tau/\tau_\lambda)]^{-2}$ so if $\tau_1\sim 69\ \tau_\lambda$ we have approximately the correct initial value of Ω for the big bang phase. Let N_0 be the number of particles in a volume a^3 in present Universe: $N_0\sim 6\times 10^{87}$. The number density of particles in the de Sitter phase is roughly[16] $n_1\sim 1.2N'(T_0)T_o^3/\pi^2\sim 0.66$ where $N'(T_0)\sim 10^2$ is the number of spin states (×3/4 for fermions) (compare with equation 7). If the number of decay products per particle present at τ_1 is of the order of unity the model predicts $N_0\sim 0.66\ a^3(\tau_1)=0.66\ \tau_\lambda^3\sinh^3(\tau_1/\tau_\lambda)$ which gives the correct order of magnitude for $\tau_1\sim 69\tau_\lambda$. With this value of τ_1 we get reasonable initial values for both Ω_1 and N_0 (details will be presented elsewhere). This result shows that the work of Guth[8] on Ω_1 and BES[4] on N_0 as the result of an exponential expansion phase can be combined.

One expects non-conformally invariant massive fields to be present (as in the BES model) in which case the de Sitter exponential expansion will cause particle creation. Adler[17] has formulated a model in which the cosmological constant Λ is fixed by the particle physics at early times and leads to a de Sitter phase. The resulting particle creation acts back on Λ lowering it to zero. This eventually stops the particle creation at $\tau\sim\tau_1$ leading to a standard big bang phase. The Adler[17] model gives a specific mechanism for a slow phase transition at τ_1 and is functionally equivalent to the late stages of BES model.

A Penrose diagram of the entire spacetime is shown in Fig. 1 and represents a mapping onto $S^3\times R$. The dashed lines represent coordinate singularities at $\chi=0$ and $\chi=\pi$. The original de Sitter space would be plotted in the square $0<\chi<\pi$, $0<\eta<\pi$. The event E is shown. The region $0<\tau<\tau_1$ is mapped into the triangular region EAi°. The Robertson–Walker phase $\tau>\tau_1$ is mapped into Ai^+i°. At late epochs this looks like a standard $k=-1$ open cosmological model. The co-moving timelike world-lines of particles in our Universe are indicated by curved lines connecting E and i^+. The region $DEAi^\circ FC$ has the metric of de Sitter space. The causal past of each event in this region includes only unperturbed de Sitter space, therefore each observer in this region sees Hawking radiation with temperature $T \sim 0(1)$. The spacetime has a classical event horizon (boundary of the past of future null infinity $\mathscr{I}^+$) indicated by the heavy diagonal line H. The horizon originates at the event F and increases in area until its area is infinite at i°. This would indicate an infinite entropy[18] and that an infinite amount of information is lost about what happens beyond the horizon. The existence of an event horizon means that there is a region (in this case $i^\circ BF$) of which we can never have any knowledge. Figure 1 shows how an event E' in this region can produce another $k=-1$ universe like our own but entirely disjoint from it. The E' universe also has an event horizon and our Universe lies beyond it. Neither universe can communicate with the other in any way. In fact an infinite number of universes can be created all disjoint from each other. The original de Sitter space is mapped onto $S^3 \times R$. Each universe E_i cuts out of S^3 a sphere of radius $\chi_i = \pi - \eta(E_i)$. An infinite number of such non-intersecting spheres can be constructed. The ability to make an infinite number of universes in the region $i^\circ BF$ goes with the infinite loss of information about this region suggested by the area of the event horizon.

Coleman[19] has shown that because the Minkowski vacuum is of lower density than the de Sitter vacuum, bubbles of ordinary Minkowski vacuum can form in a de Sitter false vacuum by quantum barrier penetration tunnelling. This leads to a causal structure exactly like that in Fig. 1 and provides a simplified case where we can make an exact semi-classical calculation of the Hawking radiation seen at late times in the future light cone of E. Coleman expects each bubble to have an 0(3, 1) Lorentz invariance about some event E. The bubble wall has a space-like separation σ from the event E where $\sigma \leq r_0$. The material that would have been inside the bubble is re-located in a thin bubble wall so that there is energy conservation and outside the bubble wall the metric is that of de Sitter space; inside, the metric is minkowskian. The spacetime can be embedded in the five-dimensional space of equations 2 and 3. The wall boundary is given by $X^2+Y^2+Z^2-V^2=\sigma^2$ and $W^2=r_0^2-\sigma^2$. For $W<(r_0^2-\sigma^2)^{1/2}$, equation (2) is satisfied. The inside of the bubble is embedded as the surface $W=(r_0^2-\sigma^2)^{1/2}$, so that inside V, X, Y, Z are normal Minkowski coordinates. The material in the bubble wall undergoes a proper acceleration $g=1/\sigma$. Inside the future light cone of E the metric is that of an empty $k=-1$ cosmology with $\Omega=0$ and $a(\tau)=\tau$. Coleman does not notice that his bubble formation mechanism produces an event horizon in the spacetime nor does he treat the resulting Hawking radiation. The causal structure is like that in Fig. 1: the bubble wall is a timelike hyperboloid that has a spacelike separation from E, stays just outside the dotted future light cone of E and ends at the point i_0. The positions of i^+, $\mathscr{I}^+$ and the horizon H are unchanged. The wall has an event horizon (boundary of its past) which consists of two parts, the future light cones of E and F. Unruh[20] has shown that accelerated observers in Minkowski space see Rindler–Hawking photons with a temperature $T=g/2\pi=1/2\pi\sigma$. For each timelike world-line moving with the wall material one can find a de Sitter static coordinate system[13] $ds^2 = -(1-\lambda r^2/3)\,dt^2+dr^2(1-\lambda r^2/3)^{-1}+r^2(d\theta^2+\sin^2\theta\, d\phi^2)$ such that the world-line is a line of constant θ, ϕ and $r=(r_0^2-\sigma^2)^{1/2}$. Such an observer sees Hawking photons with temperature[13] $T=1/2\pi\sigma$. So the wall sees a thermal bath with this temperature both inside and outside and to be in thermal equilibrium must be at a temperature of $T_{\text{wall}}=1/2\pi\sigma$. An observer within the future light cone of E will see thermal radiation from the wall with a temperature $T=T_{\text{wall}}\sigma/a$ where a is the Robertson–Walker expansion factor. Thus $T=1/2\pi a$ independent of the bubble size. The temperature decreases with a because at late epochs the observer is seeing portions of the wall that are receding from him more rapidly. (Details of this calculation will be presented elsewhere.) The only thing inside the future light core of E is the Hawking radiation which makes a $k=-1$ cosmology and redshifts in the usual way with $T\alpha 1/a$. The only thing that makes this universe different from our own is that $\Omega=0$ and $N_0 \sim 0(1)$. These deficiencies are due to the fact that the self-gravity of the Hawking radiation has been neglected. If the self gravity curvature effects cause the thermal radiation to have $P \sim -\rho$ then its density will not decrease appreciably in the initial expansion phase and particle creation will exponentially increase N_0. The radiation from the walls will fill the hole and lead to a solution similar to the BES solution. The phase transition simply occurs effectively at a timelike separation τ_1 from E rather than at a spacelike separation σ, the property of 0(3, 1) invariance of the bubble about E preserved. Thus we can see the formation of our Universe as a quantum tunnelling event; our Universe is one of the normal vacuum bubbles.

The causal structure of Fig. 1 at late times occurs regardless of how the de Sitter phase arises. In the Guth model the universe begins with a singularity and a Friedmann phase ($P=\rho/3$) until $\rho=\rho_c$ when a de Sitter phase is reached. The de Sitter false vacuum decays as Coleman type bubbles form; a $k=+1$ Guth model would look much like Fig. 1 except that there would be a singularity at $\eta \simeq 0$. Guth[8] wanted the bubbles to coalesce and fill space so as to eventually lead to a single Friedmann cosmology. He found that the bubbles would not in general fill the space. Press[14] has tried using the Gibbons and Hawking radiation to remedy this. Neither of these models have classical event horizons (boundary of past of $\mathscr{I}^+$). In contrast I propose that each bubble produces a $k=-1$ cosmology and it is an advantage if the bubbles do not bump into each other. Guth cosmologies with $k=+1, 0, -1$ can each produce in principle an infinite number of disjoint $k=-1$ (bubble) cosmologies. Each will have a cosmological event horizon and if the Guth epoch ρ_c occurs at the Planck epoch then all results concerning Hawking radiation will remain intact.

A self-consistent bubble formation process may require that the entire pase of the bubble ($DEi^\circ FC$) is a pure de Sitter state. If this is the case, an infinite number of disjoint $k=-1$ universes can be created. On the other hand bubbles may form randomly with a probability independent of position. For an event E to exist in the de Sitter phase there must not exist another event like E in the past light cone of E (and at a proper time at least τ_1 before E). The four-volume of this region which must be clear of events like E is infinite. For there to be a finite probability of this occurring, the probability of randomly forming an event like E per unit four-volume must be infinitesimal. Several bubbles may form, however, because the four-volume of de Sitter space is infinite. If the bubbles form randomly, they may bump into each other. There is only a 50% chance that two randomly formed E and E' universes will be disjoint as shown in Fig. 1. (E' cannot lie in the past or future light cones of E and the past and future light cones of F dominate the rest of the four-volume of de Sitter space). Such a model would make the creation of more than a few disjoint $k=-1$ universes unlikely. If the de Sitter state, however, is reached from singular or chaotic initial conditions as in the Guth model, even if the bubbles formed randomly, an arbitrarily large but finite number of disjoint universes could be created (the ratio of the four-volume of the future light cone of F to that of region $Ei^\circ F$ is infinite).

In conclusion, $k=-1$ universes may be created naturally from a de Sitter false vacuum state. These universes will have cosmological event horizons and should be filled with Hawking radiation.

Ionospheric troughs in Antarctica

Natural Environment Research Council, British Antarctic Survey,
High Cross, Madingley Road, Cambridge CB3 0ET, UK

We report here the first observations of the dynamics of both the mid-latitude and high-latitude troughs made by the Advanced Ionospheric Sounder (AIS) at Halley Station, Antarctica (76° S, 27° W; invariant lat. 61°). This experiment is part of a major international project[1] to study the sub-auroral ionosphere and its associations with the magnetosphere. Our analysis provides an accurate quantitative description of the latitudinal movements of these features and the first results delineating the orientation of the poleward edge of the mid-latitude trough. These results show that the AIS has a much greater potential for monitoring large scale ionospheric structures and for tracking their motions than more conventional radio wave experiments.

The AIS[2] uses radio waves in the frequency range 0.1–30 MHz for remote sounding of the ionosphere. It provides a complete vector description of the ionospheric echoes obtained from each transmitted pulse, giving considerable advantage over the ionosonde. This, together with powerful online computing facilities, provides a very flexible tool for radiowave studies of the ionosphere. We concentrate on the ability of the AIS to locate the echoing region in range, azimuth and elevation, and thus to track the motions of large scale ionospheric features. The azimuth and elevation are determined from the spatial change of echo phase measured across an array of receiving antennas[3], whilst range is determined from the echo travel time.

The mid-latitude trough[4] is a major, but incompletely understood, feature of the sub-auroral ionosphere, which has very significant effects on radio wave propagation[5]. It consists of a circumpolar depletion of the night-time plasma concentration (the 'trough minimum') which extends over several degrees of latitude. It is bounded on the high latitude side by a 'wall' of ionization, the 'poleward edge', created primarily by soft (<1 keV) electron precipitation from the magnetosphere[6]. The low latitude boundary (the equatorial edge) is highly variable and is an extension of the mid-latitude ionosphere[7]. The trough is most pronounced at the peak of the F2 layer[8], but has been detected up to 2,500 km (ref. 9). The mean position of the trough is at about 60° invariant latitude, but moves equatorwards through the night as a function of geomagnetic activity[10]. It is statistically associated with the mean position of the plasmapause, although correspondence does not necessarily occur[11,12].

The processes responsible for trough information and their relative importance have yet to be confirmed. However, a very complex dynamic interaction clearly occurs involving the redistribution of plasma under the action of electric fields of magnetospheric origin[13,14] and thermospheric winds[15]; plasma production due to particle precipitation[6] and solar UV radiation; and plasma loss through charge exchange and recombination processes[16,17].

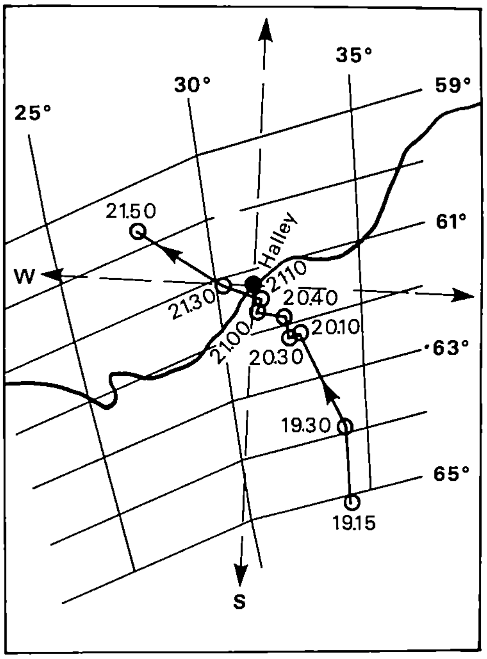

Fig. 1 The ground track of the reflection from the mid-latitude trough observed on the magnetically active night of 22 April 1981 in relation to the shelf ice coast line and Halley. The data come from tracking the poleward edge of the trough; and the numbers by each data point give the local times of the observations. The graticule represents invariant latitude and longitude at 100 km altitude[21].

Halley is an ideal location for ground-based studies of the sub-auroral ionosphere and its associations with the magnetosphere[7]. It is particularly well suited to studies of the mid-latitude trough because this is observed in the vicinity of Halley on most winter nights, over a wide range of geomagnetic activity[18].

The transit of the trough and its associated boundaries produces a characteristic signature on a sequence of ionograms recorded at a particular location[7,19,20]. Normally, echoes from both the trough minimum and the poleward edge can be distinguished. The AIS allows the positions of these features relative to the observing point to be determined and their temporal evolutions to be studied.

The full data from the current Antarctic winter will not be available until May 1982 when RRS Bransfield returns to the UK. However, we have used the local computing power provided with the AIS to analyse data for two nights when the trough was observed. The study periods were selected to provide a contrast between magnetically quiet (9–10 April 1981, $K_p = 1$) and active (22 April 1981, $K_p = 5$) conditions.

Turning first to the magnetically active night, Fig. 1 gives the ground track of the reflection from the poleward edge in relation

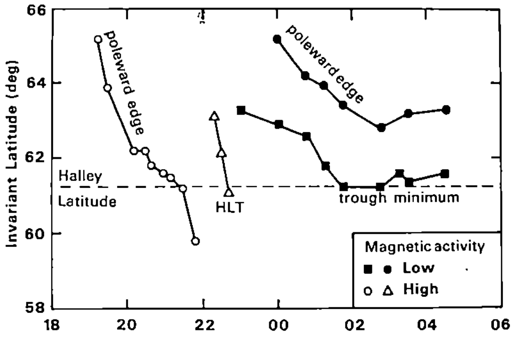

Fig. 2 The temporal evolution of the mid-latitude trough (MLT) and high-latitude trough (HLT) observed at Halley on the night of 22 April 1981 constructed from a combination of the AIS observations and contemporary knowledge of trough structure.

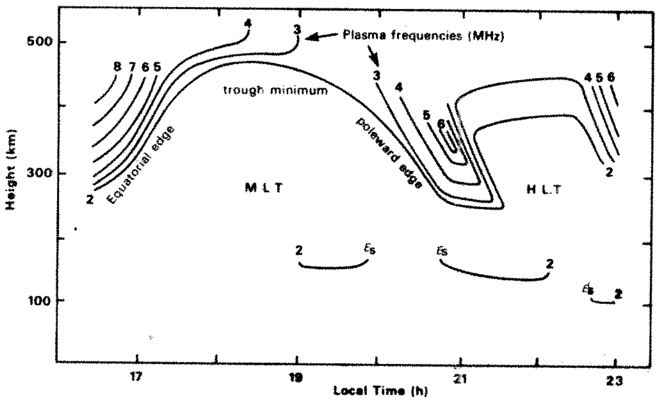

Fig. 3 Comparison of the trough event of 22 April 1981 ($K_p = 5$) with that on the 9–10 April 1981 ($K_p = 1$). The positions of various features identified in Fig. 2 are plotted in terms of their southern range of the reflection point (expressed in invariant latitude) as a function of local time. Local magnetic midnight occurs at 01.30 LT.

to Halley and an invariant coordinate grid[21]. It was first possible to locate the reflection point at 19.15 LT when it was 4° of invariant latitude to the south. It subsequently moved to lower latitudes, passing over Halley at approximately 21.20 LT.

The westward motion of the reflection point, evident in Fig. 1 as the trough moves equatorward, is expected because of the geometry of the trough in Sun–Earth coordinates. However, the actual displacement shown is greater than would be expected from the published statistical relationships[10] linking the invariant latitude of the trough to local time for a fixed level of geomagnetic activity. In fact, this deviation becomes progressively more marked as the event progresses. However, the location of the reflection point moves within the trough structure as the latter transits Halley equatorwards. Thus although firm conclusions cannot be drawn from this one example it will be worthwhile to use a larger data set to investigate the discrepancy and test whether a longitude term should be included in statistical relationships.

The echoes from the trough minimum showed no clear temporal evolution, suggesting that there was considerable fine structure within it; consequently, no single feature was consistently tracked. Following the passage of the poleward edge, a further trough was detected and tracked. This 'high latitude trough' ultimately passed to the north of Halley at about 22.00 LT.

The measured range, maximum plasma frequency and bearing information for the features have been combined with contemporary knowledge[4,6,18,19] of trough structure to give a schematic view of the event as seen from Halley. This is shown in Fig. 2, in which the major assumption is in the choice of the true height of maximum plasma frequency and consequently of the higher frequency iso-ionic contours. Note that in Fig. 1 there is an apparent tendency for the poleward edge reflection point to dwell in the vicinity of Halley between 20.10 and 21.30 LT. We interpret this as that between 19.15 and 20.10 echoes are being returned from the steeply sloping contours of the poleward edge and, although the reflection point moves slightly down in height as the feature approaches, the sequence represents the bulk movement. However, as the feature nears Halley, the reflection point moves relatively rapidly around the lower edge of the poleward edge, causing an apparent reduction in the rate of approach. Subsequently, as the poleward edge goes north of the station the echoes are from the high latitude trough minimum. This hypothesis is consistent with the observed variations in the slant ranges and matches well with structures observed by the Chatanika radar[22].

The patches of sporadic-E ionization (E_s) indicated in Fig. 2 are of a type normally associated with particle precipitation. The decrease in virtual height of the patches with local time suggests a hardening of the particle spectra.

The differences in behaviour between the geomagnetically quiet and disturbed nights are summarized in Fig. 3 which shows the southern component of the range for several trough features plotted as a function of local time. There is a local time difference of 5 h between the onset of the two events, with the active night leading. The rate of movement on the active night is much greater than on the quiet one and the trough moves to considerably lower latitudes. These findings confirm our previous results using more approximate techniques[18]. The trough minimum is apparently unstructured when the magnetic activity is low, and follows the behaviour of the poleward edge closely. Also on this occasion the mid-latitude trough appears to drift slowly poleward after magnetic midnight. A very well defined high latitude trough is observed in active conditions, but is too far south to be seen on the quiet night.

We have demonstrated one of the capabilities of the AIS at Halley to make observations of the sub-auroral ionosphere. We now plan to make detailed studies of the morphology of the trough using this and other sensors at Halley; and then test contemporary theoretical ideas.

We thank many members of BAS, and in particular the base personnel at Halley, for assistance.

Two-dimensional modelling of potential ozone perturbation by chlorofluorocarbons

J. M. Steed, A. J. Owens, C. Miller, D. L. Filkin & J. P. Jesson

E. I. du Pont de Nemours and Company, Experimental Station, Wilmington, Delaware 19898, USA

The possible adverse effect of man-made chlorine compounds, particularly chlorofluorocarbons (CFCs), on the stratospheric ozone layer has been studied intensely in the past few years[1,2], with assessments being based primarily on one-dimensional (1-D) mathematical models of atmospheric transport and chemistry. Two-dimensional (2-D) models now permit a more realistic comparison of model predictions with observational data over the full range of latitudinal and seasonal variations in many of the important atmospheric trace species[3–8]. We report here 2-D model calculations of the hypothetical steady state arising from constant CFC releases continuing indefinitely into the future. Latitudinal and seasonal variations in the calculated reduction of stratospheric ozone are discussed and contrasted with the calculated perturbation up to 1980. The global average is compared with the corresponding 1-D model. Several changes in the vertical structure of the ozone perturbation are found to result from recent revisions in chemical reaction rates.

The important chlorofluorocarbons FC-11 (CCl_3F) and FC-12 (CCl_2F_2) had historically been released in rapidly increasing quantities until 1974. Since then, global production and release rates have declined by ~20%. These compounds are currently believed to have long atmospheric lifetimes (40–150 yr). For constant release, a 'steady state' would be reached within several hundred years.

The 2-D model used for the present calculations has been described elsewhere[5,6]. Its principal features include a chemical scheme as complete as that in advanced 1-D models and a transport representation based on a parameterization of the lagrangian mean circulation[9,10]. The chemical reaction rate set used is that recommended at the joint meeting of the CODATA Panel and the NASA Panel for Data Evaluation[11] (March 1981). The 1-D model results discussed below use the same rate set and the model described in ref. 12.

Model calculated species concentrations have been compared elsewhere[5] with measurements, for most species of current interest. The model calculated variation of total ozone with latitude and season is given in Fig. 1. The qualitative features of the observed ozone distribution[13] are quite well reproduced, including the spring maximum and the Equator-to-pole gradient. In what follows changes in total ozone are referred to this calculated ambient distribution.

The calculated change in local ozone concentrations arising from the release of FC-11, FC-12 and CH_3CCl_3 up to July 1980 is shown in Fig. 2. Except near the poles, latitudinal variations are small. Maximum depletion for all latitudes is near 6% at ~42 km. A major consequence of recent revisions in chemistry is the local increase in ozone between 10 and 25 km from 30° N to 30° S, and over part of that range at other latitudes. The increase exceeds 1% between 18 and 22 km in the tropics. This net local ozone increase is associated both with increased vertical penetration of solar UV light due to ozone depletion at higher altitudes (the 'self-healing effect') and with interactions of chlorine species with HO_x and NO_x, reducing the efficiency of natural odd oxygen recombination cycles.

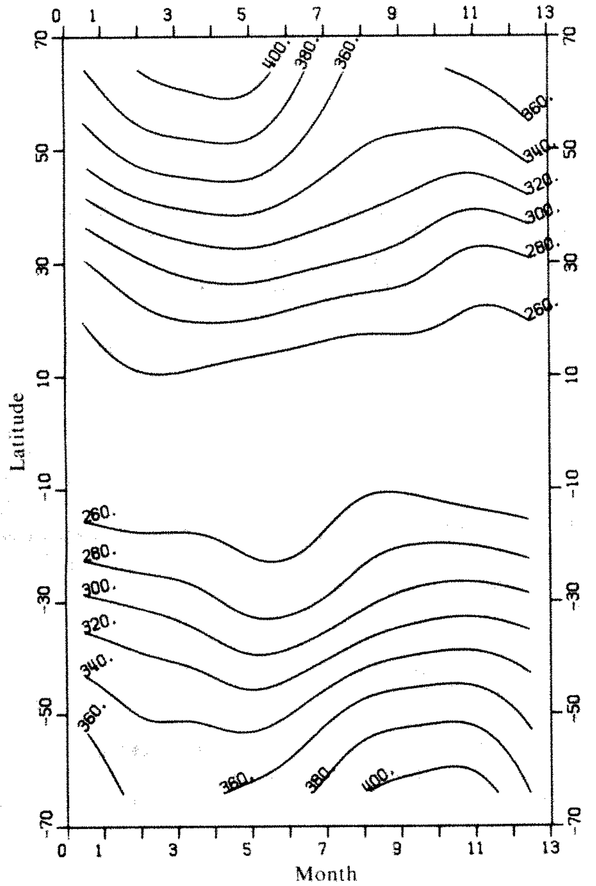

Fig. 1 Latitude–time contour plots of the calculated ambient ozone distribution, in Dobson units. Positive latitudes are North. 1 January corresponds to month 0.0.

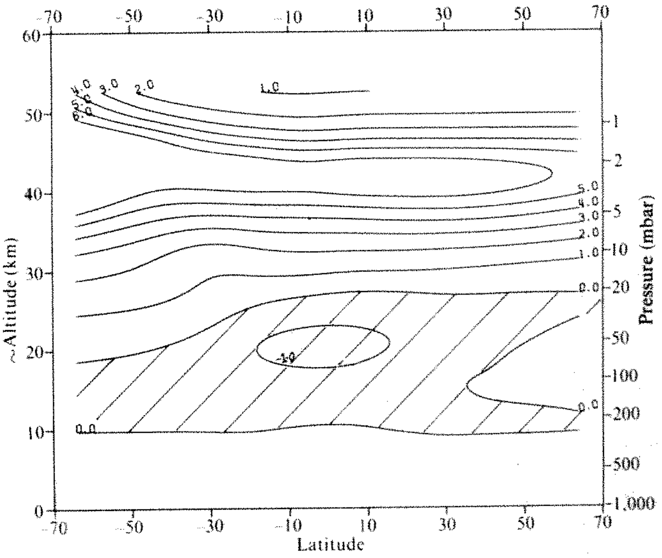

Fig. 2 Calculated latitude–altitude cross-section of percentage ozone decrease up to July 1980 arising from historical releases of FC-11, FC-12 and methyl chloroform. Striped region corresponds to ozone increase.

The calculated latitude–season cross-section of percentage total ozone column depletion for 1980 is shown in Fig. 3*a*. In contrast to the calculations of Pyle and Derwent[4] made with earlier chemical rate recommendations, the annual mean depletion is nearly constant with latitude at ~0.9%. Calculated depletion in the region 30° N–30° S remains in the range 0.90 ± 0.15% throughout the year, whereas the calculated ozone change in polar regions is twice as large (~1.2%) during local winter as in summer (~0.6%). The reduction in polar depletion relative to that in the tropics since the work by Pyle and Derwent[4] arises primarily from an increase in the recommended rate constants for reactions (1) and (2).

$$OH + HNO_3 \rightarrow H_2O + NO_3 \qquad (1)$$

$$OH + HNO_4 \rightarrow H_2O + O_2 + NO_2 \qquad (2)$$

These reactions serve as sinks for OH and are expected to be most important where calculated local HNO_3 and HNO_4 concentrations are large, that is at higher latitudes, especially in winter. Reduced OH slows conversion of HCl to Cl by reaction (3), and thereby increases the effectiveness of HCl as a sink for chlorine.

$$OH + HCl \rightarrow H_2O + Cl \qquad (3)$$

In absolute terms, the calculated change in column ozone up to 1980 is between 2 and 3 Dobson units throughout midlatitude

Table 1 Calculated atmospheric changes due to constant CFC release-initial to steady state

	2-D model				
	5° N	30° N	65° N	Global mean	1-D model
$-\Delta O_3$ (column) (%)	6.1	6.0	6.5	6.2	7.0
ΔClX (at 50 km) (p.p.b.)				7.2	8.4
$\lvert \Delta O_3/\Delta ClX \rvert$ (%/p.p.b.)				0.87	0.84
ΔUV (DNA weighted) (%)	16.5	16.2	15.8	16.2	20
$\lvert \Delta UV/\Delta O_3 \rvert$				2.6	2.8

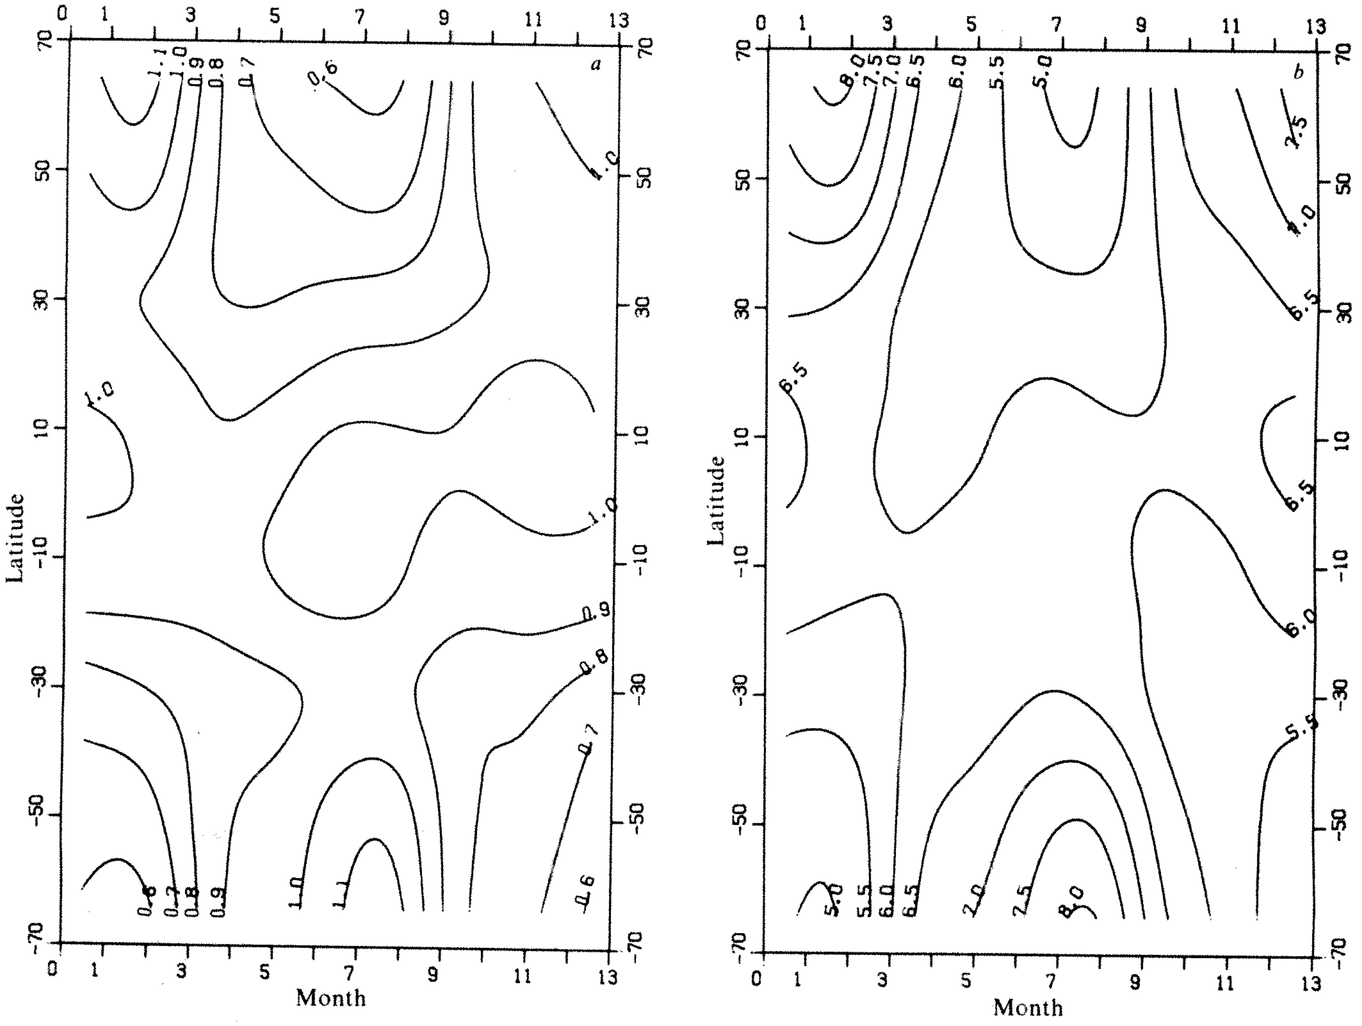

Fig. 3 *a*, Latitude–season contours of percentage ozone depletion up to 1980 relative to the ambient atmosphere based on historical releases of FC-11, FC-12 and methyl chloroform. *b*, Latitude–season contour plot of calculated steady-state percentage ozone depletion due to continued release of FC-11 and FC-12 at mid-1970s release rates.

regions and polar summer, and increases to more than 4 Dobson units during the ozone maximum in polar winter.

Pyle and Derwent[4] noted the expense of calculating a time-dependent approach to steady-state CFC perturbations with a 2-D model. For the present calculations, a method of rapid convergence has been developed which allows an accurate, economical calculation of the steady-state results. The method takes advantage of the slow transport and photolysis of CFCs and relatively fast subsequent photochemistry, by alternating long time-dependent runs retaining CFCs as the only active species (~300 yr of problem time) with short runs in which all species are active.

Assuming the continued release of FC-11 and FC-12 at rates characteristic of the mid-1970s (340×10^3 and 410×10^3 tonnes yr^{-1}, respectively), the calculated global average column ozone depletion at steady state is 6.2%, with a ClX increase at ~50 km of 7.2 p.p.b. (parts per 10^9) over the unperturbed atmosphere. This is compared in Table 1 with the corresponding values of 7.0% and 8.4 p.p.b. obtained with the 1-D model using identical chemistry. Note that $\Delta O_3(\%)/\Delta ClX(p.p.b.)$ is quite similar in the two models, so that the difference in calculated ozone depletion may be partly due to different effective rates of vertical transport in the two models. The 1-D model also neglects the latitudinal covariance between fluorocarbon concentration and photolysis rate, both of which reach maxima near the Equator, so it underestimates the rate of CFC destruction in the lower stratosphere. The neglect of the latitudinal covariance by the 1-D model thus contributes to a longer lifetime for CFCs and more ClX at high altitudes in the steady state.

Figure 3*b* shows the steady-state 2-D calculations of the seasonal and latitudinal variations in column ozone. The calculated depletion for latitudes from 30° N to 30° S varies by <1% for all seasons. The largest ozone change (~8%) occurs in the polar winter, at the time of the ozone maximum. Seasonal variations of nearly a factor of two persist near the poles.

Several interesting features are evident when Fig. 3*a* (for 1980) is compared with Fig. 3*b* (for the steady state). By 1980, the CFCs had not yet reached steady state in the atmosphere. They are more heavily concentrated near their Northern Hemisphere, ground-level sources. As the upward transport of tropospheric trace species is most rapid in the tropics, the CFC and the reactive Cl concentrations in the tropical stratosphere for 1980 are enhanced. This leads to a larger calculated ozone depletion near the Equator (~1.0%) than at higher latitudes (~0.8%). In the steady state, once the CFCs have had time to be transported more effectively to the polar regions, this latitudinal effect is reduced and the yearly-averaged ozone depletion remains essentially constant (~6.2%) for all latitudes. Also note a slight hemispheric asymmetry for 1980 (as shown in Fig. 3*a*), with the ozone depletion in the Northern Hemisphere being slightly higher. The almost perfect north–south symmetry in the steady state (Fig. 3*b*) is due to the input transport data base, which is symmetric about the Equator except for a 6-month seasonal time lag.

An important characteristic of the calculated ozone change is its rate of increase with time. Consistent with the effectively shorter lifetime for CFCs in the 2-D model, the calculated global-mean present day (1980) depletion (0.89%) exceeds that from the corresponding 1-D model (0.50%). However, both are small compared with calculations made over the past few years[1–4]. The currently calculated rate of change in global ozone is between −0.05 and −0.09% yr^{-1}, beginning in about 1970. This is, of course, for CFCs alone. Effects of opposite sign arising from the CO_2 increase and jet aircraft exhausts result in a combined effect on total ozone which is not significantly different from zero in recent 1-D model calculations[14].

The use of 2-D models to calculate potential ozone perturbations due to chemical releases of manmade origin provides a more detailed simulation of the real atmosphere than is possible with 1-D models. Various statistical techniques have been applied[15–18] to the analysis of ground-based ozone measurements made over the past 20 or more years in an attempt to detect trends suggested by 1-D models. Use of 2-D models allows the trend appropriate to a latitude region to be calculated, and information on changes in the seasonal variations as well as long-term trends can be used in the analysis. As noted above (Fig. 3*a*), the latitudinal variation in the present calculations of annual average ozone depletion is small, but the magnitude of the seasonal component increases towards the poles. Incorporating this additional information into analyses of ozone measurements may permit a better identification of any observed trend.

Accompanying a decrease in the amount of atmospheric ozone is an increase in the UV radiation reaching the Earth's surface. We have selected for a UV weighting function the action spectrum for DNA damage[19], which is one of the most sensitive to ozone changes. In general, changes in UV reaching the ground follow the total ozone column. In the steady state, for example, the yearly-averaged DNA-weighted UV dose is calculated to increase by 16%, essentially independent of latitude (Table 1). The largest percentage change occurs during the polar winter when the UV dose is smallest. The 2-D model gives an 'amplification factor', $\Delta UV/\Delta O_3 = 2.6$, while in the corresponding 1-D model this factor is 10% larger (2.8). Unlike calculations performed with previous chemical rate sets[4], we do not find a large variation of this amplification factor with latitude.

In the real atmosphere, more is changing than just the CFC concentrations. Prime examples are the CO_2 concentration, NO_x arising from conventional jet exhausts, and N_2O arising from the application of manmade fertilizers. While it is important to study the potential CFC effect in isolation as we have done here, 2-D models are approaching a degree of refinement where the estimation of multiple perturbations may become feasible. This type of investigation will be reported later.

Electromagnetic jet-propulsion in the direction of current flow

Peter Graneau

MIT Francis Bitter National Magnet Laboratory, Cambridge, Massachusetts 02139, USA

Two simple experiments are reported here which demonstrate jet-propulsion in the direction of current flow between liquid and solid conductors. The observed effects seem to conform with Ampere's force-law, but no qualitative nor quantitative explanation has so far been found in terms of lorentzian forces and associated magnetohydrodynamics (MHD) phenomena. This research forms part of a wider investigation of the Ampere–Neumann electrodynamics and its relationship to modern science and technology.

In a classical experiment (Fig. 1) Ampere[1] claimed to have shown that, in addition to transverse forces on the conductor, the electric current creates repulsion between adjacent current-elements on the same straight line. He incorporated both transverse and longitudinal forces in his force-law (equation (1)). The longitudinal forces should place wires in tension and create relative motion between liquid and solid portions of a circuit. In Ampere's experiment the insulated or bare copper hairpin *cdefg* of Fig. 1, floating on two liquid mercury troughs *ab* and *a′b′*, will move towards *bb′* when sufficient current flows in and out of terminals *t* and *t′* connected with copper bars to the *a* and *a′* ends of the troughs. A transverse lorentzian force acts on the upturned hairpin bend *e*, but this should have its reaction force in the legs *cd* and *fg* of the hairpin, because the legs contain the source of the magnetic field at *e*. With action and reaction in the same rigid body, the Lorentz force at *e* should not be able to produce relative motion between hairpin and mercury. This point relating to Newton's third law has been argued strongly elsewhere[2–7].

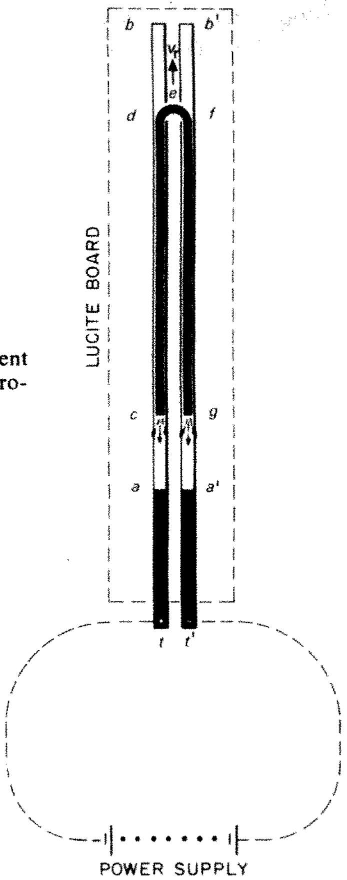

Fig. 1 Ampere's experiment demonstrating longitudinal propulsion.

0028-0836/82/040311—02$01.00

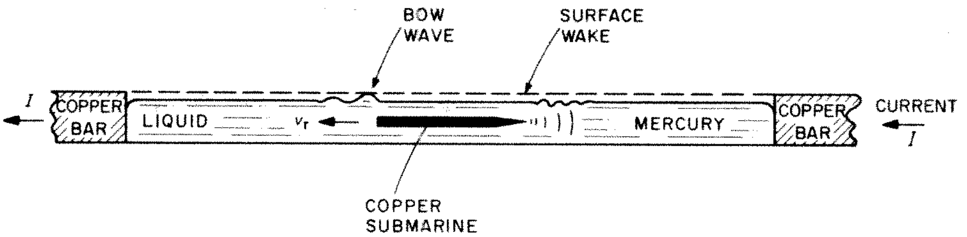

Fig. 2 Copper submarine experiment. Mercury trough length = 30 cm; cross-section 0.5×0.5 inch. Copper extension of troughs 30 cm long, 0.5×0.5 inch cross-section. Remote return circuit. $I = 400$ A. Copper submarine; 5 cm long, 3 mm diameter, 1 cm long taper. $v_r = 15$ cm s^{-1}.

Ampere did not mention that close to *c* and *g* liquid mercury moves relative to the trough walls and away from the ends of the hairpin. This motion confirms longitudinal propulsion, independent of any recourse to Newton's third law. The observation of this motion and the discovery of another longitudinal propulsion effect is now reported. While repeating Ampere's experiment, but mechanically blocking the forward motion of the hairpin, it was found that a wake formed in the liquid as though jets were mounted on the ends of the hairpin. A depression was detected in the liquid level close to *c* and *g*. When the hairpin ends were placed near to *a* and *a'*, liquid would well up on the copper walls and could be made to overflow. Short pieces of copper and stainless-steel wire laid on the mercury next to the hairpin ends were pushed away from *c* and *g*. Finally, a thin dielectric rod driven into the mercury near *c* or *g* and pivoted vertically above the point of immersion moved towards *a* or *a'*. These experimental facts leave little doubt that the longitudinal propulsion forces suggested by Ampere do exist. In showing that the net force of all amperian components on a rectangular circuit is zero, Cleveland[3] proved that longitudinal forces are of the same order of magnitude as transverse forces.

While trying to modify Neumann's[8] demonstration of longitudinal forces, I discovered another, even more remarkable propulsion arrangement. Figure 2 gives the details of this experiment. A copper 'submarine' consisting of a short piece of straight wire, squared off at one end and pointed at the other, has to be placed on the surface of a straight-through mercury trough conductor. When current is forced to flow along the trough, the transverse forces submerge the wire and longitudinal forces drive it along the centre of the trough until it strikes the solid copper bar. The wire travels with its blunt end forward. Its velocity is apparent from the bow wave on the liquid surface. The direction of travel does not depend on the direction of current flow and the experiment works equally well with 60-Hz alternating current.

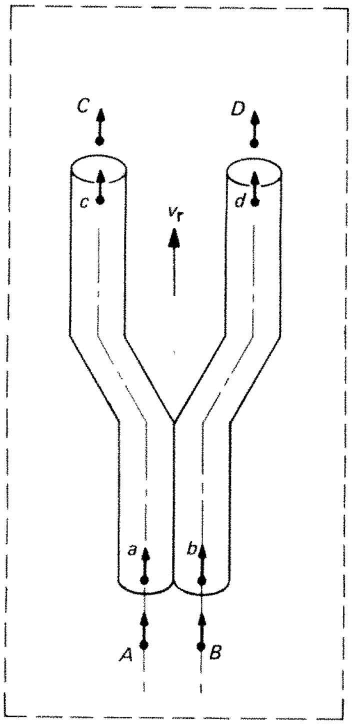

Fig. 3 Two-filament copper wishbone in liquid mercury bath.

Figure 3 explains the amperian submarine propulsion mechanism. This simplified representation shows a wishbone made of two solid current filaments immersed in liquid metal. Only two sets of four current-elements are considered. One set is *a*, *b*, *c* and *d* located in the ends of the wishbone filaments. The other four, *A*, *B*, *C* and *D* are adjacent in-line elements in the liquid. The Ampere force $\Delta F_{m,n}$ in dyn between two current-elements at points *m* and *n* of lengths d*m* and d*n* and separated by the distance $r_{m,n}$ is given by

$$\Delta F_{m,n} = -i_m i_n (\mathrm{d}m \cdot \mathrm{d}n / r_{m,n}^2)(2 \cos \varepsilon - 3 \cos \alpha \cos \beta) \quad (1)$$

where i_m and i_n are the element currents in absolute ampere, ε is the angle of inclination between the elements, and α and β are the angles which the elements make with the distance vector $\mathbf{r}_{m,n}$. When the force is positive it represents repulsion and when negative it represents attraction. Using this law to compute the repulsion between solid and liquid elements at one end of the wishbone and then at the other, it can easily be shown that the solid object is being pushed relative to the liquid in the direction of the velocity v_r indicated on Fig. 3. According to Ampere's law, therefore, it is the current concentration in the pointed end of the wire which is responsible for the propulsion of the copper submarine of Fig. 2.

So far the longitudinal propulsion mechanism has not been explained in terms of relativistic field theory and associated MHD effects. In view of the widespread acceptance of Ampere's force law during the nineteenth century and its implications with regard to solid-state physics and MHD technology, I urge others to repeat these simple experiments and comment on their observations.

A composite semiconductor photoanode for water electrolysis

Yoshihiro Nakato, Nobuyuki Takamori & Hiroshi Tsubomura

Department of Chemistry, Faculty of Engineering Science,
Osaka University, Toyonaka, Osaka 560, Japan

Photoelectrolysis of water by means of semiconductor photoelectrochemical cells has attracted much attention from the point of view of solar energy conversion[1-5]. Metal oxides such as TiO_2, WO_3, or Fe_2O_3 act as stable photoanodes, but they need an external bias for the photodecomposition of water to compensate for their too low surface band energies. We report here that water can be photodecomposed effectively without external bias by using a semiconductor/redox electrolyte/semiconductor junction (SES) as the photoanode.

The structure of the SES is indicated in Fig. 1. It consists of single crystal wafers of n-CdS and n-TiO_2 (0.3–0.7 mm thick) separated by ~0.2 mm by an aqueous solution containing 1 M NaOH, 1 M Na_2S and 1.5 gram atom l^{-1} S which dissolves in a concentrated sulphide solution. The inside wall of TiO_2 is coated with palladium (<5 nm thick) by vacuum evaporation to mediate electron transfer between n-TiO_2 and the sulphide–polysulphide couples.

As shown in Fig. 2, the onset potential of the anodic photocurrent of the SES electrode in a 1.0 M NaOH aqueous solution lies much more negative than that of an n-TiO_2 electrode. It is ~0.5 V more negative than the onset potential of dark cathodic current in a platinum electrode (Fig. 2). This means that water can be photodecomposed efficiently by a photocell equipped with a SES photoanode, a platinum counter electrode and a 1.0 M NaOH aqueous solution. Such a photocell showed steady photocurrent of ~2 mA cm^{-2} for more than 1 h under illumination with a 250-W mercury lamp. Considerable gas evolution was observed at both electrodes. The current was generated by illumination with polychromatic light containing the wavelengths 300–520 nm. The current was also generated with two monochromatic light beams, one in the range <410 nm and the other in the range 450–520 nm, but not with either of them alone. These results suggest that the current flows only if both n-TiO_2 and n-CdS are excited. The light in the range of 410–450 nm seems to be absorbed mostly by the sulphide–polysulphide solution.

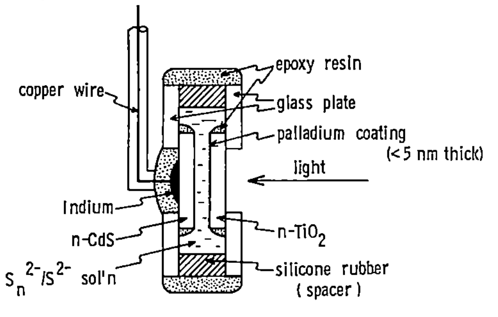

Fig. 1 Schematic diagram of an n-CdS-S_n^{2-}/S^{2-} solution–n-TiO_2 junction (SES) electrode.

The above results can be explained by an energy level diagram for the photocell (Fig. 3), drawn on the basis of the reported flat-band potentials[6,7]. It is known that n-CdS is stable in a solution of the sulphide–polysulphide couple[3–6]. Because the inner sulphide-polysulphide solution and the solution outside the SES electrode have nearly the same *p*H (~14), the energies of the conduction band edges of n-TiO_2 in the dark at both inner and outer surfaces must be equal. However, the accumulation of positive charges in the sulphide–polysulphide solution by injection of holes from the n-CdS under illumination will press down the conduction band energy at the inner surface of n-TiO_2. A stationary state will be attained by balancing the hole injection from n-CdS with the electron injection from n-TiO_2. The electrons are excited twice in the SES, reaching a level high enough to reduce water at the counter platinum electrode.

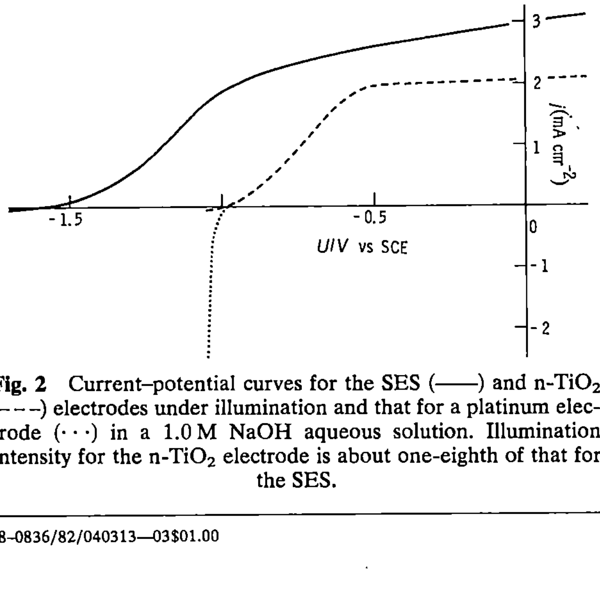

Fig. 2 Current–potential curves for the SES (——) and n-TiO_2 (– – –) electrodes under illumination and that for a platinum electrode (· · ·) in a 1.0 M NaOH aqueous solution. Illumination intensity for the n-TiO_2 electrode is about one-eighth of that for the SES.

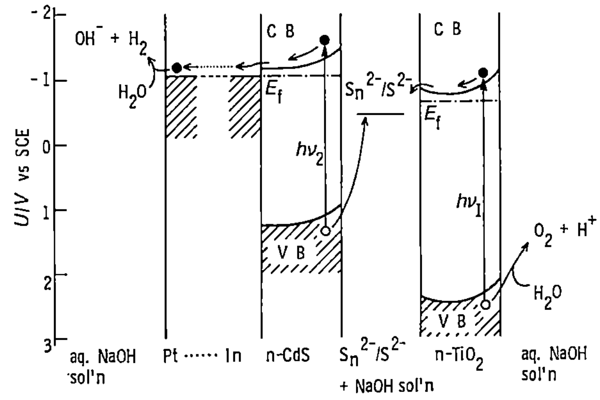

Fig. 3 An energy level diagram for a photocell made of SES and Pt electrodes.

The present SES electrode uses n-TiO_2 which is sensitive to the UV light only. A semiconductor with a narrower bandgap is more desirable for the efficient utilization of solar energy. With such a material the SES electrodes can in principle utilize solar energy of wide spectral range effectively, the shorter wavelength part by the front semiconductor and the longer wavelength part by the rear one. Photoelectrodes with solid n–n (ref. 8) or n–p–n (ref. 9) heterojunctions have been reported to have the same function. Note that the construction of a SES electrode has the advantage that the two semiconductors are prepared separately at their best conditions before they are combined.

Thermoluminescence dating of sand dunes in Rajasthan, India

A. K. Singhvi, Y. P. Sharma* & D. P. Agrawal

Physical Research Laboratory, Ahmedabad 380009, India

We report here a new application of thermoluminescence (TL) for dating sand dunes. This application assumes that exposure to sunlight causes bleaching of the geological TL of a sediment to a residual value and that TL accumulation starts again when the sediment is buried under fresh deposit and is thus shielded from the Sun. Although the TL method has been applied to loess[1,2] and ocean sediments[3,4], the application of this technique to sand dunes provides the first reliable dating control for dune dynamics, palaeoclimatology and spread of deserts.

Samples were collected from the stabilized sand dunes that had archaeological association, so that an independent dating control on the TL dates obtained was available. The location of the dunes are: (1) Langhnaj (23°29′ N, 72°26′ E); (2) Amarpura (27°23′ N, 74°37′ E); and (3) Bagor (25°21′ N, 74°23′ E), all in Rajasthan. The fine grain technique[5] was used for the TL analysis. Grains 1–8 μm in size were extracted after pretreatment of the sample with 1M HCl to remove the carbonate fraction which could be post-depositional. The apparatus has been described elsewhere[6]. Glow curves were recorded in an

ambient atmosphere of ultra-pure nitrogen (5 l min^{-1}) at a heating rate of 5 °C s^{-1}. Photon counting was used and the optics channel comprised a EMI 9635QA photomultiplier tube coupled with Chance Pilkington HA3 and Corning 7-59+5-58 blue filters. β irradiations were carried out using ^{90}Sr/^{90}Y β plaque and α irradiations were made in vacuum using ^{241}Am foils. A 300 W ultra vitalux 'WOTAN' sunlamp[7], kept 30 cm from the samples, was used.

Although sunlamps are richer in UV than sunlight, we consider that adverse effects would be small and would not upset any of the present conclusions. Typical natural, β, α and post-sunlamp exposure glow curves are given in Fig. 1. Thick source ZnS(Ag) counting was used to estimate the uranium and thorium series α activity, and γ spectrometry was used to estimate potassium. The dose rate was estimated assuming the equilibrium of ^{238}U and ^{232}Th series. No wetness correction was considered necessary as the average water content in stabilized sand dunes does not exceed 1–2% (ref. 8). Typical component dose rates are α dose (U, Th) ~ 40–45%, β dose (U, Th) ~ 10–20%, β dose (K) ~ 10–20%, γ dose (U, Th) ~ 15–20%, γ dose (K) ~ 5%. Cosmic-ray dose rate was taken to be 15 mrad yr^{-1} for all the samples. All the samples were checked for anomalous fading for a storage period of 14 days. No loss of signal was seen within experimental reproducibility limits of ~5%. In addition, TL-S-7 showed no loss of signal for a storage period of 57 days. As a further precaution, all the sample disks were read only 15 days after an irradiation.

The observed TL (I_{nat}) in the sample comprises[3]: (1) the unbleachable TL that was already present in the sample at the time of deposition (I_0); and (2) the TL acquired by the sample since deposition as a buried sediment (I_d)

$$I_{\text{nat}} = I_0 + I_d$$

or equivalently

$$D(I_{\text{nat}}) = D(I_0) + D(I_d)$$

where $D(I)$ refers to the equivalent β radiation dose required to give TL of intensity I. $D(I_d)$ divided by the appropriate dose rate gives the date of depositional event. Thus the estimation of I_d requires determination of I_0 and I_{nat}. A clue to the estimation of I_0 is provided by Fig. 2, which gives the bleaching behaviour of two samples with Sun/sunlamp exposures. The bleaching curve quickly approaches an asymptotic value indicating that TL cannot be bleached beyond a finite residual value by any length of Sun/sunlamp exposure. Taking this residual TL level to represent I_0 and expressing it as a fraction R of I_{nat} we have:

$$I_0 = RI_{\text{nat}}$$

or

$$D(I_d) = (1-R)D(I_{\text{nat}})$$

In the above, $D(I_{\text{nat}})$ can be determined by the additive β dose procedure[9], which implicitly assumes a linearity of the TL growth curve. However, in view of the low equivalent doses, we consider that the assumption of a linear growth applies for the samples reported here. R was estimated from the residual TL level after a prolonged (1,000-min) sunlamp bleach. The 1,000-min exposure was considered to be long enough to approach the asymptotic value (Fig. 2). Indeed, for samples TL-S-9 and TL-S-14, for example, the residual TL after a 250-h Sun exposure was within 20% of the values obtained after a 1,000-min sunlamp bleach. Thus this estimation of $D(I_d)$ is not only

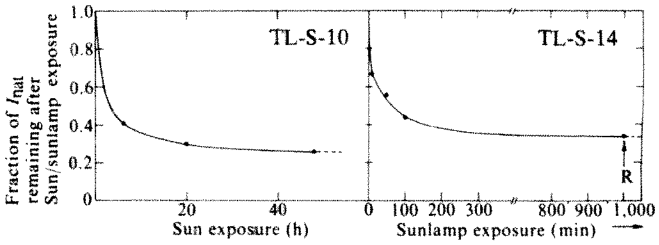

Fig. 2 Effect of Sun/sunlamp exposure on TL. The glow curve temperature is 320 °C. R corresponding to a 1,000-min sunlamp is also indicated.

simple, but has the advantage of circumventing any error due to sensitivity changes following a sunlamp exposure. The method therefore avoids any β exposure that is post-sunlamp bleach[4].

Table 1 summarizes the experimental data and Fig. 3 shows, for three of the samples, the dependence of $D(I_d)$ and R on the glow curve temperature. In most cases a good plateau (~80 °C) began at ~300 °C, as shown in Table 1. Because a glow curve is generally a composite of many glow peaks, the α efficiency (a), $D(I_{nat})$, $D(I_d)$ and R, were all estimated at regular intervals (10 °C) on the glow curves, and an age was estimated for each glow curve temperature. The estimates presented in Table 1 refer to a particular glow curve temperature (340 °C) and the final date is an average over the region where $D(I_d)$ showed a plateau.

A plateau behaviour of $D(I_d)$ in these samples also implies an age plateau as the α efficiency remains practically constant (a change of <10%) over the plateau region. Typical experimental errors are estimated to be 15%.

Note that the equivalent doses corresponding to both I_{nat} and I_d are only a few krads, indicating that the TL in the sample reflects a recent depositional event and not a geological dose. Also in all the cases the TL ages increase with depth; the average sand accretion rates are different for different periods; and the accretion rates are very small, suggesting a gradual buildup of dunes. Multiple exposures, in view of a very easy TL bleachability and very intense Sun exposures available in desert regimes, should not cause any significant errors in the estimates (dates) arrived at using TL. After all, only the last Sun-bleaching event is being dated.

In the Bagor sequence, the TL date of ~2,100 BP on S-13 agrees well with the TL date of ~2,060±210 yr BP on *in situ* pottery (PRL: TL: 42). The TL date of ~3,420 yr BP on S-14 also agrees reasonably well with the radiocarbon dates of 3,945±90 and 4,585±105 yr BP on adjacent coeval stratum. For S-11 a radiocarbon date of 3,990±100 yr BP for the associated bone (on carbonate) and the TL date of ~8,630 yr BP for dune sand from the same stratum seems sensible in view of the possible contamination of bone carbonate by modern carbon.

The agreement between these results confirms the applicability of the TL method in dating sand-dune deposits. The results also indicate that the formula used for estimation of $D(I_d)$, although simple, does provide sensible estimates.

Australian–Antarctic depression from the mid-ocean ridge to adjacent continents

J. J. Veevers

Australian Plate Research Group, School of Earth Sciences,
Macquarie University, North Ryde, New South Wales 2113,
Australia

A morphotectonic depression, some 15×10^6 km^2 in area and centred on the Australia–Antarctic discordance[1], extends across the southern half of Australia through the south-east Indian Ocean to Wilkes Land in Antarctica (Fig. 1*a*, *b*). The depression is co-extensive with a negative satellite free-air gravity anomaly[2] which suggests that the region is underlain by downward convecting asthenosphere. Here I outline the depression and explore its age. In a pre-breakup (>55 Myr) reconstruction (Fig. 1*c*), the Eastern Highlands of Australia and the Transantarctic Mountains are colinear; because the Eastern Highlands were notably high during the late Cretaceous, and shared with the Transantarctic Mountains a history of volcanism in the Jurassic, both highlands probably constituted the eastern flank of the past depression, in the centre of which thick (>8 km) late Cretaceous sediment in the Ceduna Saddle[3], and a possible mirror-image in offshore Antarctica, mark its depocentre. A broad area of late Carboniferous marine sediments in southern Australia[4] may represent the earliest sign of the depression.

The modern morphology of southern Australia and the opposite part of Antarctica (Fig. 1*a*) is dominated by a sinuous depression. A median morphological axis may be drawn through Lake Eyre (12 m below sea level) across the Australian–Antarctic discordance, where the south-east Indian Ocean Ridge (SEIR) has an anomalously low depth of 3.4 km, 1 km deeper than expected[5], to Adelie Land. Two parallel subsidiary axes can be defined: one from the Nullarbor Plain through the ocean to the Budd Coast and thence across an area of poorly-known sub-glacial bedrock topography into the sub-ice Aurora

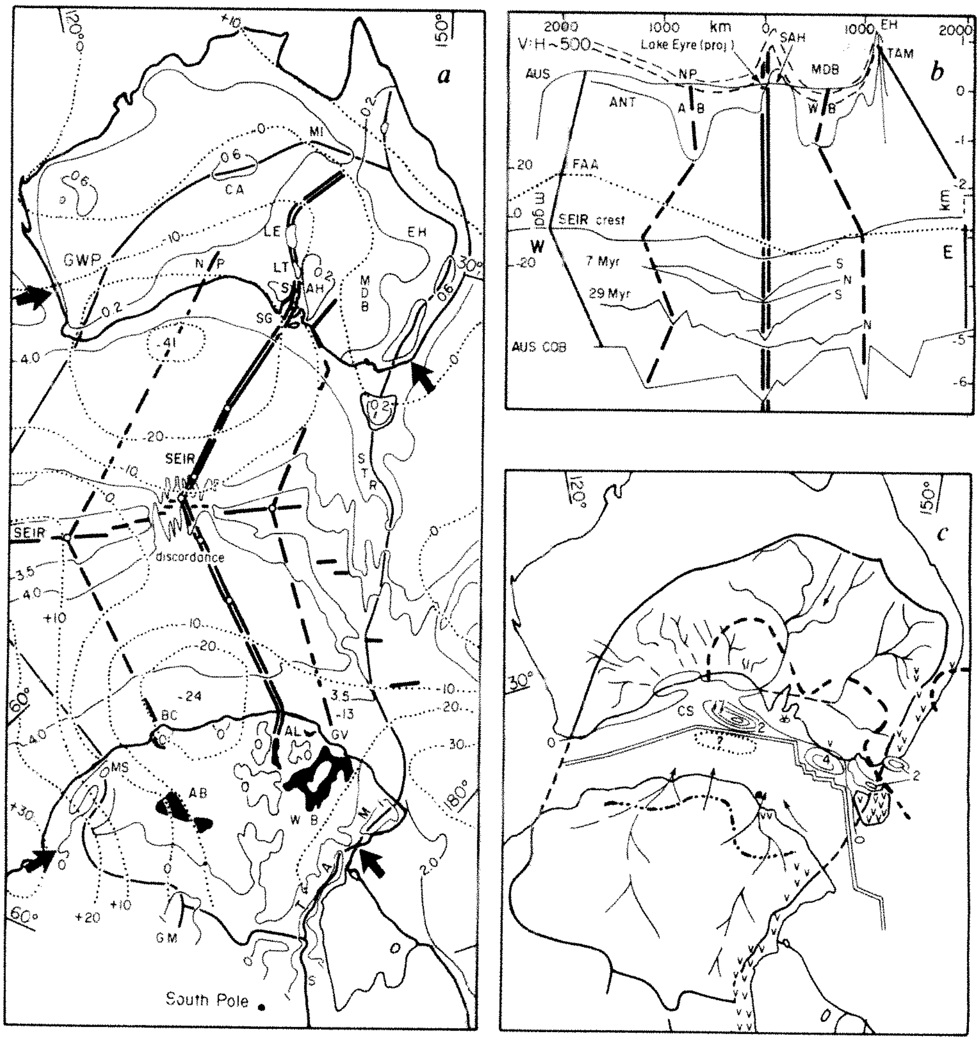

Fig. 1 *a*, Morphology of Australia (contours in km of 1° × 1° area mean rock altitude[21]), the south-east Indian Ocean[22], and Wilkes Land, Antarctica (sub-ice contours in km, < −1 km in black, refs 23–25), and satellite free-air gravity anomalies (in mGals, ref. 2) shown by dotted lines. The Australian–Antarctic depression is outlined (solid line) on the east by the crest of the Eastern Highlands (EH), Tasmania, the South Tasman Rise (STR), a high point on the crest of the south-east Indian Ocean Ridge (SEIR) at long. 150° E, and the Transantarctic Mountains (TAM); on the south by the sub-ice Gamburtsev Mountains (GM); on the west by Mt Sandow (MS), a high point on the crest of the SEIR at long. 95° E (not shown), and the Great Western Plateau (GWP); and on the north by central Australia (CA) and the Mt Isa block (MI). The median morphological axis of the depression (a double line) extends from Lakes Eyre (LE) and Torrens (LT) and Spencer Gulf (SG) within the South Australian Highlands (SAH) through the SEIR discordance[1] to Adelie Land (AL). Subsidiary lowland axes (broken lines) that lie on either side of the continental axial highlands extend on the west from the Nullarbor Plain (NP) to the Budd Coast (BC) and Aurora sub-ice basin (AB), and on the east from the Murray–Darling Basin (MDB) to George V Land (GV) and the Wilkes sub-ice basin (WB). Ends of arcuate continental profiles of *b* shown by arrow tips. Lambert equal-area projection. *b*, Profiles, from top downward, of southern Australia (with the Lake Eyre axis projected southward), Wilkes Land (sub-ice bedrock surface)—the broken lines above show the limits of the profile isostatically adjusted on an ice-free basis according to the method of Brotchie and Silvester[7]—, the crest of the south-east Indian Ocean Ridge (SEIR) and the satellite free-air gravity anomaly[2], the 7- and 29-Myr isochrons[1] on either flank of the SEIR, and the Australian continent–ocean boundary (COB)[3]. As in *a*, the axis is shown by a double line, subsidiary axes by broken lines, and the bounding ridges by a single line. *c*, Pre-breakup reconstruction of Australia and Antarctica (from B. D. Johnson and J.J.V, in preparation) with suture marked by the COB (double line). Present-day outlines of Australian–Antarctic depression, inferred to mark the Mesozoic position, shown by a heavy line, isopachs (km) of late Cretaceous sediments[12,26] by solid lines, direction of post-Cenomanian–late Cretaceous sediment transport[12,13] by arrows, post-Cenomanian–late Cretaceous drainage (a modified modern drainage in Australia, speculative in Antarctica) shown by networks, the single *in situ* occurrence of Mesozoic (Aptian) sediment in East Antarctica[16] by a dot, early and middle Jurassic (185–165 Myr) volcanic rocks[27–30] by Vs, and late Carboniferous (300 Myr) shorelines[4] by heavy broken lines. –·–·– Indicates the approximate position of the shoreline today on an ice-free basis. Note that the Eastern Highlands of Australia and the Transantarctic Mountains are colinear in this and previous reconstructions[31,32]. Lambert equal-area projection; grid applies to present-day Australia only.

basin; the other from the Murray–Darling drainage basin across the ocean to George V Land and thence into the sub-ice Wilkes basin. The profiles (Fig. 1*b*) have a gross symmetry about the median axis. The continental profiles differ from those of the ocean in having the median axis enclosed by highlands. The amplitude of the Antarctic profile is much greater than that of the others, but without its load of 4 km of ice, which has appeared only since the mid-Tertiary[6], the Antarctic profile would rebound by as much as 1 km, according to the method of Brotchie and Silvester[7], and the difference would be greatly reduced, although the great relief of the highlands about the axis would remain (broken lines in Fig. 1*b*).

The correspondence of topography with the satellite free-air anomaly at the discordance led Weissel and Hayes[1] to infer downward convecting currents in the asthenosphere, and the continuation of this correspondence both to the north and south leads me to infer that the entire depression is held down dynamically. How long has the depression existed, and hence how long has this dynamic state applied?

Stratigraphical[8], fission-track age[9], and palaeomagnetic[10] evidence indicate that the Southeast Highlands of Australia date back to the mid-Cretaceous. Voluminous coarse detritus shed into the rift-valley system along south-west Australia during most of the Mesozoic, and in particular during the late Jurassic and early Cretaceous[11], indicates late Mesozoic highlands in the west of Australia. Conclusive evidence of substantial relief in the late Cretaceous is provided by the depocentre of the Ceduna Saddle (Fig. 1*c*), which contains 0.5×10^6 km^3 of post-Cenomanian late Cretaceous sediment, and dwarfs the adjacent south-east Australian basins. If this were an extra-arch basin that formed in a saddle between major uplifts[3], all of its sediment would be derived from north of the suture, which, being marked by a rifted arch, constituted a dam across the centripetal drainage from the highland perimeter. Seismic profiles across the Ceduna Plateau[12] show that this sediment prograded into the sea towards the south. Barely any sediment lodged on the land, which consequently must have had higher stream gradients than at present. And the only known sediment of this post-Cenomanian–late Cretaceous age onshore is fluvial sandstone north-east of Lake Eyre with a southwestward direction of transport[13]. I speculate that the bulk of the sediment in the Ceduna Saddle came from the Eastern Highlands, and that the ancestral Murray–Darling drainage system crossed the site of the South Australian Highlands. With the subsequent uplift of these highlands in the Palaeocene, the Murray–Darling system was impeded, except perhaps for short intervals in the Eocene and Miocene[14], and as a result Cenozoic sediment was deposited to form the Murray Basin[8].

Little direct evidence of the age of the geomorphic elements is available in Antarctica. The Transantarctic Mountains in the Scott Glacier area (S in Fig. 1*a*) existed 18 Myr ago[15], and Drewry[6] argues for uplift in the late Eocene ($\sim$40 Myr ago) but their earlier history is unknown. The late Mesozoic existence of the eastern flank of the Australian–Antarctic Depression is postulated (Fig. 1*c*) because the terrains of the Transantarctic Mountains and the Eastern Highlands are linked today; were colinear before break-up; were the locus of Jurassic volcanism; and the Eastern Highlands stood high during the late Cretaceous. This speculation could be tested by palaeomagnetic and fission-track dating in Antarctica.

The single known *in situ* occurrence of Cretaceous sediment[16] in East Antarctica is Aptian and non-marine. Sediments of this age on the southern margin of Australia, which are also non-marine, in contrast to the widespread marine sediment of this age to the north, reflect the uplift about the suture before and during breakup. Symmetry with Australia about a presumed rift-valley arch[3] suggests a mirror-image of the Ceduna Saddle on offshore Antarctica, a speculation that could be tested by aeromagnetic and seismic surveys. Of the few published thicknesses of sediment off Antarctica[17], this area (at long. 127° E) contains $\sim$5 km of sediment, but how much of this predates break-up is unknown. This postulated depocentre presupposes feeding by an extensive drainage system; the low relief of the South Australian Highlands contrasts with the high Antarctic highlands that today rim the main axis of the depression, so that in the late Cretaceous the Antarctic part of the depression might have been drained by two centripetal networks. As in Australia, so in Antarctica the flanks of the depression may have had sufficient slope to prevent any large accumulation of sediment outside the depocentre, and the shoreline, which on an ice-free basis would now lie some distance inland, as outlined in Fig. 1*c*, probably lay at least as far north as the present coast, and sediment, as in the Ceduna depocentre, reached the postulated depocentre by marine progradation. In this view, the remotely sensed sediment at the axis of the Wilkes sub-ice basin[18] would be either Cenozoic (as in the Murray Basin) but pre-glacial (Palaeogene), or older than late Cretaceous.

The near-restriction of the late Carboniferous sea[4,19] to the southern part of Australia, and the inferred relief at this time of the South Australian Highlands[20] suggest that the morphology of the depression as it is today, with subsidiary lowland axes on either side of a median axis through a highland, is a repeat of that in the late Carboniferous.

I conclude that the morphological depression that extends from southern Australia through the south-east Indian Ocean to Wilkes Land, Antarctica, coincides with a negative gravity anomaly, suggesting that the depression is determined tectonically by downward convection in the asthenosphere. In Australia, the depression can be traced back to the late Cretaceous through a thick pile of sediment deposited in the offshore Ceduna Saddle midway across the southern margin between flanking highlands, and possibly to the late Carboniferous through a broad area of marine sediments in the central and eastern parts of southern Australia. In a pre-breakup ($>$55 Myr) reconstruction of Australia and Antarctica, the eastern flanks of the present depression, comprising the Eastern Highlands of Australia and the Transantarctic Mountains, are colinear; they are also linked by their common history of widespread volcanism in the Jurassic, so that like the Eastern Highlands, the Transantarctic Mountains were highlands during the late Cretaceous. It then follows that a mirror-image of the Ceduna Saddle, with a thick pile of late Cretaceous sediment, may exist in offshore Antarctica.

I thank P. G. Quilty and R. J. Tingey for help with references, J. G. Jones for valuable discussion, B. D. Johnson for comments, and the Australian Research Grants Committee for support.

Phylogeny and classification of thecodontian reptiles

Sankar Chatterjee

Department of Geosciences, Texas Tech University, Lubbock, Texas 79409, USA

Thecodontians have long been recognized as the basal stock from which all other archosaurs were derived, but their phylogeny and classification are very confused, and the origin and evolution of archosaurs are consequently still poorly understood. The skull and skeletal morphology of thecodontians is confusingly uniform, and many palaeontologists feel that the ankle joint may provide a more useful clue to the phylogeny and classification of these groups[1,2]. I attempt here to trace some of the thecodontian lineages on the basis of tarsal anatomy. The major structural changes from thecodontian to dinosaurs are most clearly visible in the pelvis and hind-limbs, associated with improvement of gait from the 'sprawler' through the 'semi-improved' to the 'fully-improved' condition[3,4]. As a result, the function of the ankle joint was modified from a simple flexible base for the leg to the more advanced role of a lever. For this reason, an understanding of thecodontian tarsi is necessary if we are to understand the evolution of the later archosaurs.

Existing classifications[5-7] recognize four suborders within Thecodontia: (1) Proterosuchia, primitive quadrupeds with no armour, such as *Proterosuchus* and *Erythrosuchus*; (2) Aetosauria, armoured, herbivorous quadrupeds, such as *Stagonolepis* and *Typothorax*; (3) Parasuchia, long-snouted parasuchids (phytosaurs); (4) Pseudosuchia, various unrelated groups such as ornithosuchids, sphenosuchids, rauisuchids and euparkeriids. Pseudosuchia constitutes the largest and most heterogeneous group and may be regarded as the 'catch all' suborder into which it has been customary to place all thecodontians other than the Proterosuchia. Although these four categories are accepted by most workers, opinions differ greatly concerning the classification and grouping of the lower ranks; many of the genera are known only from fragmentary and incomplete material, and the interrelationships among them are obscure.

The thecodontian tarsus, where adequately known, consists of two large proximal elements, the astragalus and calcaneum, and two smaller distal tarsals, usually identified as the third and

0028-0836/82/040317—04$01.00

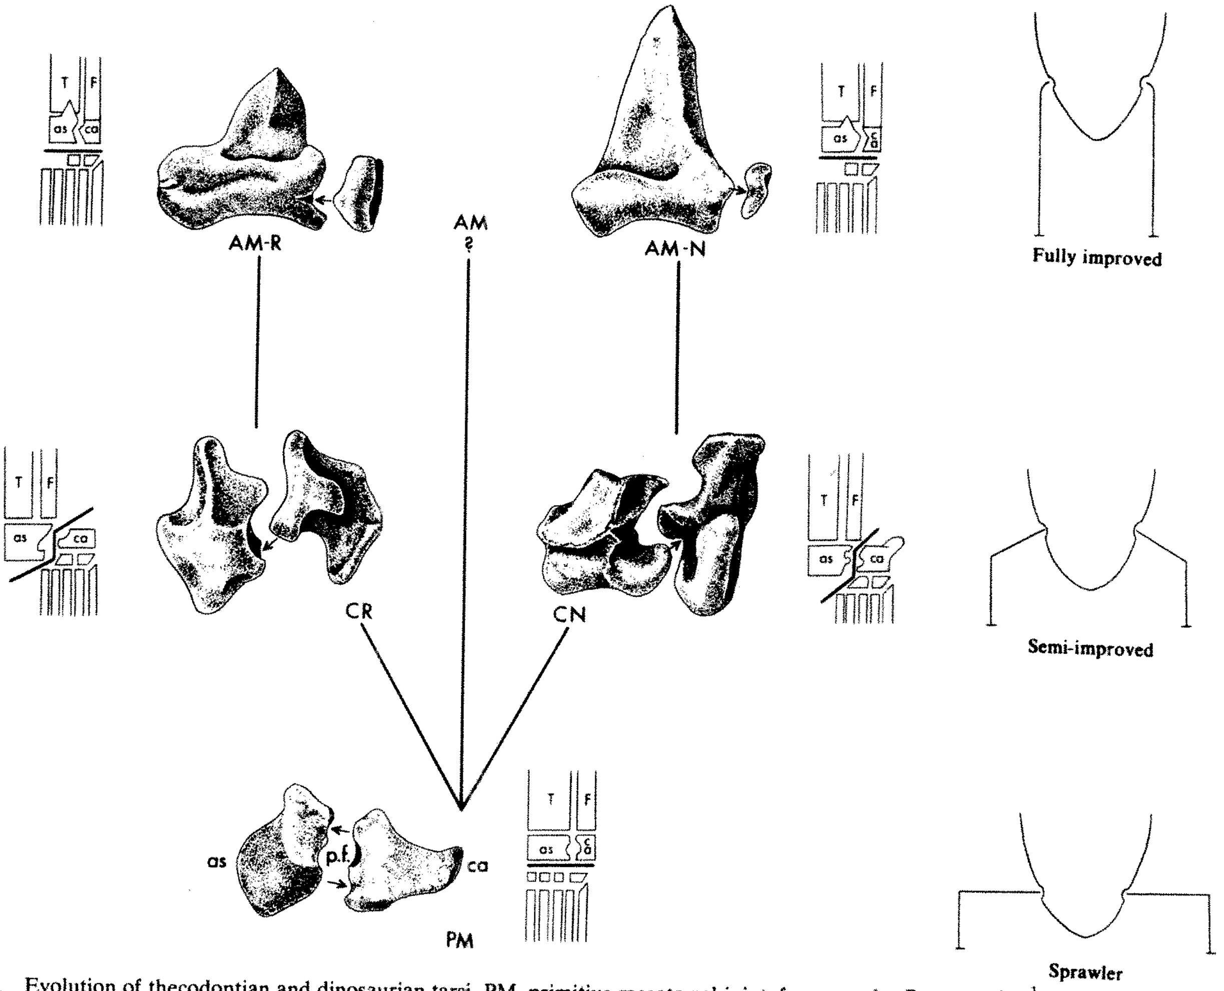

Fig. 1 Evolution of thecodontian and dinosaurian tarsi. PM, primitive mesotarsal joint, for example, *Proterosuchus*[1]; CN, crocodile-normal joint, for example, poposaurid (TTU 9001); CR, crocodile-reverse joint, for example, *Riojasuchus*, drawn from the cast MCZ 4894 (reversed); AM, advanced mesotarsal joint as seen in dinosaurs; AM-R, advanced mesotarsal-reverse joint, for example, *Allosaurus*[20]; AM-N, advanced mesotarsal-normal joint, for example, *Albertosaurus*[21]. All views of the tarsal structure are left anterior; arrow indicates the position of the socket opposite to the corresponding peg; the postures associated with corresponding ankle structures are shown in the right column[3]. Abbreviations: as, astragalus; ca, calcaneum; p.f., perforating foramen; T, tibia; F, fibula. Institutional acronyms: MCZ, Museum of Comparative Zoology, Harvard University; TTU, Texas Tech University.

fourth. Primitive forms also retain free centrale and distal tarsals I and II. The way in which the astragalus and calcaneum articulate with each other and function in relation to the crus and pes is the major characteristic used to classify Thecodontia.

A survey of the thecodontian tarsi reveals that four basic types of ankle joint have evolved in this group of reptiles (Fig. 1):

(1) Primitive mesotarsal (PM) joint: This is the most primitive ankle joint, exemplified by *Proterosuchus*[1], where the astragalus and calcaneum are firmly articulated with the crus, and the hinge of the ankle runs transversely between the proximal and distal rows of the tarsi. The astragalus and calcaneum articulate with each other by means of double convex–concave complementary facets, with a perforating foramen between them. Proximal to the foramen, a concavo–convex joint is present, with the concavity on the astragalus, whereas distal to the foramen the reverse is the case. The calcaneum has a laterally extending tuber. This type of joint occurs in various eosuchians and rhynchosaurs exhibiting a sprawling gait[8]. The arrangement is a precursor to the crocodilian pivot joint[1,2].

Although erythrosuchid tarsi[1] have a perforating foramen between the astragalus and calcaneum similar to that seen in the PM joint, and could therefore be derived from this joint, poor ossification obscures the details of the astragalo–calcanear joint. Cruickshank[9] maintained that such a specialized ankle (highly abbreviated astragalus and calcaneum) indicates that erythrosuchids are a 'dead-end line' that could not have given rise to any other group. The tarsus of *Erythrosuchus* is best considered as a poorly ossified PM joint, and the reduction of ossification may reflect the animal's aquatic habitat.

(2) Crocodile-normal (CN) joint: This pivotal joint between astragalus and calcaneum is found in extant crocodilians[10] and in many thecodontians[11,12]. It differs structurally from the PM joint in that: the calcaneal tuber is extended posteriorly and the perforating foramen has been eliminated; the lower convexo–concave joint is highly elaborated so that the astragalus forms a peg which fits into a deep socket of the calcaneum, allowing rotational movement about a horizontal axis; the calcaneum has developed a rolling convex surface proximally for sliding on the fibula. Functionally the tarsus differs from the PM joint in that the astragalus forms part of the crus, but the calcaneum, distal tarsals and the combined metatarsals move as a unit on the astragalus and fibula. The modification of the CN joint from the PM joint is associated with an improvement in gait from the sprawler to the semi-improved condition[3]. The CN joint occurs in rauisuchids[12,13], stagonolepidids[14,15], parasuchids[16], sphenosuchids[17], *Gracilisuchus*[18] and in poposaurids. Parasuchian tarsi[16] show an intermediate stage between PM and CN joints, where the perforating foramen is highly reduced or lost, the peg and socket joint are not pronounced, and the calcaneum has developed a rolling convex surface for sliding on the fibula, which indicates that some rotational movement was possible at this joint. However, the calcanear tuber is directed laterally, as in the PM joint.

(3) Crocodile-reverse (CR) joint: Bonaparte[5] first recognized this type of pivot joint in ornithosuchids, in which the peg is on the calcaneum and the socket on the astragalus, the opposite condition to that in the CN joint. The calcaneum has a sliding convex surface for the fibula and the perforating foramen

Table 1 Classification of Thecodontia

Nature of ankle joint	Order Thecodontia Owen, 1859
PM joint	1. Suborder Proterosuchia Family Proterosuchidae Broom, 1906 Family Erythrosuchidae Watson, 1917
CN joint	2. Suborder Pseudosuchia a. Infraorder Parasuchia Family Parasuchidae Lydekker, 1885 b. Infraorder Aetosauria Family Stagonolepididae Lydekker, 1887 c. Infraorder Rauisuchia Family Rauisuchidae von Huene, 1942 Family Poposauridae Nopsca, 1928
CR joint	3. Suborder Ornithosuchia Family Ornithosuchidae von Huene, 1908 Family Euparkeriidae von Huene, 1920
AM joint	4. Suborder Lagosuchia Family Lagosuchidae Bonaparte, 1975
Unknown	Thecodontia incertae sedis Family Proterochampsidae Sill, 1967 Family Scleromochlidae von Huene, 1914 Family Dosweliidae Weems, 1980 Family Longisquamidae Sharov, 1970

between the two elements is lost. Cruickshank[1] suggested that the CR joint is present in *Chanaresuchus* (Proterochampsidae), but the critical region of the astragalo–calcanear articulation in available specimens is badly damaged, and thus obscures the nature of ankle joint.

Cruickshank[1] showed that the PM joint is an excellent structural ancestor to both CN and CR joints. The major changes involved in such a transition would be the re-orientation of the calcaneal tuber posteriorly, with the development of the convex sliding surface of the fibula on the calcaneum and the elimination of the perforating foramen. According to Cruickshank, in the CN joint, the lower convexo–concave joint below the perforating foramen was elaborated so that the astragalus formed the peg and the calcaneum the socket. In the CR joint, he believes, the proximal concavo–convex joint was elaborated.

Although the evolution of the CN joint from the PM joint seems straightforward, closer scrutiny reveals that this may not be the situation for the CR joint. Rather, the peg on the calcaneum can be interpreted as being homologous to the whole medioventral process of the calcaneum of the CN or PM type. As a result, the peg of the astragalus below the articulation remains free and wraps around the undersurface of the calcaneum. This indicates that the CR joint might have evolved from the PM joint, not by the elaboration of the upper concavo–convex facets as Cruickshank envisaged, but by the upward migration of the calcaneum above the level of the astragalar peg (Fig. 1).

Both CN and CR joints are associated with the presence of a semi-improved gait, but they differ functionally in that the CN joint is more flexible and allows a greater degree of rotation between the astragalus and calcaneum than does the CR joint. In the CN joint, the peg is directed horizontally, whereas in the CR joint it is projected almost downward. As a result, the CR joint is a better locking and stabilizing device, and is better adapted to withstand the body weight than is the CN joint.

(4) Advanced mesotarsal (AM) joint: Functionally this is similar to the PM joint in that the hinge movement occurs between the proximal and distal rows of the tarsi. However, the astragalus is a mediolaterally elongated hemi-cylinder with an ascending dorsal process for locking the tibia; the calcaneum is reduced and lacks the 'heel'; the perforating foramen is absent. The joint is found in *Lagosuchus*[18] among thecodontians, and in all dinosaurs.

The AM joint could have evolved not only from the PM joint, but also from the CN and CR joints. There are vestiges of the peg and socket in many forms, and accordingly two subtypes of AM joint (AM-normal (N) and AM-reverse (R)) have been distinguished. In *Lagosuchus*[18], the calcaneum shows a rudimentary peg which fits into a corresponding socket of the astragalus, exhibiting the AM-R type. In *Pisanosaurus*[19], the earliest ornithischian dinosaur, the ankle retains the rudimentary peg and socket, but their relationships are not known. Cruickshank[1] remarks that in coelurosaurs, ornithischians and prosauropods, the joint may be of the AM-N type, whereas it may be of the AM-R type in sauropods and carnosaurs. At present, the dinosaur tarsi need very careful analysis before any such generalizations can be made. In most sauropods, the

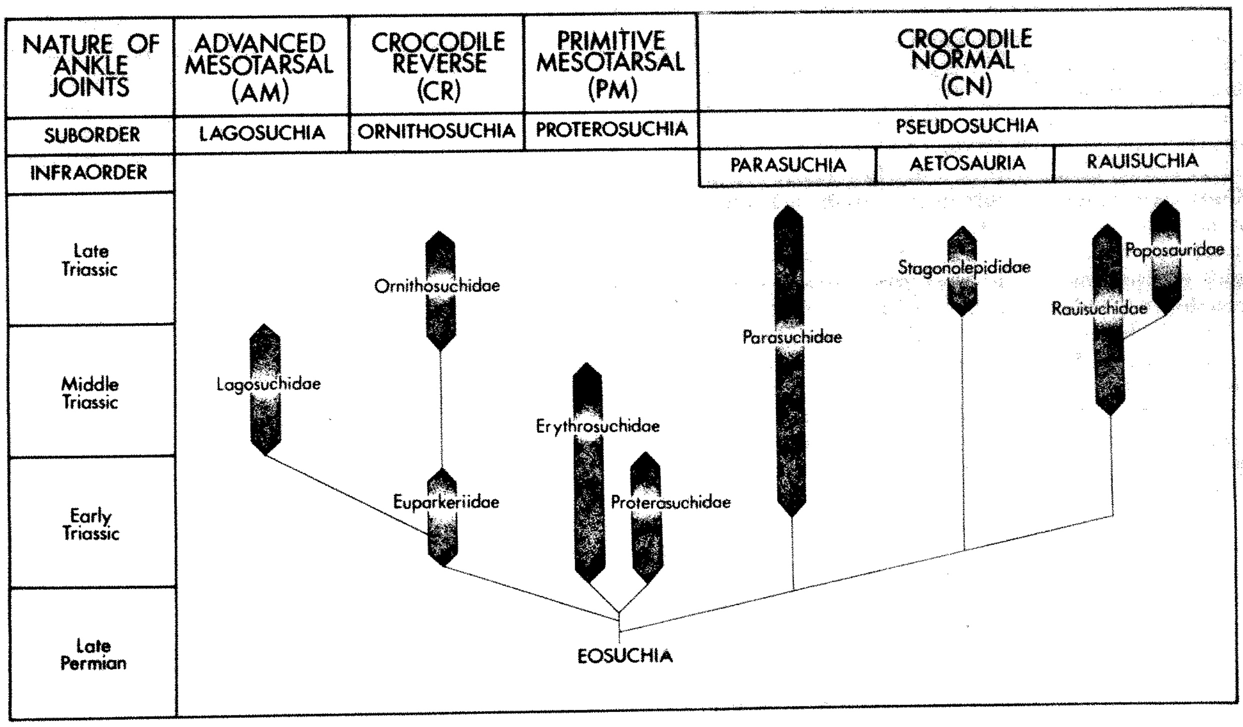

Fig. 2 The phylogeny and classification of Thecodontia.

structure of the calcaneum remains unknown, and the astragalus shows no distinct articular surface for the calcaneum. Among carnosaurs two distinct varieties can be seen. Walker[11] has suggested that two phyletic lines exist within carnosaurs, Megalosauroidea and Tyrannosauroidea, the former showing an AM-R joint and the latter an AM-N joint (Fig. 1)[20,21]. The diversity of AM joints suggests several origins of this type of ankle from different thecodontian lineages, and supports the concept of dinosaur polyphyly[14,22], not the converse[18,23].

The interpretation of the structural evolution of the thecodontian tarsus presented here implies the relationships shown in Fig. 2. This is translated into a classification (see Table 1) which differs from the existing classifications[5-7] in the following points: (1) each suborder is defined by a distinctive pattern of ankle joint. (2) Suborder Pseudosuchia is restricted to those taxa showing a CN joint. Parasuchia (*nom. transl. ex.* Suborder Parasuchia Huxley, 1875) and Aetosauria (*nom. transl. ex.* Suborder Aetosauria Lydekker, 1889) are considered herein as infraorders within Pseudosuchia. Infraorder Rauisuchia (*nom. transl. ex.* Rauisuchidae von Huene, 1942) is shown here to include the two closely related families Rauisuchidae and Poposauridae. Rauisuchia is regarded as a sister group of Aetosauria, and the two together as sister groups of Parasuchia. (3) Ornithosuchidae and Euparkeriidae are removed from Pseudosuchia and grouped into a new Suborder Ornithosuchia (*nom. transl. ex.* Infraorder Ornithosuchia Bonaparte, 1971). (4) *Sphenosuchus*, *Saltoposuchus* and *Hesperosuchus* are considered as Paracrocodylia[17]. (5) Lagosuchidae is removed from Pseudosuchia and promoted to a separate subordinal status Lagosuchia (*nom. transl. ex.* Lagosuchidae Bonaparte, 1975). (6) Proterochampsidae, Scleromochlidae, Dosweliidae and Longisquamidae are regarded as Thecodontia incertae sedis.

I thank Drs A. R. I. Cruickshank, A. D. Walker, P. M. Galton, Nicholas Hotton, Donald Brinkman and Mike Parrish for critically appraising the manuscript and for constructive suggestions, Dr Brinkman for access to *Riojasuchus* material and Mr Mike Nickell for illustrations. The research was supported by the National Geographic Society and Texas Tech University.

Tropical legumes of the genus *Stylosanthes* immobilize and kill cattle ticks

Robert W. Sutherst*, Raymond J. Jones† & Herbert J. Schnitzerling*

* CSIRO Division of Entomology, Long Pocket Laboratories,
PMB 3, Indooroopilly, Queensland 4068, Australia
* CSIRO Division of Tropical Crops and Pastures,
Davies Laboratory, PMB, PO Aitkenvale, Townsville,
Queensland 4814, Australia

Ticks affect 800 million cattle and a similar number of sheep worldwide[1] and their control by chemical 'dipping' is expensive and threatened by the widespread development of resistance[2]. Resistant varieties of crops have been used widely to control phytophagous insects[3], but larvae of all species of hard ticks (Ixodidae) ascend plants only in order to transfer to a passing host. Contacts with hosts are infrequent thus the ticks must often wait in the pasture for several weeks[4]. A substantial reduction in the life expectancy of such larvae would lower populations of the damaging parasitic stages. Molasses grass *Melinis minutiflora*, has been shown to reduce tick survival but the effect is small and slow[5]. Some highly productive, nutritious varieties of the tropical pasture legume *Stylosanthes*[6,7], are covered in glandular trichomes or hairs which secrete a viscous fluid. Such trichomes are well known for their role in defence against a variety of plant-feeding insects[3,8]. We report here that two South American species of *Stylosanthes* produce sticky secretions which immediately immobilize larvae of the cattle tick, *Boophilus microplus*. The larvae are poisoned within 24 hours by an unidentified vapour from the secretions. The legumes appear to have the potential to substantially reduce populations of all species of ticks in the extensive tropical and subtropical areas in which *Stylosanthes* sp. can be grown in pasture.

Following preliminary observations, pots were set up, each containing six to eight plants of each species or cultivar of the perennial legumes: *Stylosanthes hamata* cv. Verano; *Stylosanthes scabra* cv. Fitzroy or Seca, CPI 34925 (Commonwealth Plant Introduction number); and *Stylosanthes viscosa*, CPI 34904 and these were grown until near first flowering.

We released tick larvae onto each type of legume and compared survival per pot with that on a control pot made up of a narrow-leafed grass (*Eragrostic tenuifolia*) and one of a broad-leafed grass (*Panicum maximum*). On each occasion, two pots containing the legume of interest were used to make comparisons. Tick larvae (10,000; the progeny of 4–5 female ticks) were released on to the base of the plants in each pot at 20–24 °C. The pots were placed in trays of water to prevent any ticks escaping. On days 1 and 6 after release, live and dead larvae adhering to the trichomes were counted by destructive sampling of the plants.

Differences in larval survival rates between the various treatments were such that statistical analysis was unnecessary (Fig. 1). No larvae reached the tips of untrimmed plants of *S. scabra* and *S. viscosa*. Larvae were immobilized and killed on the glandular hairs of both species within 24 h (Fig. 2) while most of their siblings which had established themselves on grass or on *S. hamata* were alive. The viscous secretion had no repellent properties so that the ticks, which are negatively geotropic, did not attempt to retreat and seek alternative plants. Despite the very large numbers of larvae trapped, each plant was capable of trapping many more.

Table 1 Model predictions of the percentage reductions in numbers of *B. microplus* after trapping of larvae by pubescent *Stylosanthes* for different periods each year

% *Stylosanthes* in pasture	Duration of trapping period (months) 4	6	9
20	48	65	75
40	77	90	96
60	93	98	99+

We investigated the mechanism by which larvae were killed; larvae placed on adhesive tape were still alive after being held for 48 h, whereas others that had been trapped *in situ* on *S. scabra* were all dead after 24 h. We therefore concluded that physical restraint of the larvae was not alone responsible for

0028-0836/82/040320—02$01.00

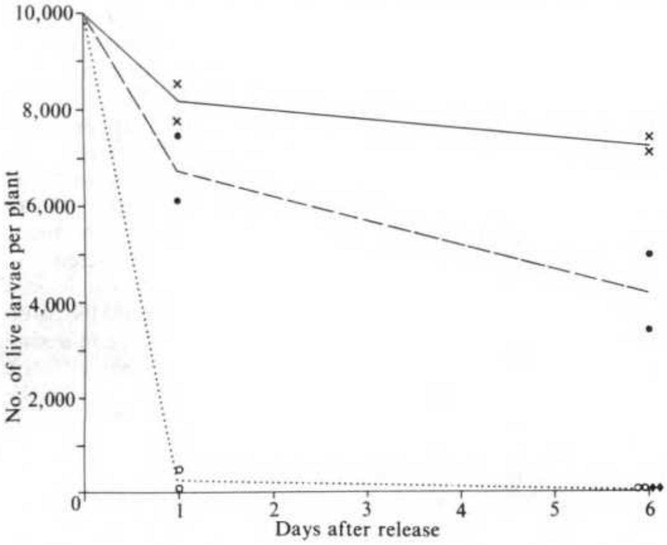

Fig. 1 Numbers of live *B. microplus* larvae recovered from pots containing different types of pasture plants onto which 10,000 larvae had been released. ×, Grass; ●, *S. hamata*; ○, *S. scabra*; ◆, *S. viscosa*.

their death, although in practice it would be adequate to prevent them attaching to a host. The contact toxicity of the secretion was tested by removing it from the trichomes with a small wad of cotton wool which was then extracted with hot methanol. The methanol was evaporated and the residue dissolved in ethanol containing 2% Triton X-100. This was then added to water to give a colloidal suspension. Larvae were dipped for 4 min in suspensions of the extract as described elsewhere[9]. The extract suspension concentrations up to 0.3% w/v failed to kill larvae within 48 h. As conventional acaricides in similar conditions are toxic at concentrations below 0.001% w/v (ref. 9 and H.J.S., unpublished data) we considered the extract to be non-toxic.

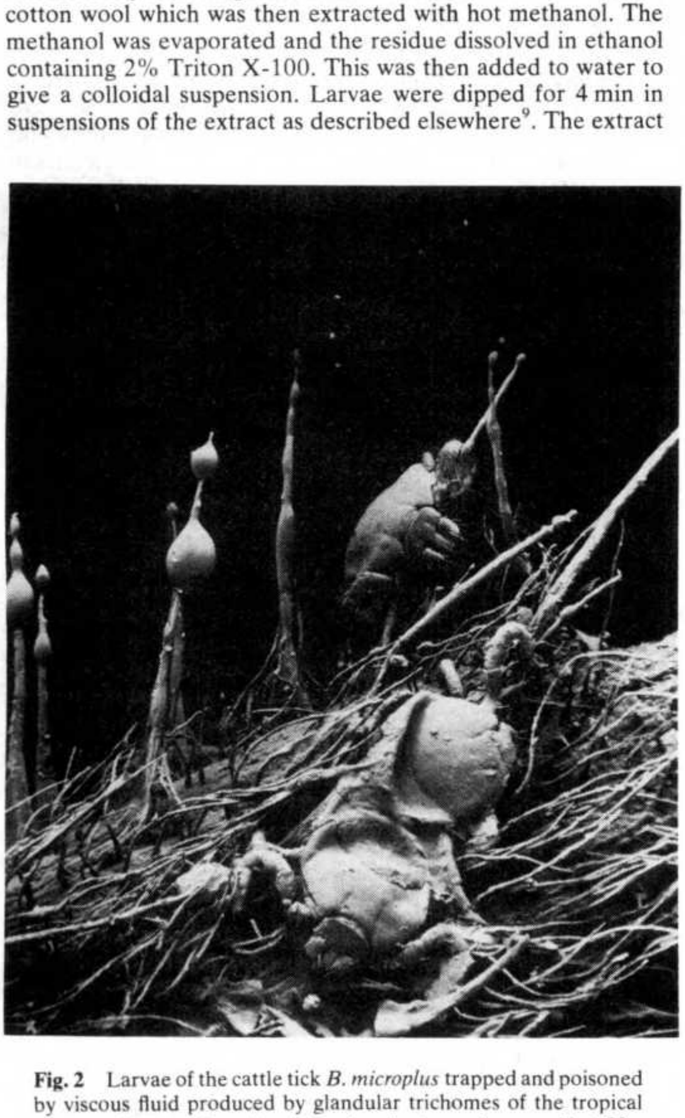

Fig. 2 Larvae of the cattle tick *B. microplus* trapped and poisoned by viscous fluid produced by glandular trichomes of the tropical pasture legume *S. scabra* (scanning electron micrograph). ×50.

The secretion had a characteristic odour, suggesting that the toxic agent might be volatile. If so it would have evaporated during preparation of the extract. The possibility of fumigant action was tested by collecting the secretion from three stems of *S. scabra*, ~15 cm long, using three pieces (16 cm^2) of fine nylon gauze. The gauze was crumpled and placed inside a larva-proof stainless steel gauze cylinder (1 cm × 1 cm). The cylinder was securely capped and held firmly in the middle of a 5 × 1.2 cm glass vial. Approximately 200 larvae were brushed on to the inside of the glass vial which was then secured at the open end with larva-proof nylon gauze. Vials were incubated at 30 °C and 85–100% relative humidity. The larvae in the vials, while being exposed to any volatile component, were not in direct contact with the secretion. This experiment was repeated three times. After 36 h, 94% of the larvae were dead while all control larvae in glass tubes without the viscous fluid were alive. Investigations are under way to isolate and characterize the toxicant.

The results demonstrate that those *Stylosanthes* species that possess glandular hairs have an extremely severe and rapid effect on tick larvae. Preliminary observations on *Stylosanthes guianensis* have shown that some accessions to the Australian collection have comparable effects on ticks to those reported here for *S. scabra* and *S. viscosa*. The effect greatly exceeds that reported for molasses grass, on which there were still 15–20% as many larvae as on other grasses 14 days after infestation[5]. If these results for *Stylosanthes* are reproducible in the field, it may be possible substantially to reduce tick populations throughout much of the tropics and subtropics. The legumes not only trap larval ticks but also improve cattle nutrition, which should enhance their resistance to ticks[10]. This effect will depend on the percentage cover of legume in a pasture and on the duration of the secretory period. Computer simulations using a model of *B. microplus* populations[11], with four generations per year, showed that the legumes are likely to reduce substantially equilibrium tick populations (Table 1). The effect may be enhanced by the observed accumulation of the secretions, especially of *S. viscosa*, on the legs and heads of grazing cattle. The exploitation of pasture plants that are detrimental to ticks is an attractive notion, particularly if the plants also improve the productivity of grazing animals.

The genus *Stylosanthes* will grow in a wide range of climates and soils[7], and it is likely that the legumes will be equally effective against all tropical and subtropical ticks which use pasture plants as a support while host-seeking. The specialized behaviour of tick larvae makes them particularly vulnerable to such a trap.

We thank Mr J. Darley (James Cook University of North Queensland) for photography, Mr D. A. Stegeman and Ms J. Everson for technical assistance, and the Australian Meat Research Committee for contributing funding. Dr J. Nolan and D. P. Sands provided helpful support and several colleagues gave helpful criticisms of the manuscript.

Role of gut flora in the genotoxicity of dinitrotoluene

Jon C. Mirsalis*, Thomas E. Hamm Jr, J. Michael Sherrill & Byron E. Butterworth

Chemical Industry Institute of Toxicology, PO Box 12137,
Research Triangle Park, North Carolina 27709, USA

Dinitrotoluene (DNT), an important industrial nitroaromatic compound, is a potent hepatocarcinogen in rats. Male Fischer-344 rats fed technical-grade DNT in the diet for 12 months showed a 100% incidence of hepatocellular carcinomas[1]. However, various *in vitro* and *in vivo* short-term tests using several genotoxic end points have failed to show activity with DNT or purified DNT isomers[2-6], including unscheduled DNA synthesis (UDS) in primary hepatocytes *in vitro*[7]. In the *in vivo–in vitro* hepatocyte DNA repair assay, which measures chemically induced UDS in hepatocytes isolated from rats treated *in vivo*[8], DNT was found to be a potent UDS inducer[9] having a peak of activity 12 h after a single dose. A possible explanation for the discrepancy between the *in vivo* and *in vitro* results is that metabolism by gut flora may be required for formation of the proximate or ultimate carcinogenic metabolites of DNT. The importance of biotransformation of toxicants by intestinal microflora has been demonstrated for cycasin[10,11] and other xenobiotics[12]. We have used the *in vivo–in vitro* hepatocyte DNA repair assay to study the role of intestinal microflora in DNT genotoxicity. We report here extensive DNT-induced DNA repair in rats having the normal complement of gut flora, but not in rats which have no gut flora. These results indicate that metabolism of DNT by gut flora is a necessary step in the genotoxicity of this compound and illustrate the value of the *in vivo–in vitro* hepatocyte DNA repair assay in assessing the carcinogenic potential of nitroaromatic compounds.

Germ-free (axenic) male Fischer-344 rats (CDF (F-344)/CrlGN) were obtained in sterile isolators from Charles River Breeding Laboratories. Two weeks previously, one group was associated with Charles River Altered Schaedler Flora (CRASF), a mixture of eight anaerobic bacterial strains similar to the normal gut microflora of rats (R. P. Orcutt, personal communication). Rats were maintained on Agway 7RF Autoclavable Rodent Diet while in transit and after arrival. Both the non-associated and associated groups of rats were given 100 mg per kg sterile DNT by gavage in sterile corn oil. (DNT was sterilized by dissolving in absolute ethanol, filter sterilizing (0.45 μm filter) and recrystallizing. Using gas chromatographic analysis, the isomeric proportions were found to be essentially unchanged.) Primary hepatocyte cultures were prepared 12 h later, cultured with ^{3}H-thymidine and UDS measured by quantitative autoradiography as previously described[8]. Cells were scored for net grains per nucleus, calculated as the silver grains overlying the nucleus minus the highest of the grain counts overlying three adjacent nucleus-sized areas of the cytoplasm; 50 cells were scored for each of three slides per animal. A cell with ≥ 5 net grains per nucleus was considered to be in repair.

Rats associated with CRASF showed a marked increase in UDS after DNT treatment (Table 1), whereas axenic rats showed no increase in UDS. Dimethylnitrosamine (DMN), used as a positive control, gave a large increase in UDS, confirming the ability of axenic animals to carry out excision repair of DNA after exposure to a genotoxic agent. This is consistent with the response induced by DMN in conventional animals[8].

The caecal contents of each rat were cultured to confirm its bacterial status; those of the associated animals contained the complete CRASF flora. Several of the non-associated animals were found to be contaminated with one or two bacterial strains. These animals, however, showed only low bacterial counts compared with those found in the CRASF-associated rats. Non-associated rats contaminated with *Streptococcus faecalis* showed a small increase in UDS after DNT treatment while non-associated rats contaminated with *Clostridium perfringens* showed no increase (Table 1). None of the contaminants were CRASF constituents, although *S. faecalis* and *C. perfringens* are frequently found in the normal gut flora of man and conventional laboratory animals. Thus, the level of DNT-induced UDS in the rats that did not have the normal complement of gut flora was significantly lower ($P < 0.01$) than that seen in rats having the complete complement.

The absence of UDS in axenic animals clearly demonstrates a requirement for metabolism by gut flora in order for DNT to be genotoxic. Other studies have indicated that intestinal flora play a part in DNT metabolism. Following treatment of axenic rats with 2,4-DNT, two of the four major urinary metabolites seen in conventional rats were substantially decreased[13]. Metabolism of 2,4-DNT by rat intestinal flora *in vitro* showed reduction of 2,4-DNT to 2-amino-4-nitrotoluene (2-A-4-NT), 2-nitro-4-aminotoluene (2-N-4-AT) and 2,4-diaminotoluene (2,4-DAT)[14]. Isolated rat hepatocytes were unable to produce 2,4-DAT, 2-A-4-NT or 4-A-2-NT at physiological oxygen concentrations[15]. The results of our DNA repair studies combined with metabolism studies provide strong evidence that reductive metabolism in the gut is necessary for formation of a genotoxic metabolite of DNT.

Short-term *in vitro* tests for genotoxicity are widely used as supportive data in the evaluation of the potential carcinogenicity of chemicals[16]. However, these assays do not reflect the species,

Table 1 Induction of UDS in CRASF-associated and non-associated rats 12 h after DNT treatment

Bacterial status	Chemical	Dose (mg per kg)	(*n*)	Net grains per nucleus	% In repair
Associated animals					
Complete CRASF	Control	–	2	−4.2 ± 0.5	7 ± 2

sex and organ specificities commonly observed in chemical carcinogenesis. Existing or future systems which will allow the evaluation of chemically induced genotoxic effects in the whole animal should provide a more realistic means of evaluating the potential hazards of be appropriate for evaluating genotoxicity of nitroaromatic and, perhaps, other compounds. In addition, the *in vivo* assays which measure genotoxicity in a target tissue that does not develop cancer[6] may also be inappropriate. The *in vivo–in vitro* hepatocyte DNA repair assay has been demonstrated to be extremely useful for the study of DNT genotoxicity and should, therefore, be one of the primary tests chosen to examine the genotoxicity of nitroaromatic compounds.

Effects of overfeeding on energy balance and brown fat thermogenesis in obese (*ob/ob*) mice

Paul Trayhurn, Pauline M. Jones,
Martina M. McGuckin & Anne E. Goodbody

Dunn Nutrition Laboratory, University of Cambridge and Medical
Research Council, Milton Road, Cambridge CB4 1XJ, UK

The genetically obese (*ob/ob*) mouse has been used extensively in experimental studies on obesity and to determine the mechanisms involved in regulating energy balance[1]. Excess energy begins to accumulate in the *ob/ob* mouse from ~12 days of age[2], but food intake during the suckling period and up to 4 weeks of age is no greater than in lean siblings[3–5]. This indicates that the initial development of obesity in the *ob/ob* mutant is entirely due to a low energy expenditure, and this has been attributed to a reduction in thermoregulatory non-shivering thermogenesis[6–8], particularly that mediated by brown adipose tissue[9,10]. Hyperphagia does, however, play an important part in the later development of obesity in *ob/ob* mice. Recent studies with young rats of the Sprague–Dawley strain fed a 'cafeteria diet' have suggested that an adaptive diet-induced thermogenesis, also mediated by brown adipose tissue, has a major role in minimizing the accumulation of energy during voluntary overfeeding[11–13]. We now report the effects of overfeeding young lean and obese mice with a cafeteria-type diet, and show that while the lean animals retain little of their excess energy intake, most of the extra intake of the obese mice is deposited. This suggests that the capacity for diet-induced thermogenesis is reduced in the obese compared with the lean mice. We also show that the energy balance measurements are paralleled by different adaptive changes in brown adipose tissue in the two genotypes.

The animals used in this study were male lean (*ob/+* or *+/+*) and obese (*ob/ob*) mice of the 'Aston' variety[2], between 23 and 28 days old at the start of the experiments. They were kept singly in wire-mesh cages in an animal room at 23±1 °C, with a 12-h light/12-h dark cycle (light period from 07.00). Half the animals were fed a standard low-fat commercial diet (Spillers–Spratts Rodent Breeding Diet 1), while the remaining animals from each group were fed a cafeteria diet. The cafeteria diet consisted of two different food items (for example, chocolate and cheese) given each day, in addition to the stock diet. All animals were weighed daily and energy intake was determined each day for the cafeteria mice and every 2–3 days for the stock-fed groups.

The energy balance results for lean and obese mice obtained over 3 weeks are shown in Table 1. The lean mice fed the cafeteria diet had a digestible energy intake that was 69% higher than that of lean animals fed the stock diet alone; thus mice, like rats, can be induced to over-eat on a cafeteria diet. Despite their increased energy intake, the cafeteria-fed lean mice did not show a significantly greater weight gain than the stock-fed controls, and although the total energy gain on the cafeteria diet was 19% greater than that on the stock diet, the increase was not statistically significant. Gross efficiency (energy deposited divided by digestible energy intake) was significantly lower on the cafeteria diet than on the stock diet.

The absolute increase in energy deposition of lean mice fed the cafeteria diet was 36 kJ and this accounted for a mere 4% of the increase in digestible energy intake which occurred during cafeteria feeding. The apparent energy expenditure of the cafeteria-fed lean mice, calculated as the difference between the digestible energy intake and the gain in body energy, was 899 kJ (or 76%) more than the control lean mice. This suggests that young lean mice of the Aston variety exhibit the same diet-induced thermogenesis during overfeeding as has been reported for Sprague–Dawley rats[11]. It is possible that greater physical activity also made some contribution to the increased energy expenditure of the cafeteria-fed mice. Note that energy expenditure in this study has been overestimated because the energy loss in urine was not taken into account. However, as the animals showed no glycosuria, urinary energy losses are unlikely to affect markedly the calculated difference in energy expenditure between stock and cafeteria-fed animals.

The obese mice also increased their energy intake on the cafeteria diet, despite the fact that on the stock diet they were already hyperphagic relative to the lean animals. The digestible energy intake of the cafeteria-fed obese mice was 49% more than in those fed the stock diet alone. In contrast to the lean mice, the obese animals gained significantly more weight and deposited substantially more energy on the cafeteria than on the stock diet. The gain in carcass energy on the cafeteria diet was 88% more than on the control diet, and the gross efficiency of the cafeteria-fed obese animals was higher, rather than lower, than the stock-fed group. The absolute increase in energy deposition (572 kJ) on the cafeteria diet amounted to 55% of the extra energy intake; thus, in the obese mice, unlike the lean, most of the extra energy intake was deposited. The apparent energy expenditure did, of course, rise in the cafeteria-fed obese animals, but it is unlikely that much of the increase was due to the energy cost of fat deposition as high-fat cafeteria diets lead to a suppression of fatty acid synthesis (N. J. Rothwell, M. J. Stock and P. T., unpublished observations), presumably because dietary fatty acids are used directly for triacylglycerol synthesis, at little energy cost.

It has recently been argued[14,15] that cumulative errors occur in energy balance experiments, necessitating the measurement of all three components—intake, output and storage—of the energy balance equation. There is no evidence, however, that the errors involved are large, and they are certainly too small to have more than a minor impact on the conclusions drawn here. Furthermore, in the present study, any cumulative errors will presumably occur for both the lean and obese animals, which showed quite different responses to overfeeding with regard to energy deposition and apparent energy expenditure.

Evidence has been presented that the main effector of diet-induced thermogenesis in rats is brown adipose tissue[11–13],

Mice 23–28 days old were fed stock or cafeteria diets for 3 weeks; the lean and obese animals received the same cafeteria foods. The energy content of all food items, carcasses and faeces was determined by bomb calorimetry using a Gallenkamp adiabatic calorimeter (model CB-100), calibrated with dry benzoic acid standards[7]. Energy intake measurements were corrected for any changes in water content of the foods. Faeces were collected throughout the experiment and their energy content measured for the determination of digestible energy intake. At the end of the experiment the mice were killed by ether anaesthesia, the gut contents removed, and the carcasses chopped into small pieces. The carcasses were then autoclaved, homogenized, and finally freeze-dried before measurement of their energy content[7]. Initial carcass energy was estimated from body weight by reference to a baseline group of 10 lean and 10 obese mice of the same age and weight range as the experimental groups[7]. Gross efficiency and the apparent energy expenditure were calculated as described in the text. Results are given as mean values ±s.e.m. for eight animals per group, except for the lean cafeteria group where seven animals were used.

which is traditionally associated with non-shivering thermogenesis in many newborn and hibernating mammals[16,17]. We therefore examined brown adipose tissue from the interscapular region of both lean and obese mice fed the stock or cafeteria diets (for results see Table 2). The total amount of interscapular brown adipose tissue was increased by 26% in lean mice after cafeteria feeding, but there was no increase in the total protein content of the tissue. The activity of cytochrome oxidase (E.C. 1.9.3.1.) was, however, increased by 53%, indicating that the total oxidative capacity of brown adipose tissue was augmented by overfeeding in lean mice. In contrast, the obese mice fed the cafeteria diet did not show any increase in the amount of interscapular brown adipose tissue, or in the cytochrome oxidase activity or total protein content of the tissue.

The primary mechanism for thermogenesis in brown adipose tissue is considered to be through a proton conductance pathway across the inner mitochondrial membrane[18], a pathway which can be inhibited by purine nucleotides that bind to a protein of molecular weight 32,000 (refs 19, 20). The extent to which purine nucleotides (for example, GDP) bind to brown adipose tissue mitochondria seems to reflect the activity of the proton conductance pathway, and this has formed the basis of an assay for the 'thermogenic state' of the tissue[21–24]. We therefore measured GDP binding to brown adipose tissue mitochondria from lean and obese animals fed control or cafeteria diets; there was a ~50% increase in binding in the cafeteria-fed animals of both genotypes, which indicates an augmentation of thermogenesis (Table 2). However, for each diet binding was lower in the obese than in the lean animals.

Cafeteria feeding, therefore, seems to result in changes in the proton conductance pathway, as well as in the total oxidative capacity, of brown adipose tissue of lean mice, changes that are similar to the changes reported in Sprague–Dawley rats[12]. Obese mice show less of a response to overfeeding, however, in that only the proton conductance pathway is increased. These different adaptive responses to overfeeding in brown adipose tissue of lean and obese mice parallel the different responses of the two genotypes with respect to whole-body energy balance.

Pair-feeding studies using the *ob/ob* mutant on a normal diet generally involve restricting the intake of the obese to the *ad libitum* intake of the lean, but in the present experiments the digestible energy intake of the cafeteria-fed lean mice proved similar to that of the obese fed the stock diet alone; 'pair-feeding' was therefore achieved with the obese eating *ad libitum*. Note that in this situation the stock-fed obese animals deposited nearly three times as much energy as the cafeteria-fed lean mice, and this was associated with substantial differences between the two groups in cytochrome oxidase activity and GDP binding in brown adipose tissue.

In conclusion, the present results demonstrate a clear difference between the lean and obese genotypes in the metabolic response to voluntary overfeeding, results consistent with the view that a regulatory diet-induced thermogenesis mediated by brown adipose tissue plays an important part in

Table 2 Properties of interscapular brown adipose tissue in lean and genetically obese mice fed control or cafeteria diets

	Lean		Obese	
	Control	Cafeteria	Control	Cafeteria
Brown adipose tissue weight (mg)	80.5±3.4 (16)	101.6±7.7* (16)	343.5±33.2 (8)	315.3±47.2 (NS) (10)
Total brown adipose tissue protein (mg)	10.6±0.8 (13)	11.0±0.6 (NS) (8)	8.6±0.3 (8)	9.7±0.5 (NS) (8)
Total cytochrome oxidase activity (μmol cytochrome *c* oxidized per min)	22.1±1.6 (13)	33.8±1.7† (8)	13.4±1.5 (8)	13.4±1.2 (NS) (8)
GDP binding (pmol GDP per mg mitochondrial protein)	345.3±13.5 (7)	502.2±30.3† (8)	272.2±12.5 (7)	421.7±136.4* (6)

Mice similar to those in Table 1 were fed stock or cafeteria diets for 3 weeks, after which they were killed by cervical dislocation, and interscapular brown adipose tissue rapidly removed, trimmed free of contaminating tissues, and weighed. The cytochrome oxidase activity of the tissue was measured spectrophotometrically[26], and the total protein content measured by a modified Lowry method[27] using bovine serum albumin as standard. For the purine nucleotide (GDP) binding assay, mitochondria were prepared as described elsewhere[28] from brown adipose tissue pooled from the interscapular, subscapular and dorsocervical sites. GDP binding was measured by incubating the mitochondria at 20 °C, *p*H 7.1 for 7 min, with 10 μM ^{3}H-GDP, essentially according to Nicholls[19], as described previously[29]. ^{3}H-GDP and ^{14}C-sucrose were obtained from Amersham. The results are mean values ±s.e.m.; numbers of observations are shown in parentheses.

* $P<0.05$; † $P<0.001$ compared with control animals of the same genotype. NS, not significant ($P>0.05$).

energy balance[11]. The results also demonstrate directly the importance of a reduced capacity for diet-induced thermogenesis in the development of obesity[25]. Obesity in the *ob/ob* mouse, in particular, may be viewed as a consequence of a reduction in both non-shivering and diet-induced thermogenesis in brown adipose tissue; reduced non-shivering thermogenesis leads to a low maintenance requirement and excessive energy gain on a 'normal' energy intake, while a reduction in the capacity for diet-induced thermogenesis leads to an impairment in the ability to dissipate excess energy intake once hyperphagia is established soon after weaning.

We thank Dr W. P. T. James for his helpful comments and the MRC for a studentship (A.E.G.). P.M.J. was a visiting student from the University of Surrey.

Expression of HLA antigens, β_2-microglobulin and enzymes by human amniotic epithelial cells

A monolayer of epithelial cells, endowed with unique secretory properties, lines the human amniochorion[1,2]. It has been shown that transplantation of these membranes into allogeneic hosts does not result in overt acute graft rejection[3–6]. We demonstrate here that HLA-A, -B, -C and -DR antigens and β_2 microglobulin (β_2m) cannot be detected by immunofluorescence on freshly collected or *in vitro* cultured amniotic epithelial cells, although small quantities of such antigens were detected when more sensitive radiobiological techniques were used. We also show that these cells, cultured *in vitro*, produce large quantities of enzymes absent in patients with lysosomal storage diseases and that their supernatants can correct glycosaminoglycan accumulation in cultured fibroblasts from patients with Hurler's and Hunter's syndromes.

Cryostat sections of human amniotic membranes were studied by immunofluorescence techniques either immediately after collection or following 24 h incubation in RPMI 1640 medium (Flow)[7]. When these sections were independently stained in three laboratories, β_2m could not be detected by immunofluorescence techniques using monoclonal antibodies and rabbit immune sera. The few fibroblasts present in the connective tissue showed intense staining. Using the same methods, β_2m molecules were not detected on the surface of amniotic epithelial cells which had been cultured *in vitro* for over 3 weeks. The expression of HLA-A, -B, -C and -DR antigens was investigated by immunofluorescence using two monomorphic monoclonal antibodies, one (W6/32) reacting with the native HLA-A, -B and -C molecules and the other (DA2) with HLA-DR antigen[8,9]. The amniotic epithelial cells were not stained by these antibodies while cells in the underlying connective tissue, predominantly fibroblasts, were positive with W6/32; another population of these cells, presumably macrophages, were positive with the DA2 antibody.

Although these results suggested the absence or poor expression of HLA-A, -B, -C and -DR antigens and β_2m on the surface of the human amniotic epithelial cells, small quantities of β_2m could be detected in the serum-free media collected from 20 samples of the cells cultured *in vitro*. In fact, 24 h incubation of the cells in a serum-free medium following culture in RPMI 1640 medium supplemented with 20% fetal calf serum for >3 weeks, revealed levels of β_2m of 1.7–14.7 mg l^{-1} (mean 5.8 mg l^{-1}) in the supernatants, using a radioimmunoassay technique (Phadebas β_2 microtest, Pharmacia Diagnostic). However, the amount of β_2m in the supernatants of the amniotic epithelial cells was less than that detected in the supernatants of adult fibroblasts (7.6–18.4 mg l^{-1}; mean 13.2), while fetal fibroblasts appeared to produce much more β_2m than adult fibroblasts (49–68 mg l^{-1}; mean 56).

The synthesis of β_2m and HLA-A, -B and -C antigens was further investigated by labelling the amniotic epithelial cells *in vitro* with ^{35}S-methionine for 4 h. Fibroblasts from adult donors were also labelled and analysed as positive controls. Detergent lysates of these cells were analysed by immunoprecipitation and SDS polyacrylamide gel electrophoresis. Faint bands corresponding to the 43,000 molecular weight HLA-A, -B and -C chain and 12,000 molecular weight β_2m were precipitated from the lysates by antibodies directed against these antigens. None of the antigens was precipitated from the medium in which the cells were grown. Newly synthesized HLA-A, -B and -C chains and β_2m were detected in both extracts and supernatants of adult fibroblasts.

Although it is possible that the few contaminating fetal fibroblasts present in the cultures have contributed to the detection of HLA chains and β_2m by the radiobiological assays, very few fibroblasts were observed in the cultures, and the epithelial cells could be subcultured several times without overgrowth of the fibroblasts.

Amniotic epithelial cells were also strongly reactive with a rabbit antiserum prepared against human amniotic epithelium (Fig. 1)[10]. This antibody reacted with amniotic epithelial cells that had been cultured *in vitro* for several weeks but did not react with fetal skin, adult epithelial cells or fetal fibroblasts.

To establish whether the production of HLA antigens detected by the radiobiological techniques could affect the possible use of these cells in transplantation, seven normal individuals were transplanted subcutaneously with a piece of amniotic epithelial membrane[6]. The results of these experiments will be published in detail elsewhere; briefly, none of the volunteers showed any signs of acute rejection after 6 weeks; four were

Table 1 Lysosomal enzyme activities of human amniotic epithelial cells

Enzyme	Amniotic epithelial cells	Normal fibroblasts	Cells from amniotic fluids	Lysosomal storage disease
α-iduronidase	49; 56	21–72	26–136	Hurler's disease
β-galactosidase	556; 1183	394–1,443	345–885	GM_1-gangliosidosis
α-galactosidase A	33	40–120	30–51	Fabry's disease
β-glucosidase	916	350–1,110	320–1,054	Gaucher's disease
α-glucosidase	138	40–90	11–45	Pompe's disease
Sphingomyelinase	251	227–775	305–602	Niemann–Pick disease
Arylsulphatase A	649; 686	325–2,000	146–600	Metachromatic leucodystrophy

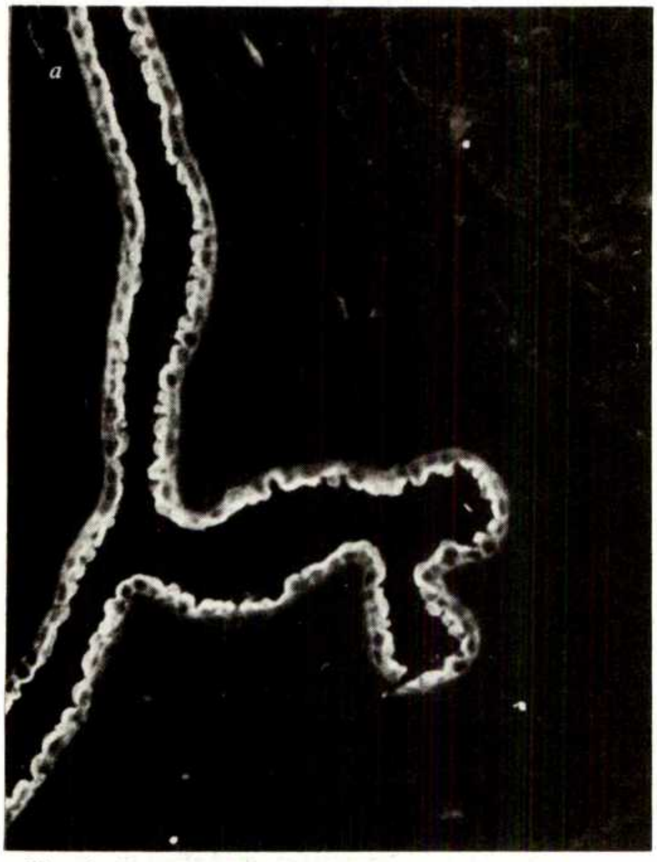
Levels are expressed as nmole per h per mg protein. The values for the different enzymes are reported as ranges or individual levels, and are those obtained in the Paediatric Research Unit, Guy's Hospital Medical School.

studied serologically and found not to produce anti-HLA response. Although the implanted tissues were not left long enough to be certain that they were not chronically rejected, the results suggest that amniotic epithelial cells are not immunogenic and can be transplanted to correct certain enzyme deficiencies.

Evidence that the amniotic epithelial cells produce enzymes deficient in some lysosomal storage diseases was obtained as follows. Human amniotic membranes were collected in sterile conditions from caesarian sections and incubated for 24 h in RPMI 1640 medium. The epithelial cells were isolated by trypsinization with 0.25% (w/v) trypsin (Wellcome) and cultured in RPMI 1640 medium supplemented with 20% fetal calf serum in a humidified incubator containing an atmosphere of 5% CO_2 in air. The cells could be maintained in culture for over 20 weeks and several passages (Fig. 2).

The enzyme estimations were performed simultaneously on the amniotic epithelial cells, fibroblasts from adult individuals and cells collected from amniotic fluids (Table 1). The cultured cells were collected, suspended in 0.01% Triton X-100 and disrupted by sonication. The activities of α-iduronidase, β-galactosidase, α-galactosidase A, α- and β-glucosidase, sphingomyelinase and arylsulphatase A were estimated on the supernatants obtained after centrifugation of the disrupted cells using minor modifications of the methods previously described[11–15]. As shown in Table 1, all the enzymes assayed were detected in the extracts from the cultured cells. The levels of all enzymes tested, expressed as nmol per h per mg protein, were similar to those produced by cultured normal fibroblasts and by the cells obtained from amniotic fluids. Figure 3 shows the rates of $Na_2{}^{35}SO_4$ uptake by fibroblasts from a patient with Hurler's disease grown in inorganic sulphate-free medium (Dulbecco's modified Eagle's medium; Flow Laboratories), with and without amnion culture supernatant from cells grown in similar medium[16], as compared with normal fibroblasts. It is clear that within 1 week the amniotic epithelial cell supernatant was able to correct the abnormal accumulation by the Hurler cells. Similar results were obtained using the fibroblasts from a patient with Hunter's syndrome.

The present results uphold the suggestion that the amniotic epithelial cells may be used for transplantation in patients with selected enzyme deficiencies, as they produce substantial quan-



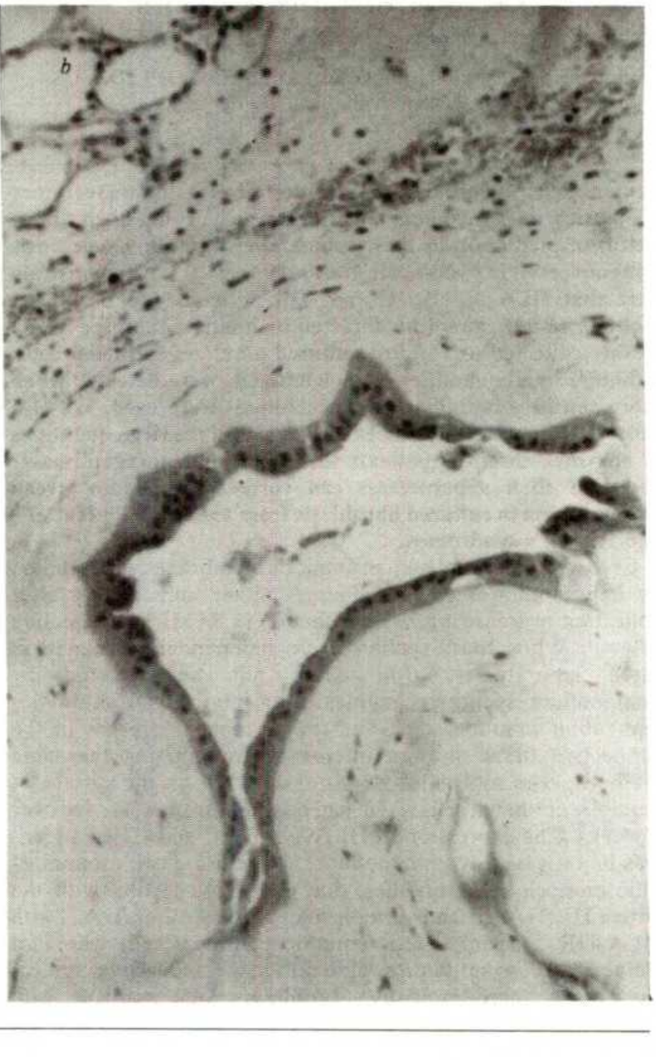


Fig. 1 Human amniotic epithelial cells: *a*, stained by immunofluorescence and a specific rabbit immune serum; the same cells did not stain when monoclonal antisera against HLA antigens or β_2m were used; *b*, in the biopsy taken from a volunteer implanted with cells 32 days previously. There is no evidence of acute rejection.

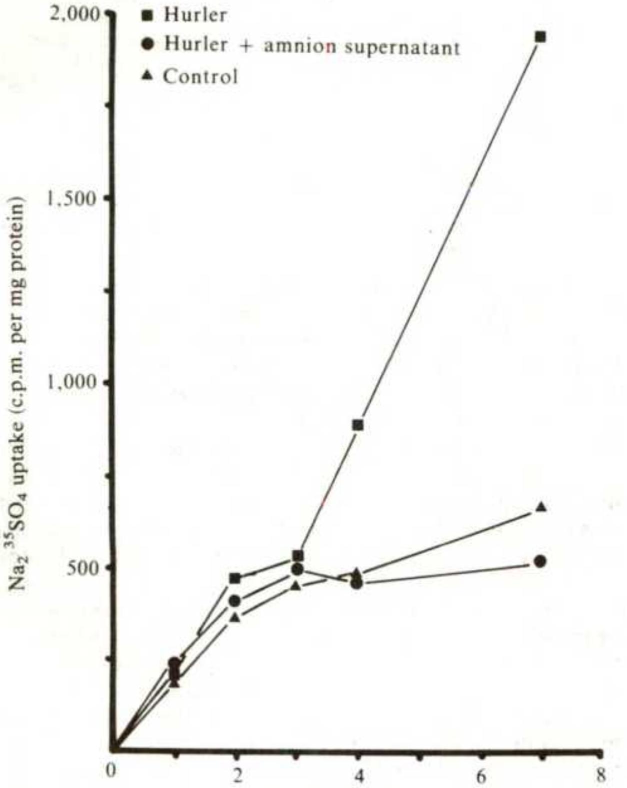

Fig. 3 Rate of Na$_2$^{35}SO$_4$ uptake by fibroblasts. All three groups of cells accumulate label for the first 3 days because of pre-culture in inorganic sulphate-free medium. Subsequently, the Hurler cells (■) continue to accumulate the label, whereas in the presence of amniotic cell supernatant (●) they equilibrate, as do normal fibroblasts (▲).

tities of enzymes lacking in some of the more common enzyme disorders[17]. Work is in progress to see if the cells produce other enzymes, such as adenosine deaminase, of diagnostic and therapeutic value.

The implantation of either sheets of amniotic epithelial cells or cells cultured *in vitro* has many advantages over the use of bone marrow or fibroblast transplants: there should be no risk of graft-versus-host reaction and probably no need to use immunosuppressive therapy with all its attendant complications. Furthermore, the availability of an immune serum which reacts specifically with the amniotic epithelial cells without cross-reacting with fetal or adult skin epithelial cells makes it feasible to identify the transplanted amniotic cells in biopsy material. Another advantage would be that supplies of these cells are readily available from any obstetric unit.

A thorough search of the literature has revealed no evidence of malignant change originating in the amniotic epithelial cells. Whether our suggestion is valid, and whether these cells may be used for transplantation following further genetic engineering remains to be proved by transplanting these cells into patients with selected inborn errors of metabolism.

We thank Dr Michael Joseph for useful discussions and Miss Carolyn Beech for her patience in the preparation of the manuscript.

Leukotriene C$_4$ affects pulmonary and cardiovascular dynamics in monkey

**Göran Smedegård*†, Per Hedqvist‡,

Leukotriene C$_4$ (LTC$_4$) and its metabolites LTD$_4$ and LTE$_4$ (Fig. 1) have been identified as the major active constituents of slow-reacting substance of anaphylaxis (SRS-A)[1–3]. Leukotrienes C$_4$, D$_4$ and E$_4$ have rapidly gained recognition as bronchoconstrictors of hitherto unsurpassed potency in the guinea pig *in vivo* and *in vitro*[4–7] as well as acting as oedema-forming substances in guinea pig[3,5,7] and hamster[8]. Here we report that LTC$_4$ is also a prominent bronchoconstrictor in the monkey; it increases transpulmonary pressure in the anaesthetized animal, mainly by decreasing pulmonary dynamic compliance, and it contracts isolated tracheal spiral tissue. Furthermore, LTC$_4$ causes transient pulmonary and systemic hypertension, followed by a prolonged hypotensive period associated with decreased cardiac output, haemoconcentration and reduction in the number of circulating leukocytes. These *in vivo* findings in a primate imply that leukotrienes may also cause important alterations of cardiovascular and pulmonary function in man.

Male monkeys (*Macaca irus*) weighing 2.8–3.2 kg were anaesthetized with ketamine HCl, and ventilated artificially through a tracheostomy. Pressure-monitoring catheters were inserted in the aorta, pulmonary artery and right and left atrium, as described elsewhere[9]. Transpulmonary pressure was measured as the difference between tracheal and intrapleural pressures. Pulmonary dynamic compliance and pulmonary resistance were calculated from simultaneous recordings of tracheal air flow, tidal volume and transpulmonary pressure[10].

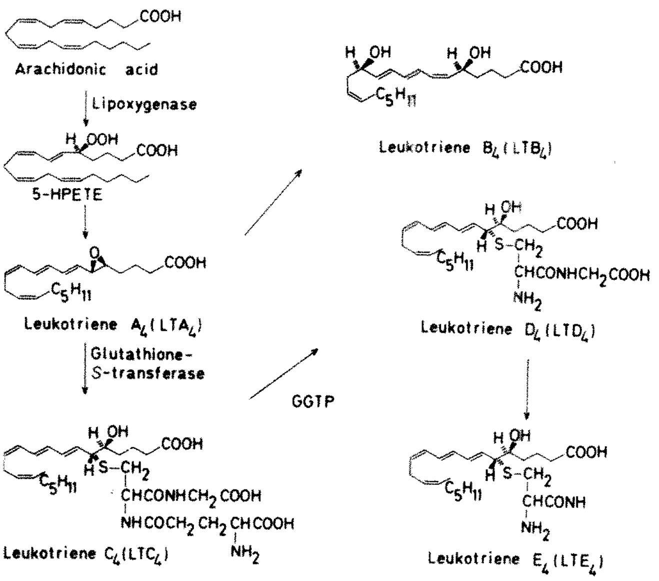

Fig. 1 Leukotrienes biosynthesized from arachidonic acid via an initial lipoxygenase-catalysed formation of 5(*S*)-hydroperoxy-7,9,11,14-eicosatetraenoic acid (5-HPETE). 5-HPETE is transformed into an unstable epoxide intermediate, leukotriene A_4 (5,6-oxido-7,9,11,14-eicosatetraenoic acid, LTA_4), which has the characteristic conjugated triene structure present in all leukotrienes. LTA_4 may form the leukotactic principle leukotriene B_4 (5(*S*),12(*R*)-dihydroxy-6-*cis*-8,10-*trans*,14-*cis*-eicosatetraenoic acid, LTB_4). Addition of glutathione yields the primary SRS-A, LTC_4 (5(*S*)-hydroxy-6(*R*)-*S*-glutathionyl-7,9-*trans*,11,14-*cis*-eicosatetraenoic acid). Successive enzymatic removal of glutamic acid by γ-glutamyl transpeptidase and glycine by a dipeptidase, converts LTC_4 into LTD_4 (5(*S*)-hydroxy-6(*R*)-*S*-cystenylglycyl-7,9-*trans*,11,14-*cis*-eicosatetraenoic acid), and LTE_4 (5(*S*)-hydroxy-6(*R*)-*S*-cysteinyl-7,9-*trans*,11,14-*cis*-eicosatetraenoic acid), respectively. (For details of biosynthesis and nomenclature, see refs 1, 2.)

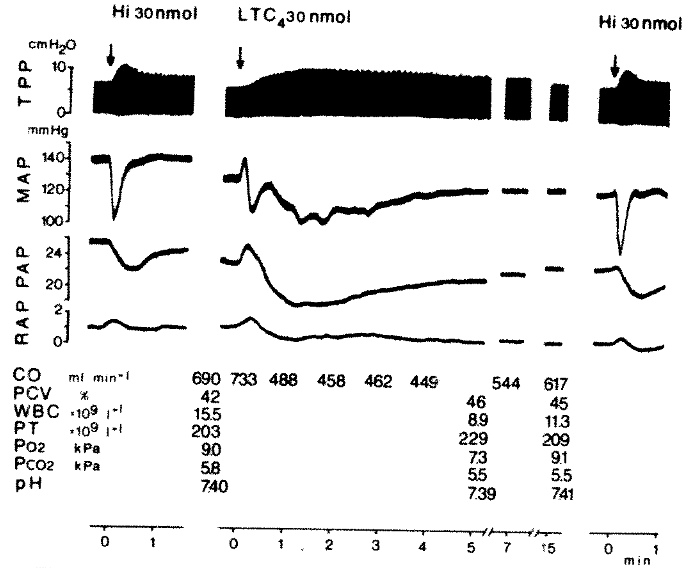

Fig. 2 Effects of systemic administration (injection through catheter placed in right atrium) of histamine (Hi) and LTC_4 in the artificially ventilated monkey. TPP, transpulmonary pressure; MAP, mean systemic arterial pressure; PAP, pulmonary arterial pressure; RAP, right atrial pressure. Cardiac output (CO) was determined by the thermodilution technique. Blood samples for analysis of haematocrit (PCV), white blood cell count (WBC), platelets (PT) and arterial P_{O_2}, P_{CO_2} and pH were drawn before and 5 and 15 min after injection of LTC_4.

Injection of biosynthetically generated[11] LTC_4 (0.5–30 nmol) into the right atrium caused a prompt and transient rise in mean arterial pressure (MAP), followed by a long-lasting hypotensive period (Fig. 2). Pulmonary arterial (PAP), right atrial (RAP) and left atrial (LAP, not shown in figure) pressures were similarly affected. The initial pressor response apparently reflects increased resistance in both the pulmonary and systemic vascular beds, in agreement with the vasocontrictor effects of LTC_4 in the guinea pig[5,7] and its arteriolar constriction in the hamster cheek pouch[8]. The subsequent sustained hypotension does not seem to be the result of changes in vascular calibre, because calculated total peripheral resistance increased during this period; for example, in the experiment shown in Fig. 2 the increase was 25 and 45% at 2 and 4 min respectively. Rather, LTC_4 seems to affect cardiac dynamics, as cardiac output was markedly decreased during the hypotension (in Fig. 2 by 35% at 2 and 4 min), concomitant with little or no change in heart rate. The reduction of cardiac output may be due to a negative inotropic effect of LTC_4 (refs 12, 13), possibly in conjunction with a decrease in plasma volume secondary to increased vascular permeability, as documented in other species[3–5,8]. Plasma leakage induced by LTC_4 could explain the haemoconcentration, which was indicated in the present experiment by a rise in haematocrit. Furthermore, the observed reduction of RAP and LAP after LTC_4 could also be consistent with a peripheral contribution to the decline in cardiac output.

Table 1 Effect of LTC_4 aerosol on transpulmonary pressure in the anaesthetized monkey

Animal	LTC_4 dose (nmol)	Response (% increase)	Equipotent dose of histamine* (nmol)	Ratio equipotent doses (dose histamine/dose LTC_4)
1	2	31	63	31.5
2	10	92	1,490	149
3	10	53	562	56.2
4	20	163	1,480	74.0
		Mean ratio (±s.e.m.) histamine/LTC_4:		77.8±25.3

* Calculated from dose–response relationships established for aerosolized histamine in the same experiment.

Compared with LTC_4, histamine (5–100 nmol, Sigma, injected into the right atrium) had short-lived cardiovascular effects related to its well known vasodilatory properties. Mean systemic and pulmonary arterial pressures were transiently decreased, while heart rate was simultaneously increased, presumably by reflex activation (Fig. 2).

Interestingly, injection of LTC_4 caused a marked but reversible drop in white blood cell count, while platelet count was unaffected (Fig. 2). The reason for this decrease is unclear, but it is possible that LTC_4 induces leukocyte trapping in various microvascular beds, as has recently been reported for leukotriene B_4 (LTB_4) in the hamster cheek pouch[8]. Accordingly, when LTB_4 (6 nmol) was injected systemically into one monkey, white blood cell count decreased from 14.5 to 5.0 × 10^9 per l in 5 min, and had returned to 15.5 × 10^9 per l 30 min later.

Leukotriene C_4 and histamine, when injected into the right atrium, increased transpulmonary pressure. They were virtually equipotent in this respect (Fig. 2), although the time course for their actions differed: the histamine effect peaked after 10–15 s and terminated within 1 min, whereas LTC_4 elicited maximal increase in transpulmonary pressure only after 2 min. The response to LTC_4 then remained at this level for several more minutes before it slowly subsided.

When LTC_4 and histamine were administered as aerosols, both effectively increased transpulmonary pressure (Fig. 3). However, the ratios of doses required to elicit responses of equal magnitude revealed that by this route of administration LTC_4

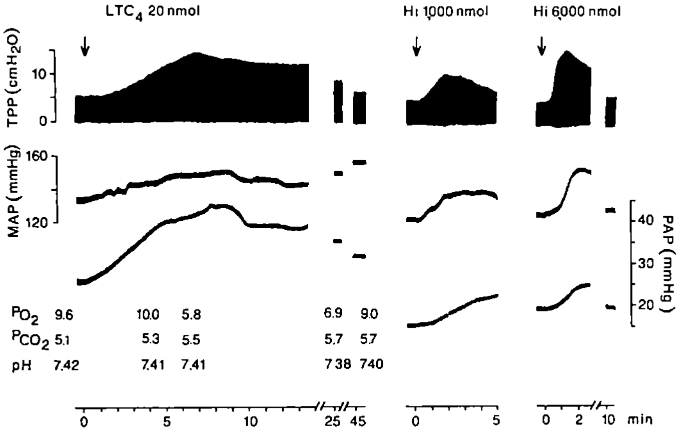

Fig. 3 Effects of aerosol administration (solution containing indicated amounts of substances nebulized into inspired air) of histamine (Hi) and LTC$_4$ in the artificially ventilated anaesthetized monkey. TPP, transpulmonary pressure; MAP, mean systemic arterial pressure; PAP, pulmonary arterial pressure. P_{O_2}, P_{CO_2} and *p*H were determined in arterial blood samples before, and 4, 7, 25 and 45 min after nebulization of LTC$_4$.

was ~100 times more potent than histamine (Table 1). In contrast, LTC$_4$ and histamine were equipotent when injected. This may be at least partly due to LTC$_4$ being rapidly metabolized and eliminated from the circulation, as was recently observed when ^{3}H-LTC$_3$ was injected systemically in monkeys in identical conditions[14]. On the other hand, nebulized LTC$_4$ might be inactivated at a considerably slower rate, as indicated from experiments where ^{3}H-LTC$_3$ was incubated with lung tissue *in vitro*[15,16].

The airway reaction to nebulized LTC$_4$ and histamine differed markedly in several important respects. Histamine caused a reversible increase of transpulmonary pressure, lasting for less than 10 min (Fig. 3), and reflected only by minor transient changes in PAP and arterial P_{O_2}. On the other hand, LTC$_4$ aerosols evoked long-lasting changes of pulmonary function (see Fig. 3). When the response to LTC$_4$ was maximal in this experiment, transpulmonary pressure had increased by 163%, while arterial P_{O_2} had decreased from 9.6 to 5.8 kPa. The hypoxaemia was accompanied by a severe pulmonary hypertension, PAP increasing by almost 100%. Induced changes of transpulmonary pressure, PAP and P_{O_2} only slowly returned to normal values over 45 min, even though the animals were subjected to positive end expiratory pressure to combat the formation of atelectases. Finally, the increase in transpulmonary pressure induced by nebulized as well as injected LTC$_4$ was mainly caused by a reduction of pulmonary dynamic compliance, whereas pulmonary resistance was only slightly affected. Histamine, on the other hand, had relatively little effect on compliance, but caused a marked rise in resistance. This observation is compatible with the view that LTC$_4$ affects peripheral airways, as previously suggested for crude SRS-A[17].

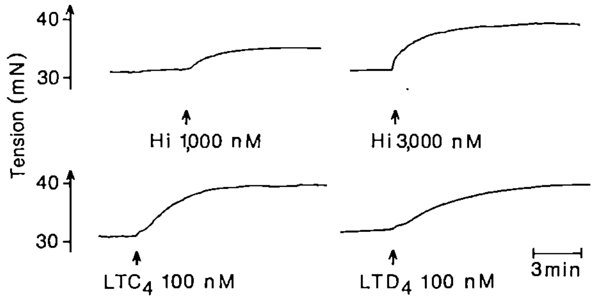

Fig. 4 Isometric recordings of basal tone and contraction responses to histamine (Hi), LTC$_4$ and LTD$_4$ in isolated helical strips of monkey trachea. Drugs were added at arrows to the indicated final concentration in a Tyrode-containing organ bath, and washed away when bath fluid was changed (end of tracing).

The view that LTC$_4$ is a bronchoconstrictor in the monkey gains further support from experiments with isolated tracheal strips. Leukotriene C$_4$ and its immediate metabolite LTD$_4$ potently contracted the monkey trachea (Fig. 4). Note that this species was less reactive to leukotrienes, as well as to histamine, than are corresponding preparations from guinea pig and man[16,18,19]. Nevertheless, the leukotrienes were ~100 times as potent as histamine.

The finding that LTC$_4$ elicits pronounced cardiovascular and bronchial reactions in the monkey *in vivo*, and that systemic injection of LTC$_4$ is accompanied by a reversible drop in circulating leukocytes suggests that these effects are also applicable in man, especially as leukotrienes are active in isolated human tissues[19,20]. Endogenous leukotrienes may contribute to the symptoms of bronchial asthma in man; and the pharmacological actions[7,16] exerted by these substances suggest leukotriene involvement in a number of other hypersensitivity states, as well as in the inflammatory reaction.

We thank Ms G Fredrickson for technical assistance, Mr R. Bentin for animal care and Ms A Lindbom for secretarial help. Lack of immune response gene control for induction of epitope-specific suppression by TGAL antigen

Leonore A. Herzenberg, Takeshi Tokuhisa*, Kyoko Hayakawa & Leonard A. Herzenberg

Department of Genetics, Stanford University School of Medicine, Stanford, California 94305, USA

Immune response genes in the *I* region of the mouse major histocompatibility complex (MHC) have been divided operationally according to whether they control responses to antigens which do or do not induce active suppression in non-responder animals (IS and IR genes respectively)[1,2]. Studies presented here, however, show that the synthetic terpolymer poly-L-(tyrosine, glutamic acid)-poly-DL-alanine-poly-L-lysine

0028-0836/82/040329—03$01.00

Table 1 C3H (Ir-1a) mice are 'non-responders' to TGAL

Strain	TGAL immunizations*		Anti-TGAL response (normalized)* IgM	IgG1	IgG2a	IgG3
C3H	Primary	TGAL	18	2	<3	5
	Primary	TNP–TGAL	7	1	<3	2
	Secondary	TNP–TGAL, TNP–TGAL	7	1	<3	2
C3H.SW	Primary	TGAL	100	100	100	100
	Primary	TNP–TGAL	93	113	65	102
	Secondary	TNP–TGAL, TNP–TGAL	51	319	74	115
	Secondary	TGAL/TNP–TGAL	40	409	85	116

Responses measured by radioimmunoassay (RIA)[20,21] 2 weeks after the last indicated immunization are reported relative to the anti-TGAL primary response of each isotype obtained in C3H.SW mice.

* See Table 4 legend for antigen dosage and immunization schedule.

(TGAL)[3,4], commonly considered the prototype of antigens which do not induce suppression, actually serves as a potent inducer of epitope-specific suppression for antibody responses in non-responder mice.

The induction of epitope-specific suppression is a general (albeit recently recognized) immunoregulatory process readily demonstrable by sequential immunizations with carrier proteins and hapten–carrier conjugates[5–7]. Primary immunization with a carrier protein induces the delayed appearance of carrier-specific suppressor T cells (CTS)[8,9] which persist and induce specific suppression for IgG antibody responses to 'new' epitopes presented subsequently on the priming carrier. The 'epitope-specific' mechanism responsible for this suppression also persists (once induced) and continues to suppress antibody responses to the 'new' epitope, whether presented subsequently on the priming carrier or on a second, unrelated carrier molecule. (We have previously referred to this system as hapten specific, using the term 'hapten' in its more general sense (synonymous with epitope) to indicate a relatively small structure which induces antibody production when presented on a larger (carrier) molecule. The term 'hapten', however, is also commonly used to distinguish artificially added structures, such as the dinitrophenyl group (DNP), from the native epitopes on a carrier molecule (antigen). Therefore, to avoid ambiguity, we have now substituted the term 'epitope-specific' for the previous nomenclature.)

For example, priming with keyhole limpet haemocyanin (KLH) and subsequent immunization with the DNP–KLH (dinitrophenyl hapten conjugated to KLH) induces specific suppression for IgG anti-DNP antibody production[5–9]. This KLH/DNP–KLH-induced suppression then serves with equal effectiveness to prevent antibody responses to DNP presented either on KLH or on chicken γ-globulin (CGG). It does not, however, interfere with antibody production to either carrier molecule.

Table 2 Anti-TNP responses to TNP–TGAL are suppressed in C3H.SW ('responder') mice preimmunized with TGAL and fail entirely in C3H ('non-responder') mice

Strain	Immunization(s)*	Anti-TNP response IgM (U)	IgG1 (μg ml^{-1})	Ig2a (μg ml^{-1})	IgG3 (U)
C3H	TNP–TGAL	144	<3	<1	10
	TNP–TGAL/ TNP–TGAL	191	<15	<3	11
	TGAL/TNP–TGAL	106	<3	<1	8
C3H.SW	TNP–TGAL	125	35	13	63
	TNP–TGAL/ TNP–TGAL	86	95	16	76
	TGAL/TNP–TGAL	96	<3	<9	12

Anti-TNP responses were measured by RIA 2 weeks after last indicated immunization. IgG1 and IgG2a responses are presented as μg antibody per ml serum; IgG3 and IgM responses as percentage of response obtained in an adoptive secondary 'standard' antiserum.

* See Table 4 legend for antigen dosage and immunization schedule.

Reversing the carriers in the immunization sequence yields similar results, that is, CGG/DNP–CGG-induced suppression also prevents subsequent anti-DNP responses to either DNP–KLH or DNP–CGG. Mismatching carriers (such as KLH/DNP–CGG immunization) results, however, in anti-DNP antibody production rather than suppression (ref. 6 and L.A.H. and T.T., in preparation). Thus epitope-specific suppression is induced by carrier-specific interactions but is mediated by an effector mechanism that operates without reference to the carrier on which a hapten (epitope) is presented.

Further selectivity displayed by this effector mechanism generates a characteristic anti-DNP response pattern in suppressed animals: high-affinity anti-DNP antibody production is preferentially suppressed; IgM anti-DNP responses are unaffected; IgG1 responses are usually suppressed initially and generally 'escape' suppression after a second or third stimulation with DNP; and the remaining IgG isotypes (IgG2a, IgG2b, IgG3) are universally suppressed at first and generally require three or four sequential stimulations with DNP to induce substantial escape from suppression (ref. 6 and L.A.H. and T.T., in preparation). Therefore, epitope-specific suppression is recognizable by both its specificity for the inducing hapten and its differential effects on the various immunoglobulin isotype responses produced to that hapten.

Table 3 TGAL/TNP–TGAL immunization induces persistent epitope-specific suppression for IgG anti-TNP antibody production in C3H ('non-responder') mice

Strain	Pre-immunization*	Serum IgG2a anti-TNP (μg ml^{-1}) Subsequent immunizations* (first) TNP–KLH	(second) TNP–KLH	(third) TNP–CGG
C3H	None	35 (2)	68 (60)	85 (40)
	TNP–TGAL	28 (7)	82 (60)	70 (30)
	TGAL/TNP–TGAL	<3	9 (<1)	16 (6)
C3H.SW	None	24 (7)	110 (50)	150 (50)
	TNP–TGAL	250 (140)	370 (220)	160 (50)
	TGAL/TNP–TGAL	14 (<1)	180 (70)	160 (50)

Anti-TNP levels in serum were measured by RIA[20,21] 2 weeks after each indicated immunization. Relative affinity (shown in parentheses) is calculated from ratios of antibody bound to differently substituted TNP conjugates (TNP7–BSA/TNP24–BSA) based on a standard curve developed for absolute measurements of anti-DNP binding affinities (K_a)[21].

* Antibody responses to TGAL and TNP–TGAL in these animals are shown in Tables 1 and 2 respectively. See Table 4 legend for antigen dosage and immunization schedule.

We have now used similar immunization sequences and response criteria in MHC congenic mice to investigate the influence of IR genes on epitope-specific suppression induction by TGAL. The C3H (Ir-1a) mice used are typically 'non-responsive' to the TGAL antigen[3,4] in that they produce no detectable IgG anti-TGAL responses and only a small IgM anti-TGAL response, even when stimulated twice with 100 μg TGAL on alum. The congenic C3H.SW (Ir-1b) mice, in contrast, produce both IgM and IgG anti-TGAL primary antibody responses and show a strong IgG secondary response to this antigen (see Table 1). Similarly, C3H mice do not produce detectable amounts of IgG antibody to the trinitrophenyl (TNP) hapten presented on TGAL whereas C3H.SW mice stimulated with TNP–TGAL produce typical primary and secondary anti-TNP responses (see Table 2).

Surprisingly, this classical difference in responsiveness to TGAL disappears when response is measured in terms of epitope-specific suppression induction by TGAL/TNP–TGAL immunization. Both the 'non-responder' and 'responder' mice respond strongly to this immunization sequence by developing a persistent suppression for IgG antibody production to TNP (see Tables 3 and 4). In fact, the 'non-responder' strain (C3H) responds even more vigorously than the 'responder' in that its

Table 4 Epitope-specific suppression in C3H mice shows typical isotype selectivity

Strain	Immunizations				% Of control anti-TNP response* IgM	IgG1	IgG2a	IgG3

	TGAL	TNP–TGAL	TNP–KLH	TNP–CGG	53	200	23	10
C3H.SW	TGAL	TNP–TGAL	TNP–KLH		120	16	6	50
	TGAL	TNP–TGAL	TNP–KLH	TNP–KLH	94	100	47	20
	TGAL	TNP–TGAL	TNP–KLH	TNP–CGG	44	70	100	13

Immunizations of 100 μg each antigen were given intraperitoneally on alum at 0, 5, 7, 10 and 14 weeks respectively.

* Serum anti-TNP levels were measured by RIA[20,21] 2 weeks after last indicated immunization. Data are presented as the percentage of the anti-TNP response obtained in corresponding control groups immunized initially with TNP–TGAL (once) rather than with the TGAL/TNP–TGAL sequence. Absolute control responses for IgG2a are shown in Table 3.

IgG2a and IgG3 anti-TNP responses generally remain suppressed following repeated stimulation with TNP (on CGG and KLH) whereas these isotype responses escape suppression in typical fashion in the 'responder' (C3H.SW) strain (see Table 4). Thus 'non-responder' animals clearly recognize TGAL in an immunological context and can use this antigen as a carrier for presenting haptens to initiate the induction of epitope-specific suppression.

These findings suggest that TGAL is capable of generating functional carrier (TGAL)-specific suppressor T cells which induce epitope-specific suppression for TNP on TGAL (as KLH-specific suppressor T cells initiate the induction of epitope-specific suppression in KLH-primed mice)[8,9]. Thus although the IR gene controlling responses to TGAL largely prevents TGAL-dependent stimulation of T-cell proliferation and IgG antibody production, it does not seem to interfere with the full set of (TGAL-dependent) T-cell interactions involved in the development of carrier-specific suppressor T cells[10–15].

Therefore, in addition to demonstrating that both IR and IS genes permit suppression induction, our results indicate that certain TGAL-specific T-cell pathways (not readily demonstrable by T-cell proliferation assays) remain intact in 'non-responder' mice, thereby suggesting several possible roles for the apparently functionless TGAL-specific T-cell clones recently isolated from 'non-responder' mice[16].

Finally, the unhampered induction of epitope-specific suppression in 'non-responder' mice suggests that the epitope-specific system may provide a versatile effector mechanism which permits *I*-region genes to exert a selective, long-term influence on the magnitude and heterogeneity of antibody responses. This would explain how certain of these genes can modify the composition of antibody responses to epitopes on antigens that induce some antibody production in 'non-responder' animals[17,18]. The restricted heterogeneity of these antibody responses, the tendency towards production of IgG1 rather than IgG2a antibodies and the apparent involvement of suppressor T cells in the regulatory process clearly point to epitope-specific regulation. Thus we suspect that diagnostic sequential immunization protocols similar to those used here would reveal the induction of epitope-specific suppression in these partially responsive mice.

TGAL and TNP–TGAL, unlike the antigens discussed above, do not induce substantial IgG antibody production in non-responder mice (see Tables 1, 2). Furthermore, a single initial immunization with TNP–TGAL does not appear to affect subsequent anti-TNP responses to TNP on other carriers (see Table 3). At face value, therefore, the evidence presented here suggests that epitope-specific suppression induction by antigens like TNP–TGAL requires prior TGAL priming (or perhaps two sequential immunizations with the TNP–TGAL conjugate). However, should TNP–TGAL immunization prove to induce B-cell memory for TNP in 'non-responders' (work in progress), this conclusion would have to be modified since the presence of such memory B cells in TNP–TGAL-primed animals would indicate that the primary level anti-TNP response observed to TNP–KLH in these animals actually represents the weak suppression of a potential secondary anti-TNP response.

That the epitope-specific regulatory system may serve to maintain antibody response characteristics dictated initially by *I*-region-defined mechanisms is consistent with evidence from studies showing that this system maintains suppression for responses prevented initially by the allotype suppression mechanism[19] and mediates suppression initiated by carrier-specific suppressor T-cell interactions[8,9]. These data suggest that the epitope-specific system provides a common effector mechanism through which non-responsiveness, whatever its genesis, can be maintained.

Furthermore, because the epitope-specific system suppresses responses to individual epitopes regardless of the carrier on which the epitope is subsequently presented, it offers a general mechanism through which undesirable antibody responses (such as to self) can be controlled should an epitope to which non-responsiveness has been induced be encountered later on an immunogenic carrier. Thus this previously unrecognized regulatory system introduces a novel immunological memory mechanism capable of being 'educated' selectively to suppress antibody production to individual epitopes according to conditions in the regulatory environment when the epitope is first introduced.

We thank Dr A. Singer for preparing the TNP–TGAL hapten–carrier conjugate and for supplying both conjugated and 'native' TGAL. We also thank Mr Timothy Gadus for technical assistance. This work was supported in part by NIH grants HD-01287 and AI-08917.

Rapid lateral diffusion of functional ACh receptors in embryonic muscle cell membrane

Mu-ming Poo

Department of Physiology and Biophysics, University of California, Irvine, California 92717, USA

During synaptogenesis of the skeletal neuromuscular junction, the acetylcholine (ACh) receptors dispersed over the surface of the embryonic muscle become highly concentrated at the subsynaptic membrane[1,2]. The mechanism by which a nerve induces such a modulation of ACh receptor topography is unknown. Of various possibilities[3], the simplest explanation is that the ACh receptors, freely diffusing in the plane of the muscle membrane, are trapped at the site of nerve contact[4,5]. This 'diffusion-trap' mechanism is plausible only if the diffusion distance covered by the ACh receptors within its lifetime on the cell surface is at least comparable with the dimension of the embryonic muscle fibre (see also discussion in ref. 1). Photobleaching studies had suggested that this was not the case. In the present study, an electrophysiological method was used to measure the lateral diffusion of the dispersed, functional ACh receptors in the plasma membrane of cultured *Xenopus* embryonic muscle cells. The results suggest that these ACh receptors undergo rapid lateral diffusion with a diffusion coefficient of 2.6×10^{-9} cm^2 s^{-1} at 22 °C. This rapid diffusion of the dispersed ACh receptors strongly supports a passive diffusion-trap mechanism for the localization of ACh receptors at the site of nerve–muscle contact.

The experimental strategy used in this study was to inactivate ACh receptors locally on the muscle surface using α-bungarotoxin (α-BTX), a snake toxin that binds irreversibly to the ACh receptor. The recovery of ACh sensitivity at the site of inactivation was mapped by an iontophoretic method[6] to reveal the lateral diffusion of the functional, toxin-free ACh receptors in the membrane. In the first series of experiments using a spindle-shaped muscle cell, ACh sensitivity was monitored continuously by intracellular recording of the membrane depolarizations following repetitive ejection of constant ACh pulses from an iontophoretic pipette. Local inactivation of ACh receptors was achieved by applying a small pulse of α-BTX (50 μg ml^{-1}) through a micropipette, the tip of which was positioned within 1 μm of the site of iontophoretic mapping (Fig. 1*a*). As shown in Fig. 1*b–d*, the local pulse-inactivation resulted in a rapid drop in ACh sensitivity, followed by a return of sensitivity to the original level with a time course of the order of minutes. Recovery of ACh sensitivity was observed in 15 out of 19 cells successfully studied. However, the rate as well as the extent of the recovery varied considerably: the greater the extent (or the wider the spread) of inactivation, the slower and less complete was the recovery.

The return of ACh sensitivity was not due to functional recovery of the inactivated receptors or insertion of newly synthesized receptors into the membrane, as (1) it is known that α-BTX binding to the ACh receptors is irreversible in the time scale of these experiments, and (2) no detectable recovery of ACh sensitivity was observed within 10 h when these cells were inactivated uniformly by bathing them with α-BTX and then extensively washing them with fresh saline. It was not the result of some unknown effect of local pressure application during the pulse-inactivation, as the same local pressure applied through a saline-filled pipette had no effect on the ACh sensitivity. Finally, this recovery of ACh sensitivity was blocked by preincubation of the cells with saline containing concanavalin A (Con A) (100 μg ml^{-1}; Sigma) for 8 min before inactivation experiments (for all 10 cells studied in two separate cultures). Con A, a tetrameric lectin that binds specifically to α-D-glucose or α-D-mannose residues of the cell surface carbohydrates, binds and immobilizes ACh receptors[7–9]. Taken together, these findings strongly suggest that the recovery of ACh sensitivity after local

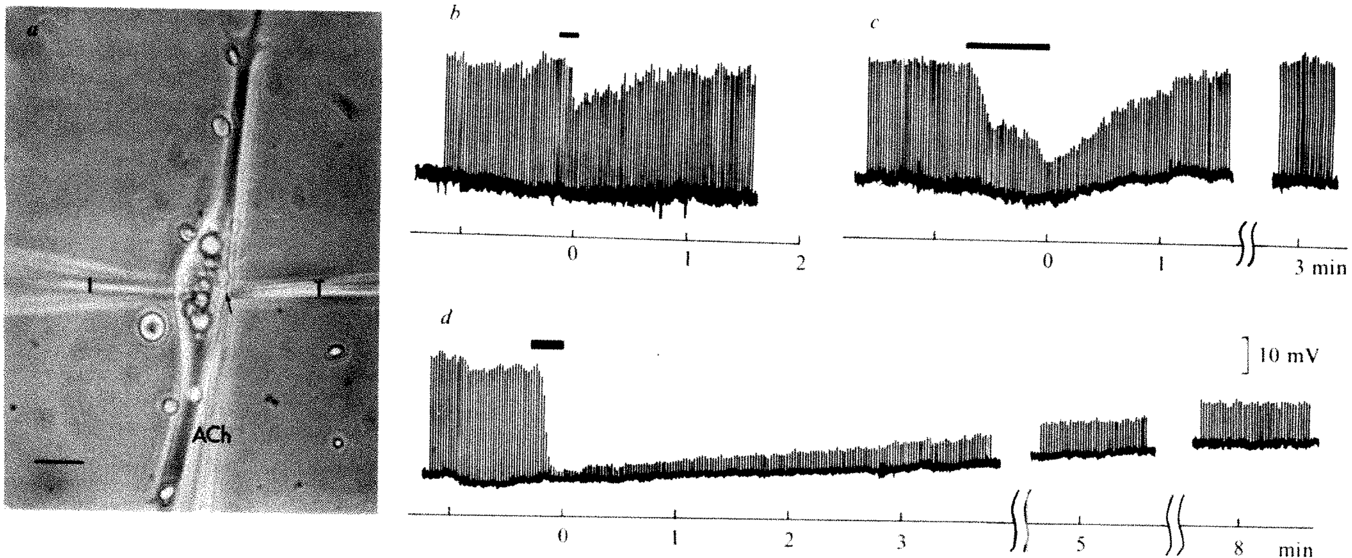

Fig. 1 Recovery of ACh sensitivity after local irreversible inactivation of ACh receptors. Spindle-shaped embryonic *Xenopus* muscle cells in $1\frac{1}{2}$-day-old cultures were used in these experiments (for culture methods, see ref. 8). ACh sensitivity at a local spot on the muscle surface was monitored by an iontophoretic method[6]. Intracellular recordings were made using a glass microelectrode filled with 3 M potassium acetate (resistance 80–150 MΩ). Microelectrodes (resistance 200–350 MΩ) for iontophoretic application of ACh were filled with 3 M acetylcholine chloride (Sigma) and required braking currents of 1.0–2.0 nA to prevent ACh leakage from the pipette and depolarization of the cells. Constant iontophoretic current pulses of amplitude 5–10 nA and 1 ms duration were delivered through a microelectrode preamplifier (Getting) to the ACh pipette near the cell surface. A third glass micropipette having a tip opening of ~2 μm was filled with α-BTX (50 μg ml^{-1}) and positioned near the iontophoretic pipette. A small negative (sucking) pressure was applied using a micrometer-controlled syringe during the positioning of the pipette, and after the local inactivation. Local inactivation of the ACh receptor was achieved by applying a positive pressure through the toxin pipette. *a*, Phase-contrast micrograph showing representative morphology of spindle-shaped *Xenopus* muscle cells, together with the positioning of the pipettes for intracellular recording (I), iontophoresis (ACh) and toxin application (T). Scale bar 20 μm. *b–d*, Continuous d.c. recording of membrane potentials and ACh-induced potentials of three different myotomal cells during the local-inactivation experiments. Solid bars indicate the duration of positive-pressure application through the toxin pipette. The constant amplitudes of membrane depolarizations resulting from constant ACh current pulses before toxin application suggest that no desensitization of the ACh receptor occurred at the frequency of stimulation (~1 Hz) used in these experiments. The rate and extent of recovery of ACh-induced response was reduced from *c* to *d*, as more ACh receptors were inactivated by the toxin. At the start of recording, the membrane potentials of the cells were 96, 92 and 105 mV for the cells in *b*, *c* and *d*, respectively.

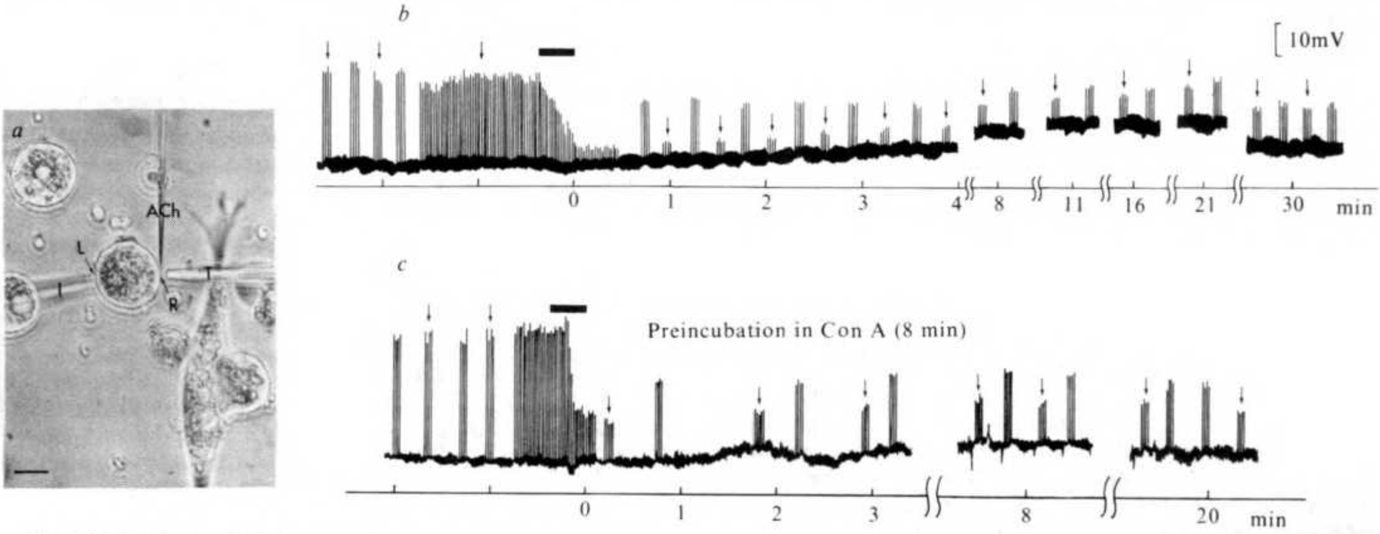

Fig. 2 Redistribution of ACh sensitivity after asymmetric inactivation of ACh receptors on two sides of spherical-shaped *Xenopus* muscle cells in $1\frac{1}{2}$-day-old culture. The electrophysiological method used was the same as that described in Fig. 1 legend, except that the toxin pipette was positioned 2–4 μm away from the cell surface, and the ACh sensitivity was monitored alternately at two opposite poles of the cell, where maximum (R) and minimum (L) inactivation was produced. *a*, Phase-contrast micrograph of a representative spherical muscle cell, showing the positions of the pipettes used for intracellular recording (I), ionotophoresis (ACh) and toxin application (T). Scale bar 20 μm. *b*, Alternating recordings of membrane depolarization responses for ACh ejected at two opposite poles of the spherical muscle cell in a typical experiment. Before preferential inactivation, the responses were almost identical. After pulse-inactivation with α-BTX, the right side (arrow) of the cell was much less sensitive to ACh than the left side (without arrow). This sensitivity asymmetry decayed with time over ~30 min after pulse-inactivation. Solid bar represents the duration of positive-pressure application through the toxin pipette. The membrane potential at the start of recording was 102 mV, and it varied by <15 mV during the 30-min period. Note the concurrent drop in ACh sensitivity on the left side as that of the right side increased. *c*, Typical recording of preferential inactivation experiments on cells pretreated with Con A. Note the absence of any significant redistribution of ACh sensitivity over a period of 20 min after asymmetric receptor inactivation.

pulse-inactivation represents a redistribution of pre-existing functional ACh receptors in the plane of the plasma membrane.

In the experiments described above, it was difficult to estimate quantitatively the diffusion coefficient of the ACh receptors from the rate of sensitivity recovery, as the extent and pattern of inactivation varied from cell to cell. To resolve this, spherical-shaped *Xenopus* muscle cells (Fig. 2*a*) were used in a second series of experiments, in which an asymmetric inactivation of the ACh receptors was produced across the entire surface of the cell. The redistribution of functional ACh receptors across the cells was then monitored by repetitive comparison of ACh sensitivity on the two sides of the cell. The diffusion coefficient of the receptors was estimated from the rate of decay of the sensitivity asymmetry, which, for a first-order approximation, is determined entirely by the size of the cell[10]. Representative results are shown in Fig. 2*b*. Depolarizations of the muscle membrane in response to identical pulses of ACh ejected at two opposite poles of the cells were monitored alternately. As seen in the initial few measurements in Fig. 2*b*, almost identical ACh sensitivity was detected on the opposite sides of the cell. A pipette containing α-BTX was then positioned ~2–4 μm from one side of the cell and used to pulse-inactivate the ACh receptors on the muscle surface, resulting in asymmetric ACh sensitivity on the two sides of the cell. Subsequent comparison of ACh-induced responses on the two sides of the cell indicated that the sensitivity asymmetry decayed with time, suggesting a redistribution of the functional ACh receptors across the cell surface.

The redistribution of ACh sensitivity was determined quantitatively by plotting sensitivity asymmetry index against time after asymmetric inactivation. The asymmetry index (A) is defined by $A=(V_A-V_B)/(V_A+V_B)$, where V_A and V_B are average peak amplitudes of membrane depolarization induced by identical iontophoretic ACh pulses on the minimally and maximally inactivated sides of the cell, respectively. The use of peak amplitude of ACh potential as a simple representation of ACh sensitivity in this formula was considered satisfactory, as these indices differed by <5% (average of three comparisons) from those calculated using ACh sensitivity determined by the conventional method in terms of mV/nC (see for example, ref. 5). Assuming the surface concentration of ACh receptors to be linearly proportional to the ACh sensitivity, the rate of decay of the asymmetry indices can be used to calculate the diffusion coefficient of the ACh receptors in the membrane. Previous analyses of the diffusion process on the surface of a spherical cell[9–11] indicated that the diffusion coefficient (D) of the diffusing molecule is related to the radius (r_o) of the cell by $D=r_o^2/2t_d$, where t_d is the characteristic $1/e$ decay time of the asymmetry in the surface distribution. In a $1\frac{1}{2}$-day-old culture, the average diffusion coefficient of the ACh receptors determined by this method was $2.6\ (\pm 1.6)\times 10^{-9}\ \text{cm}^2\ \text{s}^{-1}$ at 22 °C (±s.d., 14 cells from four separate cultures). Figure 3 shows an analysis of the decay of ACh sensitivity asymmetry in three different cells. Note that the ACh receptor density may be related nonlinearly to the ACh sensitivity[12]. However, because the time course of the decay in sensitivity asymmetry agreed

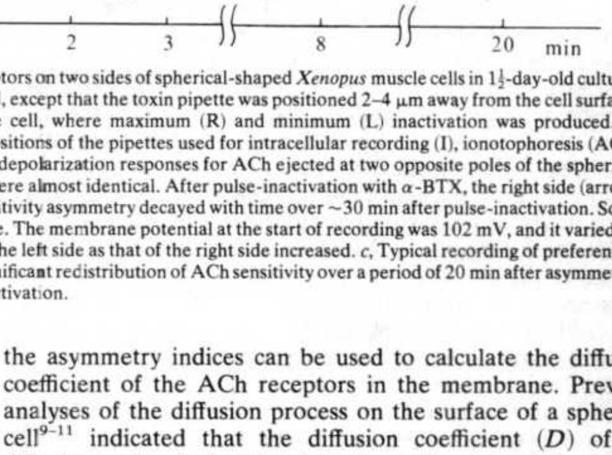

Fig. 3 Asymmetry in ACh sensitivity at two opposite poles of the spherical *Xenopus* muscle cells, plotted against the time after pulse-inactivation with α-BTX of ACh receptors at one pole. Asymmetry was determined as described in the text. Open symbols represent recordings from three different cells of a $1\frac{1}{2}$-day-old culture. Solid curves represent the best least-squares fit to these three sets of data with first-order decay kinetics, including points beyond 20 min. The characteristic $1/e$ times for the decay were 11.0, 12.8 and 11.8 min, respectively, for cells of radius 23, 20 and 20 μm. These decay rates suggest a diffusion coefficient for the ACh receptors of 4.0, 2.5 and $2.7\times 10^{-9}\ \text{cm}^2\ \text{s}^{-1}$, respectively. Solid symbols represent two sets of recordings from cells pretreated with Con A (100 μg ml^{-1}, 8-min preincubation).

satisfactorily with first-order decay kinetics (see Fig. 3), the nonlinearity of the receptor–sensitivity relationship is probably negligible in the present analysis.

The diffusion coefficient of ACh receptors in the embryonic *Xenopus* muscle observed here is surprisingly similar to that found for rhodopsin in the photoreceptor disk membrane[13], for surface antigens on cultured muscle fibres[14] and for several lectin receptors[9,10] in the same *Xenopus* muscle cells as used in the present study. However, the diffusion coefficient is 50-fold higher than that found for ACh receptor–toxin complexes in rat myotube culture by the fluorescence photobleaching method[15]. In addition, whereas 25% of the dispersed receptors were found to be immobile in photobleaching studies[15], I found no evidence of immobile fractions of the dispersed ACh receptors in these cultured muscle cells. The asymmetry in ACh sensitivity (resulting from asymmetric inactivation) always decays to a level close to zero, regardless of the extent of inactivation. For example, in the experiment represented by open circles in Fig. 3, asymmetric inactivation resulted in $\sim$93% and 12% inactivation on the two sides of the cell, respectively (asymmetry index $= 0.85$). If 25% of the ACh receptors are immobile in the membrane, there should be a persistent asymmetry of $\sim$0.2, whereas the data indicate that the asymmetry had decayed to <0.06 within 30 min. The reason for the discrepancy between my results and those from photobleaching studies is unknown. In addition to the possibility of species difference, the binding of α-BTX, a prerequisite for the photobleaching method, may greatly affect the rate of lateral diffusion of the ACh receptors. Diffusion measurements of ACh receptors by both methods using the same cell type are now being made.

Recent studies have shown a rapid accumulation of ACh receptors at nerve–muscle contacts in culture[16–19]. Extensive rearrangement of ACh receptor topography over a distance of $\sim 50\ \mu$m was observed within 6 h after the nerve contact[18,19]. The rate of lateral diffusion ($D = 2.6 \times 10^{-9}\ \mathrm{cm}^2\ \mathrm{s}^{-1}$) of ACh receptors reported here indicates that within 6 h (t), an ACh receptor is capable of diffusing laterally over an average distance ($\bar{s}$) of 150 µm ($\bar{s}^2 = 4Dt$). A simple passive diffusion-trap mechanism could thus account for the lateral rearrangement of ACh receptor topography induced by the nerve contact. By assuming that the nerve terminal region serves as a 'sticky zone' for trapping diffusing extrajunctional ACh receptors, Edwards and Frisch[4] also concluded that a diffusion-trap mechanism could account for the localization of ACh receptors at mature muscle endplates if the diffusion coefficient of the extrajunctional ACh receptors is $2 \times 10^{-9}\ \mathrm{cm}^2\ \mathrm{s}^{-1}$ or higher.

Various cellular processes could provide a trapping mechanism at the site of nerve contact. The surface of the nerve terminal may contain molecular groups that bind specifically to the ACh receptors in the muscle membrane. The nerve terminal may release locally trophic substances[20–22] which promote aggregation of the ACh receptors near the site of release. Alternatively, contact by the nerve terminal may alter the surface properties of the muscle membrane in a way that favours electrodynamic (van der Waals') attraction[23] among the ACh receptors, leading to formation of receptor aggregates at the site of contact. This last process seems the most likely mechanism for the induction of ACh receptor aggregates by nonspecific means, for example, contact with the culture substratum[24], with pieces of thread[25] or with positively charged latex beads[26] placed on top of the cell.

I have demonstrated a rapid diffusional movement of a specific, functional membrane protein/ionic channel in the plane of the plasma membrane which, together with a previous report[6], completes the description of both electrophoretic and diffusional mobilities of a defined membrane protein *in situ*. The rapidity of the lateral diffusion of the ACh receptor in the embryonic muscle membrane supports the notion that an efficient localization of the receptor can be achieved during synapotogenesis by a passive diffusion-trap mechanism. Finally, the asymmetric inactivation method reported here may also prove useful in examining the diffusional mobility of other membrane receptors/ionic channels, for which inhibitory ligands of relatively high affinity are available.

I thank Drs S. E. Fraser, D. Petersen, S. Young and I. Chow for helpful discussion and comments. This work was supported by grants from the NSF and NIH.

Reorganization of HeLa cell cytoskeleton induced by an uncoupler of oxidative phosphorylation

Bernard Maro* & Michel Bornens*

Departement de Biologie Moléculaire, Institut Pasteur,
75724 Paris Cedex 15, France

An association between mitochondria and microtubules has been suggested from microscopic studies[1,2] and by the cellular redistribution of mitochondria that is induced by colcemid, which disrupts microtubules[1]. Intermediate filaments have also been proposed to interact with mitochondria[1]. To investigate this association further, we have now studied the effect on the cytoskeleton of impairment of mitochondrial functions induced by three metabolic inhibitors: sodium azide, which inhibits electron transport; oligomycin, which inhibits ATP synthetase; and carbonylcyanide *p*-trifluoromethoxyphenylhydrazone (FCCP), a proton ionophore which uncouples electron transport from ATP synthesis. We have found that treatment of cells with FCCP leads to a disruption of microtubules and an aggregation of vimentin filaments. This effect is not provoked by mitochondrial ATP depletion, but could be linked to another event related to the rapid dissipation of the mitochondrial electrochemical gradient.

FCCP induced a disruption of HeLa cell microtubules (Fig. 1*c* and Table 1) which was complete after 1 h. The only tubulin-positive structures observed were midbodies and juxtanuclear microtubule-organizing centres (MTOC). After 6 h treatment, short microtubules were seen regrowing from the MTOC. However, this might be linked to the inactivation of FCCP because it was correlated with the reappearance of mitochondrion-specific staining by rhodamine-123, which requires a high transmembrane potential[3]. This staining was totally absent during the first hours of FCCP treatment (data not shown).

FCCP had a slower effect on vimentin filaments. The filaments began to aggregate after 1 h treatment and had gathered as

* Present address: Centre de Cytologie Experimentale du CNRS, 67 rue Maurice Gunsbourg, 94200 Ivry s/Seine, France.

0028–0836/82/040334—03$01.00

perinuclear bundles after 6 h (Fig. 1*d*). The distribution of actin, which in our culture conditions was seen mainly as a pericellular network, with numerous microspikes and few stress fibres, was apparently unchanged. The effects of FCCP on cytoskeletal components were absent with doses below 10^{-5}M, detectable at 2×10^{-5}M and complete at $\geqslant 3\times10^{-5}$M.

We have established that the doses of FCCP used were non-toxic for the cells. The normal microtubule pattern returned about 6 h after removal of the drug. 2,4-dinitrophenol (DNP) showed a similar but weaker effect compared with FCCP. The highest DNP dose we could use without provoking an effect due to the solvent (ethanol) was 2.5×10^{-3} M. In such conditions many of the microtubules disappeared, and MTOC could be easily identified. Loose bundles of vimentin filaments were observed around the nuclei, distributed in a different pattern from that seen in control cells (data not shown). The effects of FCCP were similar to those obtained with 10^{-6} M nocodazole (Fig. 1*g*,*h*), which inhibits microtubule polymerization[4], the only difference being that MTOC were more easily identified after FCCP treatment than after nocodazole treatment. To control for the method used, we applied cold treatment[5] to verify that the collapse of vimentin filaments did not occur during cell extraction with Triton X-100 in the absence of a normal microtubule network (Fig. 1*i*, *k*). In this latter case MTOC were particularly well detected. Furthermore, the collapse of vimentin filaments was also observed in human lymphoblastoid cells (KE 37 cell line) after only 30 min treatment with FCCP (data not shown).

Table 1 Effects of various treatments on the pattern of cytoskeletal elements in HeLa cells

Treatment (1–6 h at 37 °C)	Action on mitochondrial metabolism*	Action on the pattern of: Tubulin	Vimentin	Actin
FCCP 3×10^{-5} M	H^+ ionophore uncoupler (10^{-6} M)	Disruption	Collapse	None
DNP 2.5×10^{-3} M	H^+ ionophore uncoupler (10^{-3} M)	Disruption (weak)	Collapse (weak)	None
NaN_3 10^{-2} M	Inhibition of electron transport (10^{-2} M)	None	None	None
Oligomycin 2.5×10^{-4} M	Inhibition of ATP synthetase (10^{-5} M)	None	None	None

These effects were judged by immunocytochemistry as described in Fig. 1 legend, using purified anti-tubulin, anti-vimentin and anti-actin antibodies.

* Values in parentheses are the minimal dose decreasing the transmembrane potential[3].

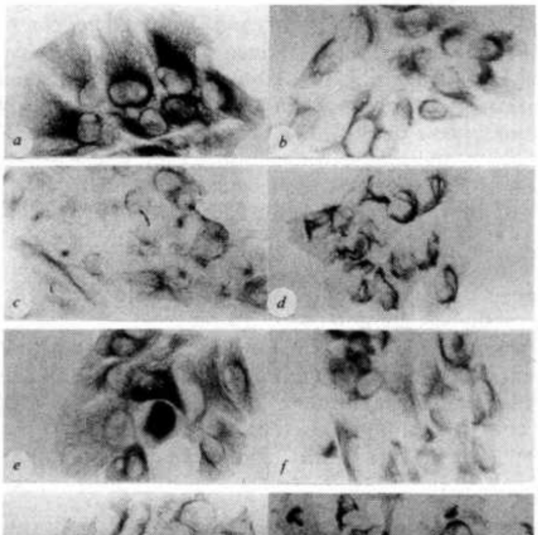

Fig. 1 Immunocytochemical staining of HeLa cells cultivated in Eagle's minimal essential medium (modified) supplemented with 10% fetal calf serum. Cells cultured for 48 h on glass coverslips were washed for 5 s at room temperature with an extraction buffer, *p*H 6.9, modified from Schliwa *et al.*[11], containing 45 mM PIPES, 45 mM HEPES, 5 mM $MgCl_2$, 10 mM EGTA, 1 mM sodium tetrathionate and 1 mM phenylmethylsulphonyl fluoride. They were lysed in extraction buffer supplemented with 1% Titron X-100 for 30 s, washed in extraction buffer, then fixed with 2% glutaraldehyde in the same buffer for 10 min at 20 °C. After three washes in 10 mM Tris-HCl *p*H 7.4, 100 mM NaCl (TBS), glutaraldehyde was neutralized with 1% bovine serum albumin in TBS for 1 h at 20 °C. Immunocytochemical staining of the cells was accomplished using purified sheep anti-tubulin antibodies or purified sheep anti-vimentin antibodies followed by peroxidase-labelled purified rabbit anti-sheep immunoglobulin antibodies as described previously[13] except that all incubations and washes were performed in the presence of 0.1% Tween-20. *a*, *b*, Control cultures; *c*, *d*, cultures treated with 4×10^{-5} M FCCP; *e*, *f*, cultures treated with 10^{-2} M sodium azide; *g*, *h*, cultures treated with 10^{-6} M nocodazole; *i*, *k*, cold-treated cultures. *a*, *c*, *e*, *g*, *i*, Anti-tubulin staining after 2 h treatment; *b*, *d*, *f*, *h*, *k*, anti-vimentin staining after 6 h treatment. ×240.

An energy requirement has been demonstrated for microtubule growth from MTOC in living cells[6,7], although in one case with very high doses of metabolic inhibitors[6]. However as reported by others for microtubule network[7,8], sodium azide (10^{-2} M, Fig. 1*e*,*f*) and oligomycin (2.5×10^{-4} M, data not shown) had no detectable effect on any of the three cytoskeletal components, indicating that FCCP was not acting via mitochondrial ATP depletion.

It is known[3] that FCCP is causing rapid dissipation of the mitochondrial electrochemical gradient; this could modify the local environment of the mitochondria and thus of the microtubules and so affect the stability of the latter. For example, a *p*H dependency of microtubule stability has been reported[9]. It is also known that a calcium efflux from mitochondria is correlated with membrane potential collapse[10]. Schliwa *et al.*[11] have recently shown that 10^{-6} M calcium induces disassembly of the microtubule network. Such effects could occur through a modulation of the activity of microtubule-associated proteins. In this connection it has been reported[8] that the colcemid-induced depolymerization of microtubules in cells is controlled by an ATP-dependent reaction probably a phosphorylation of some of the microtubule proteins. Although a direct effect of FCCP on microtubules cannot be ruled out, we have observed only a slight effect of FCCP on *in vitro* polymerization of rat brain tubulin over a wide range of drug concentrations (work in progress). Moreover, electron microscopic observation of microtubules polymerized in the presence of 4×10^{-5} M FCCP showed no detectable effect on either microtubule number or length relative to control conditions. An effect on nucleating centres is another possibility, and centrioles, which are the primary MTOC, have also been proposed to be involved in the organization of the vimentin network[12]. These possibilities are now being investigated.

We thank Dr D. Paulin for the gift of the anti-vimentin antibodies and Dr E. Karsenti for the gift of the anti-actin antibodies. This work was supported by DGRST grant 80.7.0155.

Chromaffin granule membrane–F-actin interactions are calcium sensitive

Velia M. Fowler* & Harvey B. Pollard

Exocytosis of neurotransmitters, hormones and other secretory products from many cell types is initiated by a rise in the intracellular free calcium ion concentration[1]. By analogy with excitation–contraction coupling in muscle[2], calcium-triggered acto–myosin interactions have been postulated to push or pull the secretory granule to the plasma membrane[1,3–6]. Indeed, there have been several reports of actin interacting with membranes of secretory vesicles from the adrenal medulla (chromaffin granules)[7–12]. Using sedimentation techniques and a novel application[13,14] of falling ball viscometry[15,16] to measure actin binding to membranes, we show here that purified chromaffin granule membranes bind and cause large increases in the viscosity of F-actin. The actin-binding activity of the membranes is trypsin sensitive and thermolabile and interactions between membranes and actin are reversibly inhibited by raising the free calcium ion concentration, $[Ca^{2+}]_{free}$, above 10^{-7} M. We propose that regulation of actin–chromaffin granule membrane interactions may be critical for organelle movement to the plasma membrane during calcium-mediated exocytosis in the chromaffin cell.

Intracellular organelles such as chromaffin granules are particularly suitable for studying interactions between membranes and filamentous cytoskeletal elements such as actin because the cytoplasmic surface of these organelles is immediately accessible experimentally. We have used a low-shear viscometric technique[15,16] to study these interactions partly because it is a sensitive and convenient method to measure F-actin binding to membranes[13,14] but also because it may indicate how interactions between F-actin and chromaffin granules might contribute to cytoplasmic structure and consistency[17]. This approach is thus an extension of that used previously to study gelation of actin-containing cytoplasmic extracts[15,16,18].

Purified chromaffin granule membranes cause large increases in the apparent viscosity of purified rabbit skeletal muscle F-actin (Fig. 1*a*) in conditions that may approximate the resting intracellular environment (*p*H 6.8, 20 mM KCl, 1–2 mM $MgCl_2$, $[Ca^{2+}]_{free} < 10^{-7}$ M, 30 °C). (The effect of *p*H, KCl, $MgCl_2$ and ATP on membrane–actin interactions is described in ref. 17.) Increasing the membrane protein added to the F-actin to >2.5 mg ml^{-1} results in the formation of a solid gel through which the ball does not fall. The ability of membranes to induce increases in the apparent viscosity of F-actin is almost completely abolished by prior heating of the membranes at 60 °C for 15 min (not shown) or at 100 °C for 2 min (Fig. 1*a*), and chromaffin granule membranes alone have a viscosity equivalent to that of the buffer (~1 cP), at all concentrations of membrane protein tested. The ability of membranes to bind (see below) and cause increases in the apparent viscosity of F-actin (Fig. 1*a*) is not an artefact of the lysis and purification procedure, as intact chromaffin granules prepared by centrifugation through a 1.8 M sucrose shelf also bind and induce increases in the viscosity of F-actin[17].

Pelleting of F-actin with chromaffin granule membranes in conditions that do not pellet F-actin alone (Fig. 1*b*) confirms that these increases in apparent viscosity do, in fact, represent actin binding to the membrane[13,14]. Moreover, the amount of F-actin pelleting with membranes is reduced by ~75% after heat treatment of the membranes (Fig. 1*b*), as determined by quantitative densitometry of the Coomassie blue-stained gels. However, note that because the membrane-induced increases in apparent viscosity of actin are not linearly related to the number of F-actin binding sites on the membranes (Fig. 1*a*), and because membranes may bind actin in ways that do not lead to increases in viscosity[13,14], the low-shear viscometric assay cannot be compared quantitatively with the pelleting assay.

The effect of previous heating of membranes on their interactions with actin suggests that the actin-binding components on the membrane are proteinaceous. Indeed, treatment of membranes with trypsin selectively proteolyses certain of the membrane polypeptides (Fig. 2*a*) and also abolishes completely the ability of membranes to induce increases in the apparent viscosity of F-actin (Fig. 2*b*). Controls using trypsin that had been pretreated with soybean trypsin inhibitor, or soybean trypsin inhibitor alone (Fig. 2), demonstrated that the effect of trypsin is not due to a spurious, non-proteolytic action on the membranes. The effect of trypsin was also not due to an effect on the actin itself, as trypsin pretreated with soybean trypsin inhibitor had no effect on the apparent viscosity of actin in the absence of membranes, and SDS-polyacrylamide gel electrophoresis of trypsin-treated membranes plus actin revealed that the actin was not detectably proteolysed.

The actin-binding site(s) may differ from the α-actinin-like actin-binding component reported to be present on the chromaffin granule membrane[10,12], inasmuch as we prepared membranes in conditions (low ionic strength, no Mg^{2+}) that have been reported to elute this α-actinin-like component from the membrane[10]. In contrast to the actin-binding activity of chromaffin granule membranes described by Burridge and Phillips[8], we have also observed no differences between membranes prepared in 150 mM KCl or in isosmotic sucrose media. Finally, Wilkins and Lin[11] recently suggested that exogenous actin may bind to chromaffin granule membranes by polymerizing off pre-existing actin seeds on the membrane. However, in contrast to our results[17], actin binding to membranes in their experiments was strictly dependent on the presence of $MgCl_2$.

The calcium dependence of exocytosis[1] led us to examine the effect of calcium on interactions between chromaffin granule membranes and F-actin. We found that raising the free calcium ion concentration to micromolar levels inhibited the increases in apparent viscosity of F-actin induced by purified chromaffin granule membranes, while having no detectable effect on the apparent viscosity of F-actin alone (Fig. 3*a*). The small increases in viscosity of F-actin caused by heat-treated membranes were unaffected by changes in the $[Ca^{2+}]_{free}$ (not shown). Although it is uncertain why the increases in apparent viscosity were inhibited more in some experiments than in others (compare different symbols in Fig. 3*a*), this may, for example, have been due to variable amounts of a calcium-regulatory factor present in different preparations of chromaffin granule membranes.

If the changes in viscosity as a fraction of the maximal viscosity observed in each experiment are averaged for each *p*Ca ($-\log [Ca^{2+}]_{free}$), we obtain the graph shown in Fig. 3*b*. The $[Ca^{2+}]_{free}$ at which the increases in apparent viscosity are half-maximally inhibited is $\sim 2.6 \times 10^{-7}$ M, which is comparable to free Ca^{2+} concentrations which cause half-maximal inhibition of actin gelation in cytoplasmic extracts from non-muscle cells[15,16,18,19], and inhibition of actin cross-linking and gelation by various purified proteins[16,20,21], but rather less than the micromolar levels that induce release of granule contents from chromaffin

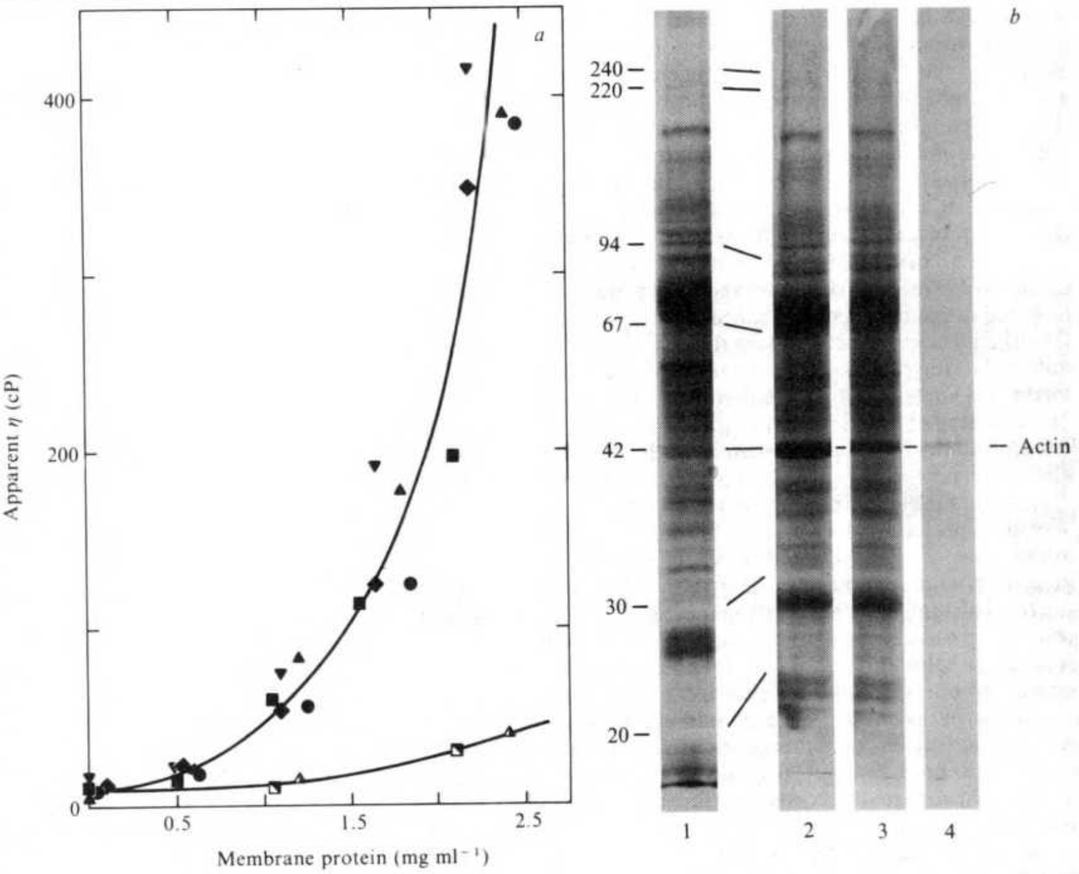

Fig. 1 *a*, Apparent viscosity (η cP) plotted against concentration of membrane protein for chromaffin granule membranes plus F-actin (●, ■, ▲, ▼, ◆) or heat-treated membranes (2 min, 100 °C) plus F-actin (□, △). Each symbol represents a separate experiment using a different membrane preparation. Membranes were mixed with 0.8 mg ml^{-1} F-actin and incubated at 30 °C for 1 h in a buffer containing 40 mM PIPES *p*H 6.8, 20 mM KCl, 1 mM $MgCl_2$ and $[Ca^{2+}]_{free}$ buffered to $\sim 4 \times 10^{-8}$ M with 5 mM EGTA (see Fig. 3). Viscosity was measured using a low-shear falling ball viscometer[15,16] as previously described[13,16,17]. *b*, SDS-polyacrylamide gels of pellets obtained from the centrifugation of (1) chromaffin granule membranes, (2) membranes plus F-actin, (3) heat-treated membranes (60 °C, 15 min) plus F-actin, and (4) F-actin alone. Membranes (0.5 mg ml^{-1}) with or without 0.4 mg ml^{-1} F-actin were incubated as described above and centrifuged through a 15% sucrose shelf to separate membrane-bound from unbound actin[14]. After solubilization of pellets in electrophoresis sample buffer[14], 25 μl of each sample were electrophoresed on 7.5–15% linear gradient polyacrylamide slab gels using the discontinuous buffer system of Laemmli[29]. Chromaffin granules were prepared from bovine adrenal medullae essentially as described by Bartlett and Smith[30], except that the sucrose solutions were buffered to *p*H 7.6–7.8 with 40 mM HEPES, and contained 1 mM EDTA, 1 mM phenylmethylsulphonyl fluoride (PMSF), 1 mM dithiothreitol (DTT) and 0.87% ethanol[17]. Membranes were prepared by lysis of granules at 0 °C in 5 mM HEPES *p*H 7.6–7.8, 1 mM EDTA, 1 mM PMSF, 1 mM DTT, 0.87% ethanol and separated from contaminating mitochondria, lysosomes and other cellular debris[17,31–33] by centrifugation over a 1.0 M sucrose shelf made up in the same buffer (26,000 r.p.m. in Beckman SW 27 rotor at 2–4 °C for 60 min)[17]. The chromaffin granule membranes accumulated as an intense salmon-pink layer on top of the 1.0 M sucrose and were collected, washed twice, then resuspended in a small volume of the 5 mM HEPES lysis buffer to give ~4–5 mg ml^{-1} membrane protein. Membranes were stored on ice for up to 10 days with no loss of actin binding activity. Actin was prepared from an acetone powder of rabbit skeletal muscle with one or two cycles of polymerization and sedimentation from 0.8 M KCl (ref. 34), and was depolymerized and stored as previously described[13]. F-actin was polymerized at 5–7 mg ml^{-1} in 100 mM KCl, 2 mM MgATP at 30 °C for 30–60 min before mixing with chromaffin granule membranes.

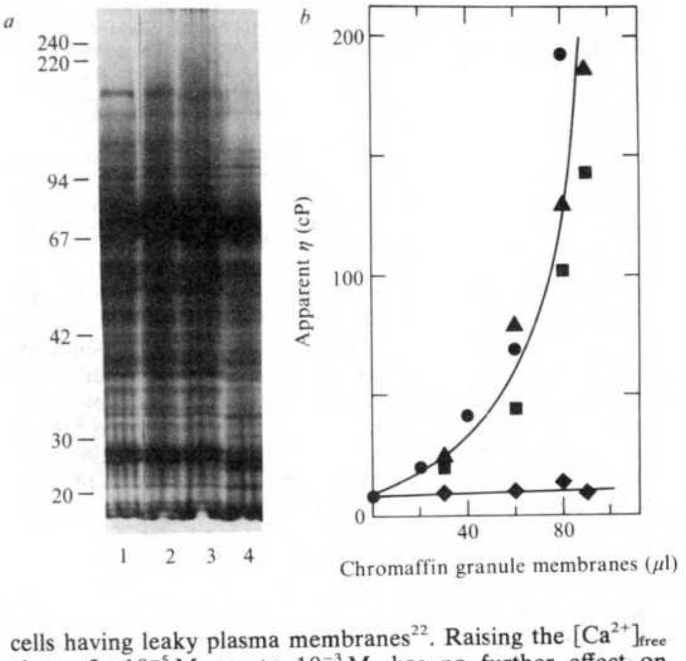

Fig. 2 Effect of trypsin treatment on *a*, 7.5–15% SDS-polyacrylamide gel profiles of chromaffin granule membrane proteins and *b*, the apparent viscosity, η (cP) of chromaffin granule membranes plus F-actin. Lane 1 (●), untreated chromaffin granule membranes; lane 2 (■), control membranes treated with soybean trypsin inhibitor; lane 3 (▲), control membranes treated with trypsin that had been preincubated with soybean trypsin inhibitor; and lane 4 (◆), trypsin-treated membranes. Chromaffin granule membranes were incubated with 100 μg ml^{-1} trypsin (Worthington) at 30 °C for 15 min, followed by an additional 15 min in the presence of 200 μg ml^{-1} soybean trypsin inhibitor (SBTI; Sigma), and then washed by centrifugation (20,000 r.p.m. in a Sorvall SS-34 rotor for 45 min) through a 5% sucrose shelf. As controls, membranes were incubated with SBTI alone at 30 °C for 15 min or with trypsin that had been pretreated with SBTI at 30 °C for 15 min, before washing. Samples were resuspended to equivalent volumes in the 5 mM HEPES buffer (see Fig. 1 legend) by homogenization and then solubilized for SDS-polyacrylamide gel electrophoresis or tested for their ability to induce increases in the apparent viscosity of F-actin. As trypsin treatment released ~35% of the total membrane protein into the supernatant, the apparent viscosity is plotted as a function of the volume (μl) of membranes added to the 150-μl assay mixture instead of as a function of the membrane protein concentration. 10 μl of untreated membranes correspond to 0.26 mg ml^{-1} membrane protein in this experiment.

cells having leaky plasma membranes[22]. Raising the $[Ca^{2+}]_{free}$ above 5×10^{-5} M, up to 10^{-3} M, has no further effect on membrane–actin interactions.

The mechanism by which micromolar free calcium ion concentrations inhibit membrane-induced increases in the apparent viscosity of F-actin is unclear. Calcium may reduce the affinity of actin for (some of) its binding sites, thus resulting in fewer actin filaments bound to the membrane and hence lower viscosities. Alternatively, a calcium-dependent influence of some membrane component on actin filament length, analogous to the calcium-mediated action of gelsolin[20], or possibly a membrane-mediated effect on the degree of actin polymerization, could also account for the reductions in apparent viscosity. However, we demonstrated that the effects of varying the free calcium ion concentration on membrane–actin interactions are reversible, and ruled out the possibility that a calcium-activated protease causes the inhibition of the membrane-induced increases in apparent viscosity of F-actin. The apparent viscosity of membranes plus actin preincubated at a high free calcium ion concentration ($\sim 10^{-6}$ M) returns to twice the original viscosity on reducing the free calcium ion concentration to $\sim 10^{-7}$ M (Fig. 4*b*). Conversely, the apparent viscosity of membranes plus actin preincubated at a low free calcium ion concentration recovers to only ~50% of the original viscosity after raising the $[Ca^{2+}]_{free}$ to $\sim 10^{-6}$ M (Fig. 4*a*). If the free calcium ion concentration is unchanged, but the mixture is vortexed, the viscosity of the membranes plus actin preincubated at low (Fig. 4*a*) or high (Fig. 4*b*) free calcium ion concentrations recovers completely to the premixing viscosity, albeit at a slower rate. Thus, these mixtures are thixotropic.

Additional evidence against involvement of a calcium-activated protease in calcium inhibition of membrane–actin interactions is that SDS-polyacrylamide gels of membranes incubated with actin are not detectably affected by increasing the free calcium ion concentration (not shown). The component conferring calcium sensitivity on these interactions does not seem to be calmodulin as up to 100 μM trifluoperazine (a drug which inhibits calmodulin function[23]) does not reverse the inhibition by calcium. Minor contaminants which have been reported in conventional preparations of rabbit skeletal muscle actin[24] are probably not responsible as membrane-induced increases in apparent viscosity of actin purified by gel filtration[24] were also calcium sensitive.

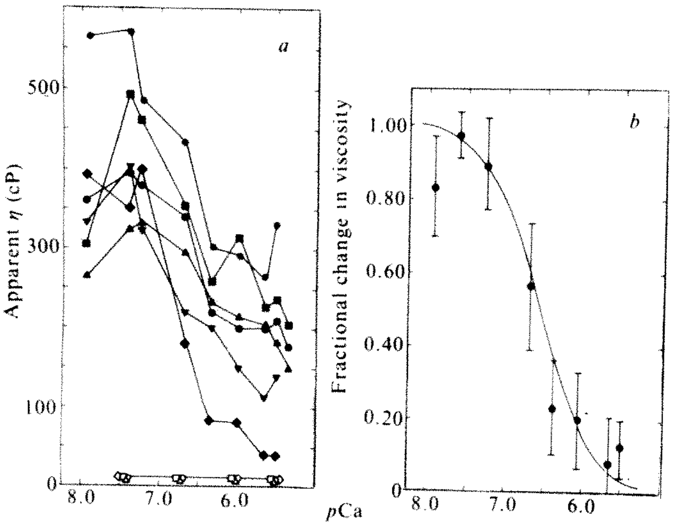

Fig. 3 *a*, Effect of the free calcium ion concentration (expressed as −log $[Ca^{2+}]_{free} = p\mathrm{Ca}$) on the apparent viscosity of chromaffin granule membranes plus F-actin (●, ■, ▲, ◆, ▼, *) and on F-actin alone (○, □, △, ◇). Each symbol represents a separate experiment using a different membrane preparation. *b*, Fractional change in viscosity of membranes plus actin as a function of *p*Ca. The lowest viscosity measured in each experiment was subtracted from the other measured values to give the change in viscosity for each free calcium ion concentration. These values were then divided by the maximum viscosity (which always occurred at *p*Ca 7.58 or 7.26) to compare results from separate experiments. The points represents means ± s.d. (error bars). The curve was drawn (ignoring the two extremes) using a least-squares fit to the Hill equation. The *y*-intercept of this line = −7.3, the slope = 1.1 and correlation coefficient, *r* = 0.92. For these experiments, membranes were dialysed overnight at 0 °C against a large volume of the 5 mM HEPES buffer (Fig. 1) containing 1 mM EGTA instead of EDTA. Chromaffin granule membranes (final concentrations 2.18 (●), 2.44 (■), 2.44 (▲), 2.16 (▼), 2.70 (◆) and 2.50 (*) mg ml^{-1}) were mixed with 0.8 mg ml^{-1} F-actin for viscosity measurements as described in Fig. 2 legend. The $[Ca^{2+}]_{free}$ was adjusted by addition of an appropriate stock to give calcium–EGTA buffer (*p*H 6.8) final concentrations of 5 mM EGTA and 0.095–4.975 mM $CaCl_2$; the free calcium ion concentration for each data point was calculated according to Caldwell[35] using a K_{app} of 1.95×10^6. Other conditions were as in Fig. 1.

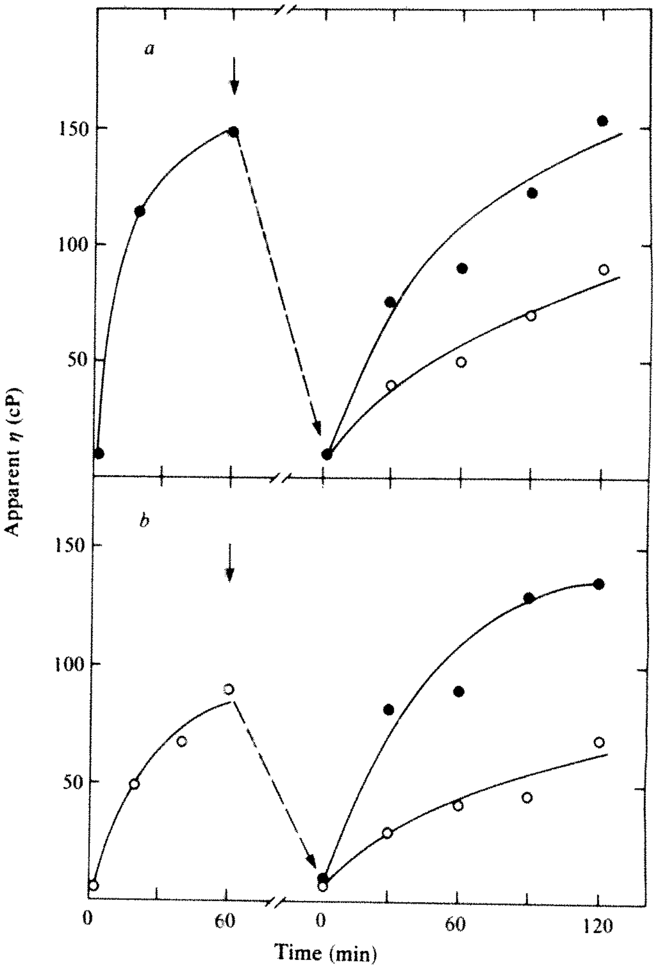

Fig. 4 *a*, Effect of preincubation at 2.7×10^{-8} M $[Ca^{2+}]_{free}$ on the apparent viscosity of chromaffin granule membranes plus F-actin incubated subsequently at 2.7×10^{-8} M (●) or 1.6×10^{-6} M (○) $[Ca^{2+}]_{free}$. *b*, Effect of preincubation at 1.5×10^{-6} M $[Ca^{2+}]_{free}$ on the apparent viscosity of chromaffin granule membranes plus F-actin incubated subsequently at 1.0×10^{-7} M (●) or 3.4×10^{-6} M (○) $[Ca^{2+}]_{free}$. Duplicate samples of chromaffin granule membranes (final concentration 2.14 mg ml^{-1}) were mixed with 0.8 mg ml^{-1} F-actin in assay buffer at low or high $[Ca^{2+}]_{free}$ as indicated above, using 2.0 mM EGTA buffer. For viscosity measurements, one set of samples was incubated in micropipettes at 30 °C for the indicated times. Parallel samples were incubated in test tubes at 30 °C for 1 h. At the time indicated by the arrow, the $[Ca^{2+}]_{free}$ was readjusted by addition of a small volume of an appropriate stock Ca^{2+}/EGTA buffer, the sample was mixed by vortexing (broken line) and then drawn up into micropipettes and incubated at 30 °C for the indicated times before measuring the viscosities. The total calcium and EGTA concentrations during the incubations after the vortexing were (*a*, ●) 0.51 and 10.40, (*a*, ○) 9.10 and 12.07, (*b*, ●) 2.01 and 12.07, (*b*, ○) 9.02 and 10.4 mM, respectively. The free calcium ion concentrations were calculated as described in Fig. 3 legend.

The ability of purified chromaffin granule membranes to bind and cause large increases in the apparent viscosity of F-actin suggests that the membrane vesicles may bind more than one actin filament and, vice versa, that an actin filament may associate with more than one membrane vesicle so as to generate an extensive cross-linked network or gel[13,14]. It is possible that such interactions may have a significant role in the maintenance of cytoplasmic structure and consistency in the chromaffin cell, as chromaffin granules comprise ~13.5% of the total cells cytoplasmic volume[25]. This corresponds to a concentration of ~30 mg ml^{-1} membrane protein (assuming the density of the granule to be 1.12 g ml^{-1} and the membrane protein to be 20% of the total granule protein[26]), which would be expected to generate an apparent viscosity much greater than that measured in our assay (Fig. 1*a*). Moreover, we measured increases in apparent viscosity of only 0.8 mg ml^{-1} F-actin, whereas the cytoplasmic actin concentration is likely to be nearer 3–4 mg ml^{-1} (ref. 27). Thus, chromaffin granules could be securely embedded within and attached to a cytoskeletal actin filament network *in vivo*.

Inhibition of chromaffin granule membrane–actin interactions by free calcium ion concentrations that are thought to activate exocytosis and other cellular movements *in vivo*[4 18 22,28] leads us to propose that dissociation of the chromaffin granules from a cytoskeletal actin filament network may be necessary for their movement to the plasma membrane during exocytosis In addition, regulation of the association of chromaffin granules with an actin network by changes in the free calcium ion concentration, or by other factors[17], could potentially control membrane recovery processes following exocytosis, as well as intracellular translocation of the secretory vesicles from their sites of synthesis and assembly to a more peripheral location in the cell in preparation for exocytosis

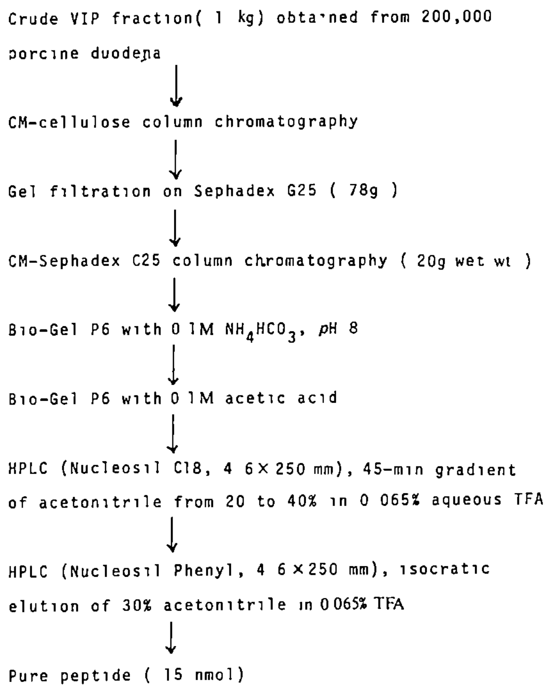
Isolation and structure of dynorphin, an opioid peptide, from porcine duodenum

S. Tachibana, K. Araki, S. Ohya & S. Yoshida

Research Laboratory of Biochemistry, Eisai Co Ltd, 4 Koishikawa, Bunkyo-Ku, Tokyo 112, Japan

The presence of endogenous ligands of opiate receptors in gastrointestinal organs has been demonstrated by both bioassay and immunoassay but so far no ligand has been precisely identified. We report here the purification from porcine duodenum of an opioid peptide whose structure coincides with that of the pituitary opioid, dynorphin[1]. Only the N-terminal tridecapeptide of pituitary dynorphin has been published; we have now determined the complete sequence of duodenal dynorphin, and measured its content in the duodenum by radioimmunoassay[2]. We report here that the complete heptadecapeptide has almost the same potency as dynorphin$_{1-13}$ in two bioassays.

Figure 1 shows an outline of the purification procedure We used as starting material the vasoactive intestinal peptide (VIP) fraction (1 kg) obtained from 200,000 porcine duodena[3] The crude material was purified by CM-cellulose and CM-Sephadex column chromatography using a linear gradient of sodium phosphate (20 mM, *p*H 10 to 100 mM, *p*H 12) The active material thus obtained was then applied in succession to two Bio-Gel P6 columns When the column was developed with a basic solvent (0 1 M NH_4HCO_3, *p*H 8), opioid activities emerged coincidently with the salt peak, the column was then eluted with an acidic solvent (0 1 M acetic acid), which gave one major peak of activity eluting immediately after the salt peak The strong affinity of the opioid peptide for Bio-Gel allowed its effective separation from large amounts of inactive material Further purification was achieved by HPLC first using Nucleosil C18 and then Phenyl (Macherly-Nagel) columns Opioid activities were determined using bioassays on guinea pig ileum preparations[4] and dynorphin-like immunoactivities were estimated by the method of Ghazarossian *et al*[2]



Crude VIP fraction(1 kg) obtained from 200,000 porcine duodena
CM-cellulose column chromatography
Gel filtration on Sephadex G25 (78g)

Bio-Gel P6 with 0 1M NH4HCO3, pH 8
Bio-Gel P6 with 0 1M acetic acid
HPLC (Nucleosil C18, 4 6×250 mm), 45-min gradient of acetonitrile from 20 to 40% in 0 065% aqueous TFA
HPLC (Nucleosil Phenyl, 4 6×250 mm), isocratic elution of 30% acetonitrile in 0 065% TFA
Pure peptide (15 nmol)

Fig. 1 Procedure used to purify the heptadecapeptide

Homogeneity of the purified peptide was confirmed by determining the N-terminal amino acids using dansyl (DNS) techniques In addition to ε-DNS-Lys, only *O,N*-diDNS-Tyr was detected An amino acid analyser (model 835, Hitachi) linked to an ammonia trapping column was used for amino acid analysis of peptide samples hydrolysed with 3 M mercaptoethanesulphonic acid (Pierce)[5] The peptide was found to consist of 17 amino acids Asp 2, Glu 1, Pro 1, Gly 2, Ile 1, Leu 2, Tyr 1, Phe 1, Lys 2, Trp 1 and Arg 3 The biological characteristics of the peptide, such as slow-reversing activity and high potency on guinea pig ileum preparations[1], as well as immunoreactivity with anti-dynorphin$_{1-13}$ antiserum, suggested that the structure of the newly isolated peptide is similar to that of dynorphin

The peptide was digested with diphenyl carbamyl chloride (DPCC)-treated trypsin (Sigma) and the resultant fragments (T-1, -2, -3, -4 and -5) separated by HPLC as shown in Fig 2 To determine the amino acid sequence of these tryptic peptides, synthetic dynorphin$_{1-13}$ (Protein Research Foundation, Osaka, Japan) was also treated with trypsin and the tryptic fragments

0028-0836/82/040339—03$01 00

separated As expected from the specificity of trypsin for dynorphin$_{1-13}$, reverse-phase HPLC yielded five tryptic peptides whose sequences were easily deduced from their amino acid compositions The amino acid compositions and retention times on HPLC of each of these tryptic peptides were compared with those of the corresponding tryptic fragments from dynorphin$_{1-13}$, four of the five peptides (T-1, -2, -4 and -5) were identical to the corresponding dynorphin$_{1-13}$ fragments

From these data, we estimated that the new heptadecapeptide contained a hexapeptide extension at the C-terminus of the dynorphin$_{1-11}$ sequence We used a manual Edman sequencing method described elsewhere[6] to degrade the tryptic peptide T-3 and the resultant phenylthiohydantoin-amino acids were identified by HPLC[7] The partial sequence Leu-Lys-Trp-Asp(Asx, Glx) was determined by microsequencing at the less than nanomolar level, we were unable to complete the sequencing due to the limited amount of material available We digested the original peptide (1 nmol) with carboxypeptidase A (Sigma) and the amino acids thus released were analysed after 2, 16 and 40 h incubation Carboxypeptidase A first released Gln, followed by the same amounts of Asn and Asp, thus the penultimate residue could not be determined clearly However, the sequencing results combined with the results of carboxypeptidase digestion allowed us to assign the following sequence to the tryptic peptide T-3 Leu-Lys-Trp-Asp-Asn-Gln

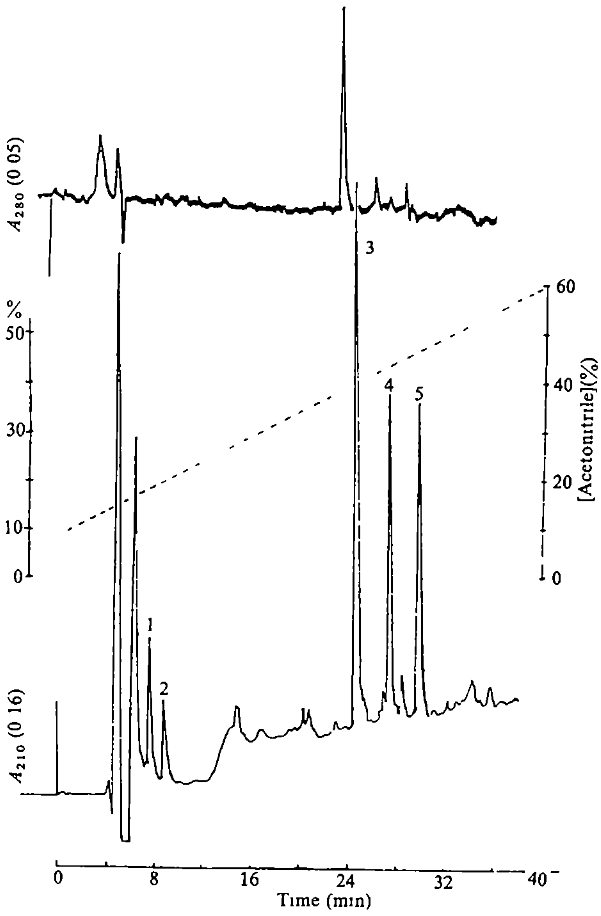

Fig. 2 Reverse-phase HPLC of the tryptic fragments of the newly isolated peptide The peptide (5 nmol) was digested with 300 ng of DPCC-treated trypsin (Sigma) dissolved in 130 µl of 100 mM sodium phosphate, *p*H 7 6, at 37 °C for 1 5 h After acidification with 50 µl of 2M HCl, the enzyme solution was directly loaded onto a Nucleosil column (5 µm, 4 6×250 mm) divided in two We applied to the column a 45-min linear gradient of acetonitrile from 10 to 60% in 0 065% TFA aqueous solution with a flow rate of 1 ml min^{-1} Column effluents were monitored by absorbance at 280 and 210 nm The numbers in parentheses on the abscissa, corresponding to 15 cm space, show the full scale unit of absorption in the detector used

Fig. 3 Amino acid sequence of the heptadecapeptide ⇒ represents DNS method, ↙, carboxypeptidase A digestion, ➡, manual Edman sequencing

The entire sequence of the heptadecapeptide and the strategy used for structural analyses are summarized in Fig. 3 We have confirmed this structure by comparing the retention times of the natural peptide on two HPLC systems with those of the peptide synthesized by the Protein Research Foundation. The HPLC pattern produced by the tryptic fragments of the synthetic peptide was identical to that of natural dynorphin The opioid potencies of the synthetic tri- and heptadecapeptides were compared in *in vitro* bioassays[2 8] The concentration of the heptadecapeptide required for 50% inhibition of the contractile twitch was 199±84 pM (mean±s d , *n* = 9) in guinea pig ileum and 4 4±1 6 nM (*n* = 8) in the mouse vas deferens assay, while the respective IC$_{50}$s of dynorphin$_{1-13}$ were 181±67 pM (*n* = 9) and 6 5±3 4 nM (*n* = 8) Therefore the C-terminal tetrapeptide has little or no influence on potency

To estimate the content of dynorphin in porcine duodenum, five fresh upper intestines (~60 cm long) were extracted individually and concentrated to give crude extracts as described previously[9] Radioimmunoassay studies revealed that porcine duodenum contained 620±120 pg (*n* = 5) of immunoreactive dynorphin and 1 82±0 49 ng (*n* = 5) of β-endorphin[10] per g wet tissue The value for dynorphin is one-tenth that of methionine-enkephalin reported for human duodenum[11] while the concentration of β-endorphin is comparable with that reported in normal rat duodenum[12] Further studies, however, are needed to determine the absolute concentrations of endorphins in gut because estimates tend to vary with the antisera and the extraction procedures used

As opiate has been used for centuries to provide relief from diarrhoea and dysentery as well as for its analgesic actions, we hope that gut dynorphin will prove valuable for clarifying physiological roles of endorphins and pharmacological actions of opiate in the gastrointestinal tract. Since submission of this paper, Goldstein has reported[13] that dynorphin extracted from porcine pituitaries has the same sequence as that determined here

We thank Dr A Goldstein for the gift of anti-dynorphin$_{1-13}$ antiserum and Dr T Suda for his cooperation in the radioimmunoassay studies

Recent studies[1,2] have shown that adrenal medullary chromaffin granules contain relatively large amounts of Met- and Leu-enkephalin and several large enkephalin-containing peptides ranging in molecular weight (M_r) from 3,200 to 50,000. The large, biologically inactive enkephalin-containing molecules can be broken down *in vitro* to give active enkephalins by two enzymes, trypsin and carboxypeptidase B[1]: trypsin liberates enkephalins (for example, Met-enkephalin-Arg^6, Met-enkephalin-Arg^6-Arg^7, Met-enkephalin-Lys^6, Leu-enkephalin-Arg^6) that are extended at their C-terminus by Lys or Arg. These C-terminal residues can be trimmed off by carboxypeptidase B, an exopeptidase that specifically removes C-terminal basic amino acid residues. Presumably, the enkephalin precursor is processed *in vivo* by trypsin-like and carboxypeptidase B-like enzymes[1,3]; it seems reasonable that these enzymes co-exist with the precursor in chromaffin granules. We describe here a carboxypeptidase obtained from bovine chromaffin granules that converts ^{125}I-labelled Met-enkephalin-Arg^6 to ^{125}I-Met-enkephalin. Fulfilment of certain criteria expected of a processing enzyme suggests that this peptidase may be involved in enkephalin precursor processing.

Chromaffin granules were isolated from fresh bovine adrenal glands and kept on ice The medulla was separated from the cortex and the granules purified by differential and discontinuous sucrose density centrifugation (for methods see Fig 2 legend)[4]

Carboxypeptidase activity was assayed by adding 10 μl of the enzyme or tissue homogenate to 25 μl of 1–5 × 10^{-5} M ^{125}I-Met-enkephalin-Arg^6 (1 μCi per tube) (for iodination procedure see Fig 1 legend) in 50 mM potassium phosphate buffer *p*H 6 0, 100 mM NaCl The samples were incubated at 37 °C for 30 min and the reaction stopped by addition of 10 μl ice-cold 95% ethanol After 30 min at 4 °C the samples were centrifuged in a Beckman microfuge for 5 min The ^{125}I-Met-enkephalin-Arg^6 and ^{125}I-Met-enkephalin were separated by TLC Radioactivity was measured along each lane using a BID System 100 radiogram imaging system (Bioscan) The two peptides were resolved on silica gel TLC plates using as solvent pyridine/ethyl acetate/H_2O/acetic acid (33 53 9 4 4 3) (Fig 1) Commercial porcine pancreatic carboxypeptidase B, having a reported *p*H optimum of 7 0–9 0 (ref 5) converted ^{125}I-Met-enkephalin-Arg^6 into a radioactive molecule that co-chromatographed with ^{125}I-Met-enkephalin in thin layer and reverse-phase high performance systems

Purified chromaffin granules were lysed by suspending them in 0 015 M KCl at 4 °C for 30 min The soluble and particulate components of the lysed granules were separated by centrifugation at 100,000*g* for 30 min in a Beckman type 40 rotor (40,000 r p m) Incubation of an aliquot of the soluble fraction with ^{125}I-Met-enkephalin-Arg^6 resulted in the appearance of a radioactive species that co-migrated with ^{125}I-Met-enkephalin (New England Nuclear) (Fig 1*d*) The new peak was not seen if the soluble fraction was boiled for 30 min before being added to the reaction mixture or if the incubation was carried out at 0 °C The behaviour of the ^{125}I-Met-enkephalin-like reaction product was the same as that of ^{125}I-Met-enkephalin when subjected to HPLC [reverse-phase C18 column eluted with 15–20% acetonitrile in TEAP (triethylamine–0 25 M phosphoric acid *p*H 3 0)]

The amount of ^{125}I-Met-enkephalin produced was linearly related to the amount of granule supernatant added The enzyme activity was optimal at ~*p*H 6 0 (Fig 2), with considerable activity being observed in the *p*H range 5 5–6 5 While the soluble fraction derived from chromaffin granules was relatively rich in carboxypeptidase B activity, the membrane fraction contained only low enzyme activity Similarly, other subcellular fractions (Fig 1) containing cytosol (S1, S2, S3), nuclei (P1), mitochondria and lysosomes showed very little carboxypeptidase activity, but these fractions did exhibit other peptidase activities as indicated by the production of a labelled substance other than ^{125}I-Met-enkephalin (Fig 1) The crude granule fraction (P3) not only displayed considerable carboxypeptidase activity, but also contained other peptidase(s) Thus the purified granules are unique in containing only carboxypeptidase B activity and in their apparent inability to cleave

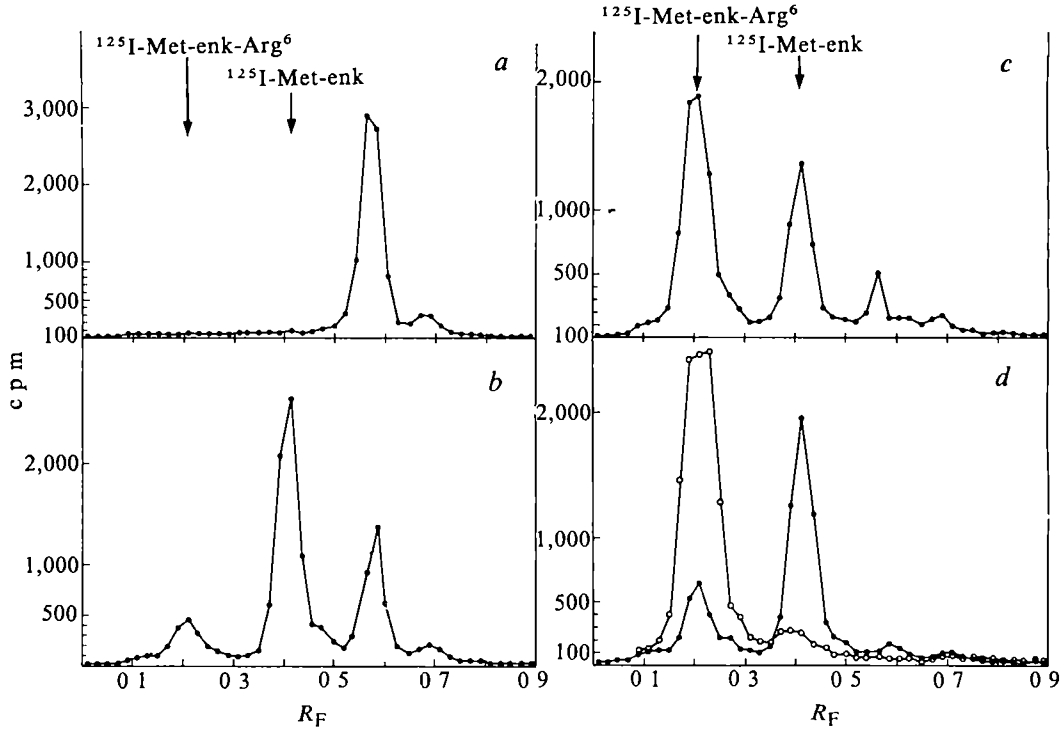

Fig 1 Carboxypeptidase activity in subcellular fractions of bovine adrenal medulla Met-enkephalin-Arg^6 (Peninsula Laboratories) was iodinated by the chloramine-T method[18] Free ^{125}I was removed with a C18 Sep-Pak (Waters Associates) and ^{125}I-Met-enkephalin-Arg^6 eluted off using 30% acetonitrile/70% H_2O Each subcellular fraction (for method see Fig 2 legend) was incubated with ^{125}I-Met-enkephalin-Arg^6 and chromatographed by TLC on silica gel G Arrows indicate the migration position of standard samples of ^{125}I-Met-enkephalin-Arg^6 and ^{125}I-Met-enkephalin *a*, Typical peptidase activity in fractions containing nuclei and large debris (P1) and cytosol (S2 and S3) *b*, Activity in crude chromaffin granules (P3) *c*, Activity in lysosomal and mitochondrial fraction obtained from sucrose gradient *d*, Activity in purified granules (supernatant of lysed granules) (●) and in boiled supernatant granule fraction (○)

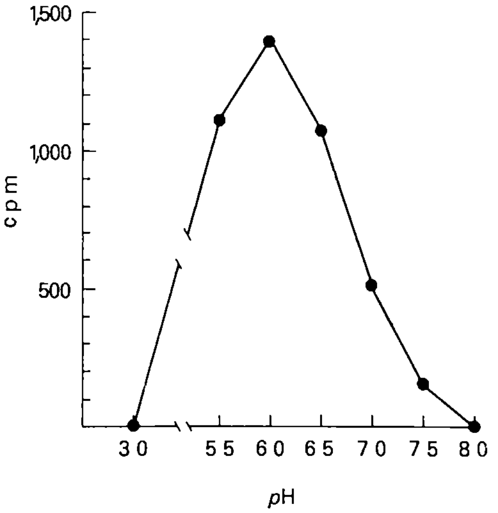

Fig 2 *p*H dependence of carboxypeptidase activity in supernatant of lysed chromaffin granules At *p*H 5–8, 50 mM potassium phosphate was used, TEAP was used for *p*H 3 0 Purified chromaffin granules were obtained by centrifuging adrenal medulla homogenate in 0 32 M sucrose at 1,500 r p m for 20 min (GS-4 rotor, Sorvall centrifuge) to give a pellet (P1) and supernatant (S1) fraction S1 was centrifuged at 8,800 r p m for 20 min (same rotor as above), yielding a pellet containing the crude granule fraction and supernatant (S2) The pellet was washed once (8,800 r p m , 20 min) and taken as the crude granule fraction (P3) Purified chromaffin granules were obtained by applying a suspension of P3 in 0 32 M sucrose on 1 6 M sucrose, and centrifuging at 25,000 r p m for 120 min (Beckman ultracentrifuge, SW-27 rotor) The pellet containing the purified chromaffin granules has been shown to be relatively free from mitochondria and lysosomes which were collected at the interface of the 0 32–1 6 M sucrose gradient[19] The membrane fraction from lysed chromaffin granules displayed a *p*H optimum of 6 0, which is similar to that of carboxypeptidase in the supernatant However, the *p*H optimum of porcine pancreatic carboxypeptidase B has been reported[5] to be in the range 7 0–9 0

^{125}I-Met-enkephalin-Arg^6 into labelled species other than ^{125}I-Met-enkephalin

To determine whether the carboxypeptidase in the soluble fraction of chromaffin granules is similar to other known carboxypeptidases, the effects of various inhibitors were examined Inhibitors of zinc metallopeptidases such as guanidinopropylsuccinic acid, aminopropylmercaptosuccinic acid, benzylsuccinic acid and 2-mercaptomethyl-3-guanidinoethylthiopropanoic acid[6–8] (provided by Dr T H Plummer, New York Department of Public Health) were found to inhibit porcine pancreatic carboxypeptidase B dramatically at concentrations of $2\ 8\times10^{-5}$ M, none of these inhibited chromaffin granule carboxypeptidase, however Similarly, the potato carboxypeptidase inhibitor[9] (given by Dr M Hass, University of Idaho) at 10^{-5} M inhibited the pancreatic but not the adrenal medullary enzyme Other inhibitors of metalloenzymes such as EDTA (10^{-3} M) and 1,10-phenanthroline (10^{-3} M)[10] also had little effect on the chromaffin granule carboxypeptidase In contrast, $HgCl_2$ (10^{-6} M), $CuCl_2$ (10^{-4} M) and *p*-chloromercuriphenyl sulphonic acid (10^{-5} M), which react with thiol groups[11 12], inhibited the carboxypeptidase Leupeptin ($3\ 7\times10^{-3}$ M) and antipain ($1\ 6\times10^{-3}$ M), which inhibit arginyl proteases[12], inhibited completely the chromaffin granule enzyme, whereas the serine protease inhibitors phenylmethylsulphonyl fluoride (10^{-4} M), aprotinin (0 017 trypsin inhibitor units ml^{-1}), and tosyllysine chloromethyl ketone (10^{-4} M)[13] and the lysosomal cathepsin B inhibitor[14], chloroquine (10^{-4} M), had no effect

The carboxypeptidase described here appears to be a unique and novel enzyme, showing a *p*H optimum and a spectrum of inhibitors different from that of other carboxypeptidases (for example, carboxypeptidases A, B and N)[6–9 15] This carboxypeptidase satisfies several criteria for it to be involved in processing the enkephalin precursor (1) it is concentrated in chromaffin granules where the precursors are found, (2) it is active at the intragranular *p*H of 5 7 (refs 16, 17), (3) it removes the basic (arginyl) residue from the C-terminus of Tyr-Gly-Gly-Phe-Met-Arg without degrading the pentapeptide itself It is not clear whether the removal of basic residues to yield the enkephalin pentapeptides is important in enhancing (or diminishing) the action of enkephalin at its physiological receptors Further studies of processing enzymes should elucidate the mechanisms by which extracellular and intracellular changes alter the synthesis of opioid peptides in the adrenal gland, and may lead to the development of drugs that specifically affect these processes

We thank Dr Julius Axelrod for his encouragement and support V Y H H and L E E are research associates in the Pharmacology-Toxicology Program, NIGMS

RNA synthesis and cytoplasmic polyadenylation in the one-cell mouse embryo

Kerry B. Clegg & Lajos Pikó

Developmental Biology Laboratory, Veterans Administration
Medical Center, Sepulveda, California 91343, USA
Division of Biology, California Institute of Technology, Pasadena,
California 91125, USA

The time of onset of transcriptional activity in the early mammalian embryo is unclear. RNA synthesis has been shown to occur at the two-cell stage in the mouse[1–4] and at the two- to four-cell stage in the rabbit[5], but the period immediately following fertilization has proved largely inaccessible to biochemical characterization of transcription because of the low permeability of early embryos to exogenous precursors such as ^{3}H-uridine[1–7]. This difficulty, and the failure to detect RNA polymerase activity in the pronuclei of one-cell mouse embryos[8], suggested that the embryonic genome was transcriptionally inactive until some time after the first cleavage. To investigate this issue further, we have now incubated one-cell pronuclear embryos with ^{3}H-adenosine, which is taken up about 1,000 times faster than uridine[3]. Three labelled RNA species could be identified. The major product is large, heterodisperse, poly(A)$^-$ RNA. High-molecular-weight poly(A)$^+$ RNA is also heavily labelled but this is mostly due to cytoplasmic polyadenylation of previously non-polyadenylated, stored RNA. A significant amount of label is incorporated into the -CCA termini of transfer RNA but some new synthesis of tRNA also takes place. No label was found in ribosomal RNA at the one-cell stage but synthesis of mature rRNA species was evident in the two-cell embryo.

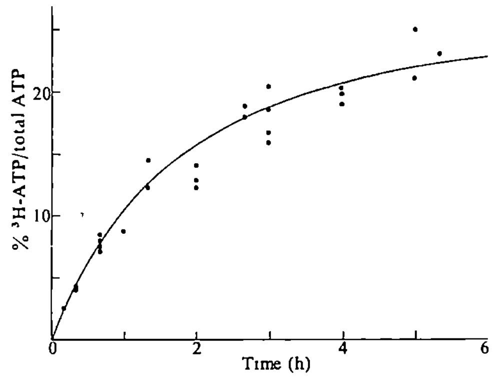

Fig. 1 Specific activity of the ^{3}H-ATP pool in one-cell mouse embryos. Fertilized ova were isolated from superovulated Swiss mice 22–24 h after injection of human chorionic gonadotropin and cultured in a pyruvate–lactate medium (PLM) containing 50 μM [2,8-^{3}H]adenosine (30–40 Ci mmol^{-1}, Amersham) as described previously[3]. At the indicated times 5–10 embryos were removed, the nucleotides extracted with 0.5 M $HClO_4$ at 0 °C, and the extract neutralized and chromatographed on polyethyleneimine (PEI) cellulose[3]. The ATP spot was cut out of the plate, solubilized with NCS tissue solubilizer (Amersham) and counted in OCS scintillant (Amersham). The specific activity of the labelled ATP pool in the mouse embryos was calculated by adding the amount of radioactive ATP to the internal ATP pool (1.1 pmol per embryo[3]) and using this value to derive the fraction of radioactive ATP—pmol ^{3}H-ATP/(1.1 pmol+pmol ^{3}H-ATP). To verify this calculation, pool specific activity measurements were sometimes made in parallel using an isotopic RNA polymerase assay[3]. The results of these assays were within 10% of the calculated value.

Figure 1 illustrates the changes in the specific activity of the total ATP pool in one-cell embryos in the labelling conditions used. The specific activity rises approximately linearly during the first 80 min and increases at a much slower rate during the succeeding 4 h, reaching about 80% of the final specific activity at the midpoint of the labelling period. We used the midpoint specific activity of the ATP pool for estimating the rates of accumulation of the labelled RNA species described below.

The labelled embryo lysates were processed as follows. After extraction with phenol–chloroform, the water phase was made 2 M in LiCl to isolate LiCl-precipitable (large molecular weight) and LiCl-soluble RNA fractions[9]. The latter was freed of labelled nucleotides by precipitation with cetyltrimethylammonium bromide[10]. The LiCl-precipitable RNA was subdivided further into poly(A)$^+$ and poly(A)$^-$ fractions by binding to poly(U)-Sepharose. The individual fractions were analysed as to electrophoretic mobility, sensitivity to RNase and distribution of labelled nucleotides, as described in the figure legends. Special care was taken to denude the eggs of any follicle cells by successive treatments with hyaluronidase and subtilisin[3]. In

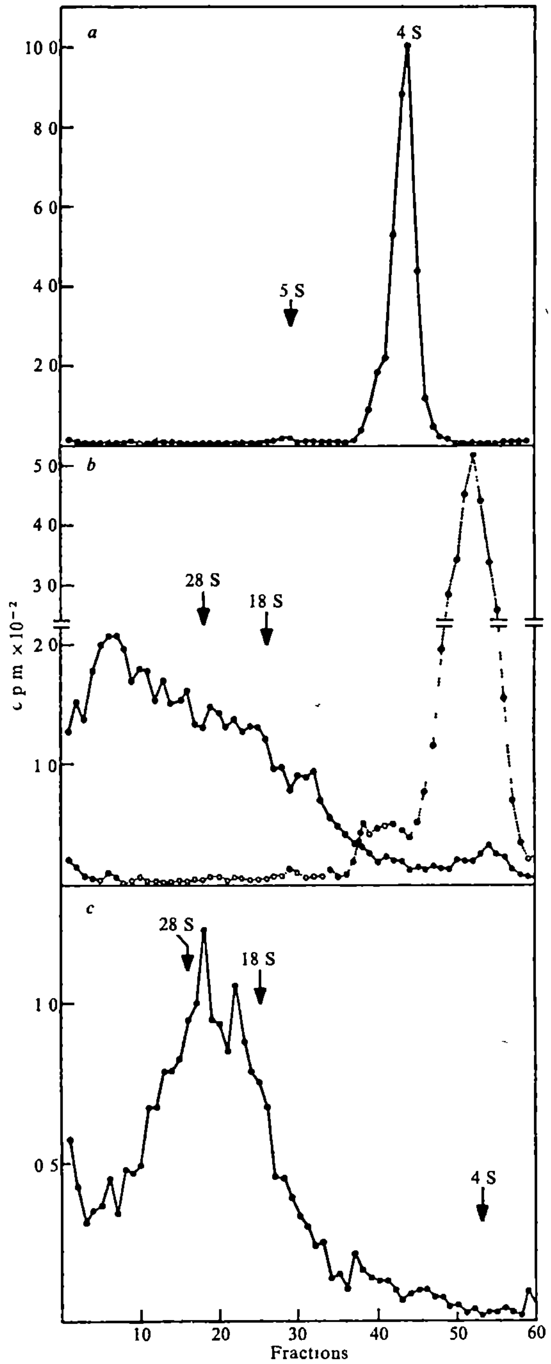

Fig. 2 Electrophoretic patterns of ^{3}H-adenosine-labelled RNAs isolated from one-cell mouse embryos. Fertilized eggs were labelled *in vitro* in PLM containing 50 μM ^{3}H-adenosine for 5–6 h, washed five or six times in HEPES-buffered saline and digested for 30 min at 37 °C in 300 μl extraction buffer (100 mM NaCl, 50 mM Tris-HCl, *p*H 7.5, 5 mM EDTA, 0.5% SDS, 100 μg ml^{-1} proteinase K) containing 10 μg mouse rRNA and 10 μg yeast sRNA (4 S and 5 S) as carriers. The digest was adjusted to 2 M in LiCl and kept at 0 °C for 18 h to precipitate high-molecular-weight RNA[9]. The precipitate was collected and washed three times with ice-cold 2 M LiCl by centrifugation at 70,000*g* for 20 min. The supernatants were pooled and used for the isolation of 4 S and 5 S RNAs. The LiCl-precipitable RNAs were dissolved in 300 μl poly(U)-binding buffer (500 mM NaCl, 10 mM Tris-HCl, *p*H 7.5, 1 mM EDTA, 0.05% SDS) and bound to 30 mg freshly rehydrated poly(U)–Sepharose (Pharmacia) at 37 °C, 15 min in a conical microfuge tube vortexed gently to keep the beads suspended. The unbound poly(A)$^-$ RNA was washed from the beads by centrifugation and resuspension six times in 0.5 ml binding buffer. The washes were pooled and the RNA precipitated with 2–3 vol 100% ethanol at −20 °C. Poly(A)$^+$ RNA was eluted from the poly(U)–Sepharose at 45 °C by six changes of 90% deionized formamide/10% eluting buffer (10 mM Tris-HCl, *p*H 7.5, 1 mM EDTA, 0.05% SDS). The eluate was adjusted to 0.1 M in NaCl, 10 μg of mouse rRNA added and the RNA ethanol-precipitated. The 4 S RNA was collected from the LiCl-soluble fraction by ethanol precipitation and further purified by dissolution in 0.1 M NaOAC, *p*H 5, and reprecipitation with 0.5% cetyltrimethylammonium bromide (CTAB)[10]. The CTAB precipitate was washed extensively with 0.1% CTAB in 0.1 M NaOAc, *p*H 5, to remove soluble nucleotides and the CTAB was removed by washing three times with 70% ethanol/30% 0.1 M NaOAc, *p*H 5. The RNAs were redissolved in Loening's E-buffer[26] (36 mM Tris base, 30 mM NaH_2PO_4, 1 mM EDTA, 0.1% SDS) for electrophoresis. *a*, Pattern of LiCl-soluble RNA from 400 one-cell embryos after electrophoresis in 10% polyacrylamide gel in E-buffer at 5 mA per gel for 3 h, the radioactive peak coincides with the 4 S absorbance marker. *b*, Pattern of LiCl-precipitable, poly(A)$^-$ RNA from 1,000 one-cell embryos after electrophoresis in 2.25% acrylamide–0.5% agarose gels at 5 mA per gel for 2.5 h in E-buffer containing 6 M urea. One-half of the sample was electrophoresed intact (solid line) and the other half after digestion with 100 μg ml^{-1} RNase A + 50 U ml^{-1} RNase T_1 in E-buffer at 37 °C for 30 min (dotted line). Before electrophoresis, the samples were brought to 6 M in urea, heated at 85 °C for 5 min, allowed to cool and layered on the gel. *c*, Pattern of poly(A)$^+$ RNA from 700 one-cell embryos after electrophoresis in 6 M urea as in *b*. All gels were scanned at 260 nm using a Gilford linear transport, sliced in 1.5-mm slices, dissolved in 0.5 ml 90% NCS/10% water at 50 °C for 2 h and counted in OCS scintillant (Amersham) at 30% efficiency.

some experiments, the zona pellucida was completely digested by subtilisin and the polar bodies removed by repeated pipetting of the eggs through a small-bore pipette The amount and distribution of label in the three major classes of RNA was the same in these eggs, suggesting that no significant RNA synthesis occurs in the polar body nuclei The possibility that the egg mitochondria may contribute to the labelling pattern is remote because mitochondrial RNA synthesis has not been detected until the eight-cell stage[11] and we observed no 12S or 16S mitochondrial ribosomal RNA species in the present study

Figure 2*a* shows the electrophoretic pattern of the LiCl-soluble labelled material The large 4 S peak was sensitive to RNase and assumed to be tRNA It was eluted from the gel and analysed further by base hydrolysis and PEI cellulose chromatography of the nucleotides[3] About 83% of the label migrated with the adenosine marker and only about 17% migrated as AMP. Although this indicates that some ^{3}H-adenosine label is incorporated into internal positions, suggesting the synthesis of a small amount of tRNA, it is clear that most of the label is localized in the -CCA terminus, about 60 tRNA molecules being terminally labelled for each newly synthesized tRNA (assuming an average of 14 adenosine residues per tRNA[12]) Terminal labelling presumably reflects the turnover of 3′-terminal adenosine residues[13]

Figure 2*b* shows the electrophoretic pattern of the LiCl-precipitable, poly(A)$^-$ fraction This fraction, which is completely sensitive to RNase, consists of large, heterodisperse RNA with a number-average size[14] of about 2 5 kilobases (kb) The amount of heterodisperse RNA accumulated over a 5-h labelling period was estimated to be ~3 pg per embryo (assuming a 25% adenosine content) However, preliminary studies on the time course of incorporation of ^{3}H-adenosine into this fraction suggest that most of the newly synthesized RNA is turning over rapidly and probably represents heterogeneous nuclear RNA (K B C and L P , unpublished observations) None of the poly(A)$^-$ RNA appears to be ribosomal, as an analysis of the gel pattern of several RNA preparations (as in Fig 2*b*) failed to reveal any evidence of 18 S and 28 S rRNA From the specific activity of the ATP pool, we estimate that the synthesis of as little as 0 03 pg rRNA per embryo during 6 h labelling would have been detected As the rate of synthesis of mature rRNA in the morula is ~2 5 pg per cell per h (ref 15), we conclude that rRNA synthesis in the one-cell embryo, if it occurs at all, is <0 2% of that in the morula on a per cell basis

The LiCl-precipitable, poly(A)$^+$ RNA fraction consists of high-molecular-weight RNA with a number-average size of 1 7 kb (Fig 2*c*) The poly(A)$^+$ RNA peak was completely abolished by digestion with RNase (data not shown) To analyse the distribution of label in this RNA, purified poly(A)$^+$ RNA was digested with RNase A+T$_1$ in conditions which leave the poly(A) tracts intact, and the digest chromatographed on a PEI plate (Fig 3) About one-third of the total label migrated with the AMP marker, suggesting that it was released from an internal location, and about two-thirds remained at the origin, suggesting localization in poly(A) tracts of about (A)$_{20}$ or larger It is unlikely that the label in the AMP peak derived from random cleavage of labelled poly(A) tracts because of the low background between the AMP peak and the origin (where partially digested fragments would appear) and the repeatability of the chromatographic pattern in three separate experiments The number-average size of the labelled poly(A) tracts was (A)$_{50}$, as determined by polyacrylamide gel electrophoresis in relation to poly(A) markers of known length (not shown) To determine what portion of the poly(A) tracts was newly synthesized, we measured the distribution of label between A and AMP by PEI cellulose chromatography of the alkaline hydrolysate of purified poly(A) This procedure gave a ratio of A/AMP of 1 42, or an average length of (A)$_{43}$, suggesting that the labelled poly(A) tracts had arisen mostly, if not entirely, from new synthesis rather than from the elongation of pre-existing tracts From the average size of the labelled poly(A)$^+$ RNA, 1,700 nucleotides, the number of adenosine nucleotides in the non-poly(A) portion of the molecule can be estimated at about 425 (assuming a 25% content in adenosine), about 10-fold higher than the average length of (A)$_{43}$ for newly synthesized poly(A) However, the observed ratio of label in the non-poly(A) portion of the molecule is one-half that in the poly(A) tail, suggesting that only about 5% of the labelled poly(A)$^+$ RNA molecules are newly synthesized, the remainder representing pre-existing maternal mRNA having undergone cytoplasmic polyadenylation As there is about a 20% increase in total poly(A) between fertilization and the late one-cell stage[15] but no increase in the average size of poly(A) tracts (K B C and L P , in preparation), it seems likely that the newly synthesized tracts are added, at least in part, to previously non-polyadenylated RNA Both turnover (and lengthening) of poly(A) and the addition of poly(A) sequences to previously non-polyadenylated RNA occur in fertilized sea urchin eggs and result in a doubling of poly(A) content[16–19] In *Urechis* eggs, total poly(A) increases severalfold as a result of polyadenylation of new RNA sequences on fertilization[20] The present findings suggest that cytoplasmic polyadenylation is an important feature of early mouse development as well A less extensive adenylation, consisting of the terminal addition of short oligo(A) segments to pre-existing poly(A) tracts, has been reported in mouse eggs 1–3 h after fertilization[21] As we used late one-cell embyros for labelling, about 11–17 h after fertilization, the difference may be due to developmental stage-specific changes in cytoplasmic adenylation

Because of the high specific activity that can be attained with the ATP pool, we have re-examined the question of rRNA synthesis by the two-cell mouse embryo Nucleolus organizing activity has been detected by cytochemical (silver) staining at the two-cell stage[22,23], and there is biochemical evidence of a low level of rRNA synthesis (with ^{3}H-uridine labelling)[2] Figure 4 shows the pattern of LiCl-precipitable, poly(A)$^-$ RNA isolated from late two-cell embryos labelled for 6 h with ^{3}H-adenosine Although most of the incorporation is in large heterodisperse RNA, distinct 18 S and 28 S peaks, as well as rRNA precursor peaks, are also evident From the amount of radioactivity under the 18 S and 28 S peaks (~25% of the total), the specific activity of the ATP pool (19%) and the base composition of rRNA (18% adenosine), the rate of synthesis of rRNA at this stage can be estimated at about 0 3 pg per embryo per h On a per cell basis,

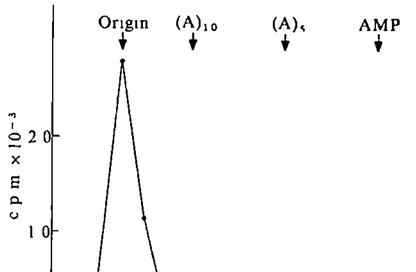

Fig. 3 PEI cellulose chromatography of RNAse A+T$_1$ digest of ^{3}H-adenosine-labelled poly(A)$^+$ RNA from one-cell mouse embryos For labelling conditions and the isolation of poly(A)$^+$ RNA, see Fig 2 legend The ethanol-precipitated RNA was dissolved in 25 μl of 5 μg ml^{-1} RNase A, 10 U ml^{-1} RNase T$_1$ in 300 mM NaCl, 10 mM Tris-HCl, 1 mM EDTA, *p*H 7 5, and incubated at 37 °C for 1 h The digest was mixed with 2–3 μmol each of AMP and the oligomers (A)$_5$, (A)$_{10}$ and (A)$_{33}$ (Miles) and chromatographed on a 2×20 cm PEI plate successively in 100% methanol, distilled water and 1 25 M Tris-HCl *p*H 8 4, to fractionate oligo(A) sequences according to size[27] The plate was cut into 1-cm pieces, digested in 1 ml 90% NCS for 30 min at 22 °C and counted in OCS at 35% efficiency The recovery of labelled nucleotides was better than 90% The position of the markers on the plate was visualized by UV

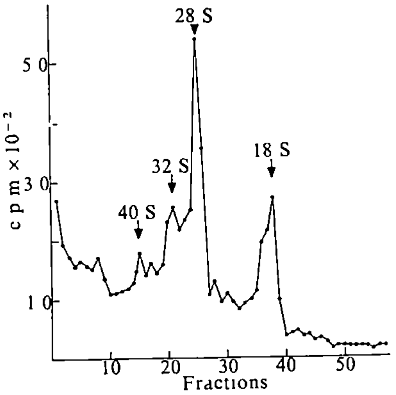

Fig. 4 Electrophoretic pattern of LiCl-precipitable poly(A)$^-$ RNA from 600 two-cell mouse embryos incubated for 6 h (46–52 h post-human chorionic gonadotropin) in the presence of 50 μM ^{3}H-adenosine Any three- to four-cell embryos at the end of the labelling period were removed Electrophoresis was in 2 25% acrylamide–0 5% agarose gels in the presence of 6 M urea For details, see Fig 2 legend

this rate is about one-sixteenth of that in the morula[15] The 4 S RNA peak is also heavily labelled in the two-cell embryo, the distribution of label between the -CCA terminus and internal locations in tRNA being very similar to that observed in the zygote (data not shown), and synthesis of poly(A)$^+$ RNA in the two-cell embryo has been reported previously[4] Therefore all the major classes of RNA seem to be synthesized by the two-cell mouse embryo RNA synthesis intensifies from the eight-cell stage onwards[3], resulting in a sixfold increase in total RNA content between the two-cell stage and early blastocyst[15] As about 40% of the bulk maternal RNA is eliminated by the two-cell stage and at most 30% persists until the early blastocyst[24], a nearly complete shift from the use of maternal to embryo-derived RNA components must take place by the early blastocyst stage The results presented here indicate that transcription has already started in the pronuclei of the zygote The role of the RNA products and the significance of cytoplasmic polyadenylation in the one-cell embryo remain to be elucidated An interesting possibility is that cytoplasmic adenylation may be involved in the selective activation of subpopulations of maternal mRNA which has been reported to take place around the late one-cell to early two-cell stage[25]

Calcitonin is a small peptide hormone (molecular weight (MW) 3,500) synthesized and secreted in mammals by the C-cells of the thyroid[1,2]. In man a major role of calcitonin is to protect the skeleton during periods of calcium stress such as growth, pregnancy and lactation[3]. Excessive calcitonin levels are associated with familial and sporadic medullary carcinoma of the thyroid[4], and in some cases with ectopic synthesis often by small oat-cell carcinoma of the lung[5]. Evidence from mRNA-directed cell-free protein synthesis suggests that in common with other small peptide hormones[6], human calcitonin is synthesized as a high-molecular-weight precursor protein[7–9]. Recently, we described the construction and partial characterization of recombinant plasmids containing human calcitonin cDNA sequences[9]. Here we demonstrate by nucleotide sequence analysis of these cloned cDNA sequences that human calcitonin resides towards the carboxy terminal of a precursor polyprotein, and is flanked at the amino and carboxy termini by cryptic peptide sequences of unknown biological significance. The cryptic peptide present at the carboxy terminus differs significantly in amino acid sequence from that present in the rat calcitonin precursor polyprotein[10–12].

We have previously described the identification and partial characterization of two cDNA clones (phT-B3 and phT-B6) containing in total an estimated 60% of a mRNA 1,000±100 nucleotides long This mRNA, isolated from a human medullary carcinoma of the thyroid, directed the synthesis in a wheat-germ cell-free system of a 21,000-MW calcitonin precursor protein, as judged by immunoprecipitation and SDS polyacrylamide gel electrophoresis[9] Nucleotide sequence analysis[13] of both cloned cDNA sequences revealed that the larger cloned fragment (phT-B3) contained most of the 3′-untranslated region of the mRNA and a sequence encoding 93 amino acids The smaller cloned fragment (phT-B6) contained the complete 3′-untranslated region, and a sequence encoding 37 amino acids No differences were detected in the nucleotide sequence of cDNA that was common to both plasmids Examination of the 93 amino acids encoded within the cloned 5′ portion of the mRNA (Fig 1) revealed a tract of 33 amino acids comprising the expected sequence of human calcitonin[14 15], with an additional glycine next to the carboxy-terminal proline This sequence is located towards the carboxy end of the precursor protein, and is separated from the adjacent cryptic peptide sequences by basic amino acid residues, presumably sites for proteolytic cleavage[16] The presence of a glycine residue immediately adjacent to the carboxy-terminal proline in the calcitonin precursor reflects the requirement of an amidated carboxy-terminal proline in the fully processed calcitonin, in common with other peptides including rat calcitonin, which contain carboxy-terminal amidated amino acid residues and are synthesized as larger precursor proteins[10–12 17]

Comparative analysis of nucleotide sequence homologies in the coding region of the human and rat[10–12] calcitonin mRNAs (Fig 1) and in deduced amino acid sequences (but excluding gap

Fig. 1 Nucleotide sequence of human calcitonin precursor polyprotein mRNA cloned into phT-B3 and phT-B6 The figure compares the known common nucleotide sequence of human and rat[10–12] calcitonin precursor polyprotein mRNA sequences, as determined by DNA sequence analysis of the cloned cDNA sequences, with gaps introduced to maximize homologies Numbers immediately above the human nucleotide sequence denote the relative number of nucleotides from the poly(A) tail Numbers above the human protein sequence refer to amino acid position amino-terminal cryptic peptide −1 to −36, calcitonin, 1–32, carboxy-terminal cryptic peptide, +1 to +25 Base substitutions are indicated by dots Where replacement base substitutions have occurred or the human nucleotide sequence is not present, the alternative or additional amino acid(s) present within the rat precursor polyprotein have been shown immediately below the codon(s) in question Boxed sections of the amino acid and nucleotide sequences indicate regions discussed in the text DNA sequence determination was performed on both strands of the cloned cDNA sequences (phT-B3 and phT-B6) using the procedure of Maxam and Gilbert[13]

sequences introduced to maximize homology) revealed greater nucleotide (85 0%) than amino acid (80 7%) sequence homology Of the 88 codons considered, we found one or more base substitutions within 32 of the codons (36 4%), and of these, 17 (53 1%) represent replacement substitutions The distribution of the replacement and silent substitutions differs, however, between those regions encoding the amino- and carboxy-terminal cryptic peptides and those encoding calcitonin, a situation reflected in the variation in amino acid sequence in the three peptide domains Thus the nucleotide sequence encoding human calcitonin (amino acids 1–32) contains seven silent and two replacement substitutions In contrast, comparison of the nucleotide sequences encoding the flanking cryptic peptides (amino acids −1 to −36, and +1 to +25), particularly the carboxy-terminal peptide, shows a preponderance of replacement substitutions Furthermore, the relative difference in amino acid sequence between human and rat flanking peptides is exaggerated by the presence of an additional dipeptide in the rat amino-terminal cryptic peptide (between positions −19 and −18 of the human sequence) and of a pentapeptide sequence immediately preceding the terminal asparagine of the human carboxy-terminal cryptic peptide which is absent from the corresponding rat peptide A computer search for homologies within established protein sequences failed to reveal homology between the human cryptic peptides and other structural or biologically active peptides Moreover, there seems to be no significant nucleotide homology between the sequence encoding human calcitonin and that present in the human pro-opiocortin mRNA, thought to encode a calcitonin-like peptide[18 19]

The 3′-untranslated region of the human calcitonin mRNA consists of 299 nucleotides including the termination codon UAA Two potential termination codons closely follow the authentic codon The first of these (UAA) remains in phase, while the second is not in phase In common with other eukaryotic mRNAs, the supposed polyadenylation enzyme recognition sequence AAUAA is present 13 nucleotides from the site of poly(A) addition[20] A palindromic-type sequence (5′ AAAAUACCAGAAAA 3′) is also present 100 nucleotides from the poly(A) tail

Although we have yet to identify and sequence cDNA clones that contain the remaining 300–400 nucleotides comprising the 5′ end of the human calcitonin mRNA, and which encode the remainder of the amino-terminal cryptic peptide sequence and presumably an amino-terminal leader sequence, our observations are important for various reasons. Human calcitonin is another of the increasing number of small peptide hormones now known to be synthesized as higher-molecular-weight precursor proteins and subsequently processed to yield one or more biologically active peptides[6] Whether the human calcitonin precursor proves to be a true polyprotein, in the sense that two or more secreted biologically active peptides are specifically processed from a common precursor, remains to be established Our comparative analysis of the nucleotide sequences encoding the human and rat calcitonin peptides implies that both have evolved from a common ancestral gene, and that selection pressures have eliminated base substitutions which might result in adverse alteration of codon specificity The accumulation of silent or supposedly neutral substitutions presumably reflects evolutionary divergence as a result of genetic drift[21] In contrast, the amino- and carboxy-terminal cryptic peptide sequences have diverged to the extent that the latter, in particular, may have acquired different functions in rat and man Equally it might be argued that such extreme sequence divergence implies that the flanking peptides do not have a significant biological role, but are present merely to ensure that the calcitonin precursor protein is in the correct conformation for processing within the secretory pathway Chemical synthesis of the human cryptic peptide sequences should resolve questions related to biological function, antibodies raised against each peptide may be used to investigate the processing of the calcitonin precursor polyprotein, and to determine the presence and levels of the circulating cryptic peptides in subjects of different age, and in varying conditions of calcium stress[3] The antibodies may also be used to characterize high-molecular-weight circulating variants of human calcitonin often associated with ectopic synthesis and secretion[5]

The availability of a cloned human calcitonin cDNA probe will allow comparisons to be made between human calcitonin gene structure and expression in normal thyroid tissue, and in familial and sporadic medullary carcinoma of the thyroid cDNA probes could also be used to investigate linked DNA polymorphisms, thereby providing a quick and reliable means of distinguishing between familial and sporadic medullary carcinoma of the thyroid, avoiding extensive and often invasive investigations[22,23] Finally, the probes may be used for definitive studies of the molecular mechanisms involved in ectopic synthesis of calcitonin

We thank Professor P N Campbell for his continued support and encouragement and Dr M O Dayhoff of the National Biomedical Research Foundation for the computer search for homologies within the cryptic flanking peptides

Heterogeneity of the BALB/c IgM anti-phosphorylcholine antibody response

Judith A. Owen*, Nolan H. Sigal† & Norman R. Klinman‡

Although recent advances in the study of the molecular genetics of the antibody system have greatly increased our understanding of the generation of immunological diversity[1–7], the state of B-cell differentiation at which diversification and specificity commitment occur has yet to be determined. In particular, it is unclear whether the entire repertoire of antibody specificities in an individual is expressed in the absence of selective forces, such as antigenic stimulation or network regulation. It has recently been suggested that some elements of variable region diversification, particularly somatic mutations, may accompany the shift from the IgM to IgG isotype[8–10]. These findings support the view that much of B-cell repertoire diversity is the result of antigen-driven somatic events, because isotype shifts normally occur after antigenic stimulation[11–13]. As these experiments used antibodies obtained after at least one *in vivo* antigenic stimulation, they do not address the possibility that the selection occurring during clonal expansion and subsequent IgG synthesis may favour the use of clones expressing unique antibody specificities (clonotypes) far removed from the innate or frequently occurring germ-line sequences. To test whether B-cell diversification may precede IgM expression, we have now determined the range of diversity available in the primary IgM antibody repertoire by studying the clonal heterogeneity of monoclonal IgM antibodies expressed by BALB/c mice in response to phosphorylcholine (PC). Our results indicate that the repertoire of IgM antibodies in an inbred murine strain exceeds 10^7 clonotypes. This diversity is sufficiently large to preclude meaningful comparisons between the IgM and IgG repertoires and suggests that antibody diversification may occur early in B-cell differentiation.

Spleen cells from non-immune adult BALB/c mice were injected intravenously into irradiated (1,300 rad) BALB/c recipients that had been immunized with 0 1 mg of *Limulus polyphemus* haemocyanin (Hy) 1–2 months previously Splenic fragment cultues were established as described elsewhere[14 15] and stimulated with 3-*p*-azophenyl-phosphorylcholine-*N*-acetyl-L-tyrosyl-glycylglycine-BOC-hydrazide–Hy to obtain monoclonal anti-PC responses[15] A radioimmunoassay (RIA) was used to identify fragment cultures containing monoclonal anti-PC antibodies and to determine the immunoglobulin isotype[16] Similar to previous results[15], one B cell in 8×10^4 produced monoclonal anti-PC antibodies which were idiotypically indistinguishable from the TEPC-15 (T15) myeloma protein by either purified rabbit anti-T15 idiotype antibody or anti-idiotypic antisera raised in A/J mice using assay methods and reagents which have been previously described[15] An additional 1 in 10^5 B cells yielded non-T15 anti-PC monoclonal

Table 1 Classification of monoclonal antibodies into indistinguishable groups by the criterion of hapten inhibition of antibody binding

Monoclonal antibodies had hapten inhibition profiles which were unique or representative of several antibodies The haptens PC, α-glycerophosphorylcholine (GPC) and choline (C) were used to inhibit binding by monoclonal antibodies to polyvinyl plates coated with the antigen PC–BSA by a method reported previously[17] 0 1 ml of the appropriate hapten in phosphate-buffered saline (PBS) was added individually to each well The plates were incubated for 2 h at room temperature and then washed and labelled with ^{125}I-labelled anti-μ antibody After incubation at 4 °C overnight and washing, each well was counted in a γ-counter Each culture fluid was run in triplicate for each hapten concentration and controls in quadruplicate with PBS The percentage of control binding which remained in the presence of each hapten concentration tested was then calculated IC_{50} is expressed here as the concentration of hapten (in mmol) giving 50% inhibition of binding

0028–0836/82/040347—02$01 00

antibodies and 109 of these, derived from 14 donors, produced sufficient IgM antibody (> 100 ng) to permit a comprehensive analysis

The fine specificity of the non-T15 IgM anti-PC monoclonal antibodies was assessed by hapten inhibition (HI) of their binding to phosphorylcholine–bovine serum albumin (PC–BSA)[17] Using the standard errors derived from replicate assays of both T15-positive and T15-negative IgM foci, we estimate that two antibodies can be distinguished from one another if their IC_{50} values differ by greater than twofold for any of the three haptens Table 1 gives the IC_{50} values of all 109 non-T15 IgM antibodies Twenty-three HI patterns were observed The reactivity patterns of focus 5112 and those of 44 other non-T15 antibodies are indistinguishable from that of the T15 myeloma protein and 26 tested IgM monoclonal antibodies bearing the T15 idiotype The single focus (5275) reactive with a rabbit anti-MOPC 167 idiotypic serum is also indistinguishable from MOPC 167 by reactivity pattern analysis Insofar as hapten inhibition of binding can be used as a measure of affinity of antibody for antigen[18], it is clear that non-T15 IgM monoclonal antibodies exist which possess both higher and lower affinity for PC than does the T15 myeloma protein

To discriminate further between the antibodies with indistinguishable HI patterns, the isoelectric points (*p*I) of all 109 antibodies were determined by sucrose gradient isoelectric focusing (IEF)[19] The *p*Is of the 45 antibodies which shared HI properties with the T15 myeloma protein ranged from *p*H 3 35 to *p*H 6 05 Similarly, the *p*Is of antibodies indistinguishable by HI analysis from foci 5292 and 5388 were *p*H3 7–6 4 and *p*H 3 9–5 95 respectively Since antibodies that focus at isoelectric points > 0.2 *p*H units apart can be unambiguously distinguished from one another, each group of antibodies defined by HI criteria could be subdivided on this basis

As a final criterion for discriminating antibodies not clearly distinguishable by HI or IEF, each IgM monoclonal antibody was assessed for partial reactivity with rabbit or mouse anti-T15 idiotype specific antisera Of the 109 non-T15 antibodies, 42 displayed partial cross-reactivity with the mouse anti-T15 idiotype Of these, 23 displayed no reactivity with the rabbit anti-T15 reagent, 3 reacted with the rabbit anti-T15 on a 1 1 weight basis and 16 showed partial reactivity One other antibody reacted with the rabbit anti-T15 reagent 1 1 by wt but showed no cross-reactivity with mouse anti-T15 None of the four antibodies showing complete reactivity with rabbit anti-T15 shared HI characteristics with the T15 protein (for example, antibodies 5358 and 5635, Table 1) However, of the 42 antibodies displaying partial reactivity with mouse anti-T15, 24 (57%) shared the HI pattern of the T15 protein, which may imply a preferential, but not absolute, association of partial mouse anti-T15 reactivity with T15 HI characteristics

Because the distinguishing criteria for each method were set well within their discriminatory limits, some groups of antibodies classified as indistinguishable by our criteria may not be identical by amino acid sequencing On the other hand, differences among antibodies detected by the identification techniques used are unambiguous

By combining all three methods, monoclonal antibodies displaying 60 distinct sets of properties could be discerned among the sample of 109 splenic foci tested Statistical treatment of single (42) versus recurrent (18) clonotypes (counting clonotypes which recur in an individual only once to avoid the effects of clonal expansion[20]) gives a minimum extrapolated value for total IgM anti-PC clonotypes in BALB/c mice of $>10^2$ (ref 21) Note that the vast majority of B cells responding in these conditions can be classified as primary by several criteria[22]

By far the most important implications of the present study relate to the question of the degree of diversity in the primary IgM repertoire Several recent findings have been interpreted as demonstrating that the IgM repertoire is far more restricted in clonotype heterogeneity than the IgG repertoire and that diversification may occur at the clonal level in conjunction with the switch from IgM to IgG production[8–10] Gearhart and colleagues have sequenced a set of hybridoma IgM and IgG anti-PC antibodies, both positive and negative for the T15 idiotype[8], and find that the variable region amino acid sequences of all the IgM antibodies are identical to that of a germ line-encoded variable region gene, whereas the sequence of the IgGs differ considerably from their germ-line counterparts As IgG is known to eventuate from clones which also express IgM[11–13], the finding that IgG diversity may exceed IgM diversity is consistent with the postulate that both diversification and IgG commitment are consequences of antigenic stimulation

An alternative possibility is that all diversification occurs at the stem cell stage before surface immunoglobulin expression by expanded B-cell clones[23] If this were the case, then the apparently greater diversity of the IgG, compared with the IgM, repertoire would be the result of differential selection and expansion of particular pre-existing clones from an already vast repertoire, rather than a consequence of *de novo* antigen-induced diversification Indeed, that a MOPC 167-like specificity is expressed in the IgM repertoire suggests that a clone which is a likely somatic variant of the T15 germ-line V_H[6] and V_L[7] sequences can be triggered in the primary IgM immune response given the appropriate stimulatory conditions However, this possibility could be verified only by analysis of the relevant antibody or nucleotide sequences

The findings reported here demonstrate the extreme diversity of the IgM primary B-cell repertoire Non-T15 B cells represent 1 in 10^5 of all responsive B cells and display at least 10^2 IgM clonotypes, including one which is indistinguishable by idiotypic and HI characteristics from MOPC 167, a known somatic variant[6,7] If such clonotypes are representative of the repertoire as a whole, then an inbred murine strain can synthesize $>10^7$ different IgM antibodies Such diversity effectively precludes accurate comparisons between repertoires of individuals or repertoires expressed in one isotype compared with another These data do not prove that the IgM repertoire is as diverse as the IgG repertoire, but do suggest that conclusions concerning the diversity of the IgM and IgG repertoires may be premature, as the apparent restriction observed in the IgM repertoires may be an artefact of the sampling techniques Conclusive proof that diversification accompanies isotype switch will come only from amino acid sequence analysis of antibodies of two isotypes derived from a single B-cell clone.

Excision of polyoma virus genomes from chromosomal DNA by homologous recombination

Luigi Lania*, Sharon Boast & Mike Fried

Imperial Cancer Research Fund, Lincoln's Inn Fields,
London WC2A 3PX, UK
*Istituto di Biologia Generale e Genetica, Università di Napoli, Italy

Head-to-tail tandem duplications of DNA sequences have been observed to occur naturally in chromosomal DNA of mammalian cells[1,2] and head-to-tail tandem arrays of DNA sequences can be induced upon gene amplification[3,4]. In these cases such sequences have not been detected as free or plasmid forms. After transformation by the two papovaviruses, polyoma and simian virus 40 (SV40), the viral DNA sequences integrated into the host chromosome are often found in head-to-tail tandem arrays[5-11]. When either a partially permissive environment for viral DNA replication exists (polyoma-rat or SV40-human cells) or after fusion of non-permissive transformed cells with permissive cells (polyoma-mouse or SV40-monkey cells), free viral forms are induced provided that a functional viral replication protein and a competent viral origin of DNA replication are present[12]. These results have led to the hypothesis that excision of integrated sequences occurs by viral DNA replication within the chromosomal DNA[6,13]. We show here that free polyoma molecules can be excised from partial head-to-tail duplications of integrated viral sequences in the absence of a functional viral replication protein (large T antigen [T-Ag]) after fusion of transformed rat cells (partially permissive) to permissive mouse cells. The amount of free viral forms produced appears to be proportional to the extent of duplicated integrated viral sequences.

Table 1 gives some properties of the five polyoma-transformed rat cell lines used One cell line, polyoma-rat, contains multiple inserts of integrated viral sequences, free viral genomes and at least one complete early region containing an intact coding region for the polyoma large T-Ag The maps of the single inserts of the integrated viral sequences of the other four lines are shown in Fig 1 These lines do not contain free viral forms or an intact coding region for the polyoma large T-Ag All five lines contain intact coding regions for, and produce, the polyoma small and middle T-Ag species, one or both of which are involved in polyoma-mediated transformation[7 14-19] Only the polyoma-rat cells contain functional polyoma large T-Ag of molecular weight 100,000 (ref 7), whereas the 2b-C2, 2b-C3 (ref 20) and 7axT (ref 14) lines contain other anti-T-Ag immunoreactive proteins which may be truncated forms of the large T-Ag (Table 1) No anti-T-Ag immunoreactive proteins other than the polyoma small and middle T-Ags are detectable in the 53-rat cells[7]

The 53-rat and 2b-C3 inserts contain partial head-to-tail tandem duplications of viral sequences which are respectively 1 17-1 34 and 1 05-1 32 genomes long[7 20] These two lines are able to form an intact coding region for the polyoma large T-Ag as a result of homologous recombination within the duplicated sequences Duplicated viral sequences are not found in either the 7axT (0 79 genome) or the 2b-C2 (0 97-1 0 genome) inserts[14 20]

All five lines were fused either to themselves or to mouse cells and the fused cells were assayed for free viral forms (at varying times) or the production of infectious virus (after 5 days) In the self-fused cells, free viral forms were found only in the polyoma-rat cells (also present in the unfused polyoma-rat cells), no virus was detected (<50 plaque-forming units (PFU) per 10^6 cells) in the self fusion of the polyoma-rat cells The production of both free viral genomes and infectious virus was detected after fusion to mouse cells of polyoma-rat and the two lines, 2b-C3 and 53-rat, containing partial duplications of viral sequences (Table 1, Fig 2) Free viral DNA could be detected as early as 12 h after fusion of 53-rat or 2b-C3 to mouse cells (data not shown) In the two lines that did not contain partial duplications of viral sequences, 2b-C2 and 7axT, no free viral forms or infectious virus could be detected after fusion to mouse cells (Table 1, Fig 2) In the fusions of 2b-C3 and 53-rat with mouse cells, the amount of viral DNA and infectious virus produced (Table 1, Fig 2) seems to be related to the amount of duplicated viral sequences present (more in 53-rat than in 2b-C3), suggesting that excision may be a function of the target size for possible recombination events as has been observed in other systems[21-24]

The production of detectable levels of free viral DNA from 2b-C3 and 53-rat after fusion to mouse cells presumably occurs in two steps The first step would be the excision of a complete viral genome by homologous recombination in the duplicated sequences forming a viral molecule, with an intact coding region for the viral replication protein (large T-Ag) The second step would be amplification of the complete viral genomes by large T-Ag-dependent replication in the permissive environment supplied by the mouse cells As no large T-Ag was detectable before fusion, we conclude that the excision event does not depend on replication at a viral origin as a result of a virus-encoded replication protein as has been postulated for SV40[13] We cannot rule out the possibility that replication in either the

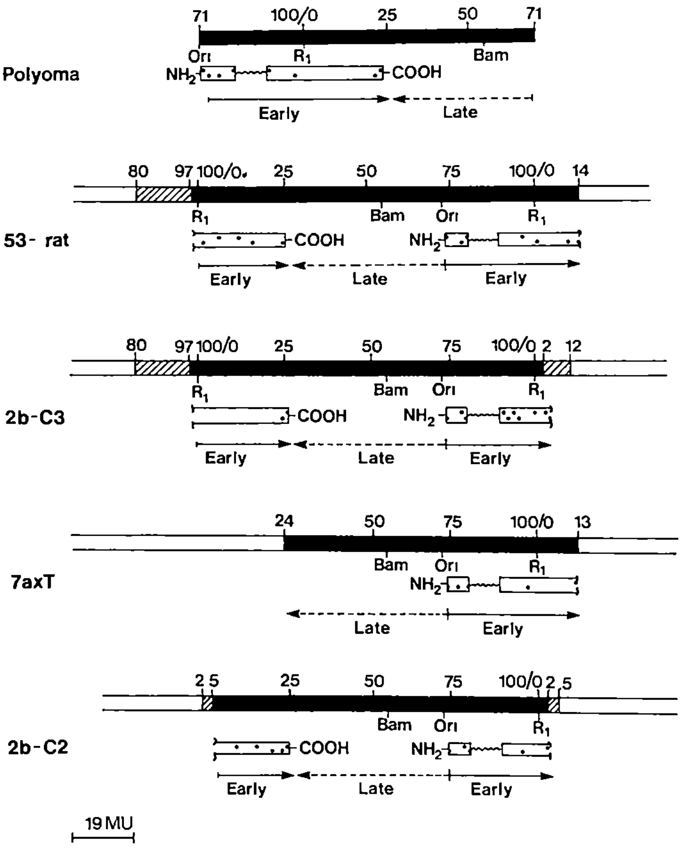

Fig. 1 Maps of the integrated viral DNA sequences in 53-rat, 2b-C3, 7axT and 2b-C2 cell lines as determined by Southern blot hybridization[7 14 20] and molecular cloning (A Hayday, E Ruley, L L and M F, in preparation) The heavy lines represent integrated polyoma DNA sequences The hatched boxes define the regions in which the viral and cellular DNA sequences are joined The positions of the cleavage sites for *Eco*RI and *Bam*HI, the coding region for large T-Ag and the direction of the viral early and late transcription units are indicated Ori represents the origin of the viral DNA replication The region of the DNA not represented in the mRNA for large T-Ag (spliced-out) is indicated by a wavy line The map of polyoma DNA (top) is linearized at the Ori position The numbers above the map of each line are map units (MU) as defined by Griffin *et al*[29]

0028-0836/82/040349—02$01 00

Table 1 Properties of the five polyoma-transformed rat cell lines used

	Viral DNA state		T-antigen species				After fusion with mouse cell	
Cell lines	Free	Integrated	Large-T (100,000)	Middle-T (55,000)	Small-T (22,000)	Others	Free DNA*	PFU per 10^6 cells fused†
Polyoma–rat	+	Multiple inserts tandem duplication	+	+	+	None	+++	2×10^8
53-rat	−	Single insert tandem duplication (1 17–1 34 genome)	−	+	+	None	++	5×10^6
2b-C3	−	Single insert tandem duplication (1 05–1 32 genome)	−	+	+	(50,000)	+	2×10^5
7axT	−	Single insert (0 79 genome)	−	+	+	(75,000)	−	<50
2b-C2	−	Single insert (0 97–1 genome)	−	+	+	(78,000)	−	<50

The organization and expression of the polyoma DNA sequences of the cell lines used have been reported previously polyoma–rat and 53-rat (ref 7), 7axT (ref 20), 2b-C2 and 2b-C3 (ref 14) Numbers in parentheses are molecular weights

* The presence of free viral DNA was determined as described in Fig 2 legend + Indicates the relative abundance of polyoma DNA in the Hirt supernatants

† 10^6 transformed cells were seeded together with 5×10^6 mouse embryo cells in 90 mm Petri dishes After 24 h at 37 °C the cells were fused using the polyethylene glycol procedure described by Pontecorvo[28] The cells were then incubated at 37 °C for 5 days, then collected and assayed for the presence of infectious virus The average value of six independent experiments is shown

integrated viral sequences or the adjacent host DNA sequences was not induced by fusion with the mouse cells It is also possible that the fusion event itself enhances homologous recombination, resulting in the excision of complete viral genomes Although we could not detect free viral genomes before fusion it is possible that homologous recombination was occurring at a low level in the 2b-C3 and 53-rat cells but the amount of excised genomes, which do not replicate efficiently in the rat cells, was below our detection level unless amplified by replication in the permissive environment supplied by the mouse cells Recently, Varmus *et al*[25] have also reported the excision of Moloney murine leukaemia virus DNA from cellular DNA apparently by homologous recombination between repeated sequences at the ends of the provirus

Our results may have implications for cellular DNA A mechanism of rearrangement of genetic information may involve homologous recombination in head-to-tail tandemly duplicated cellular DNA sequences, with the excised circular DNA becoming inserted in another region of cellular genome It would be interesting to know whether the 'minicircles' observed by others[26 27] in many cell types are actually derived from duplicated cellular sequences

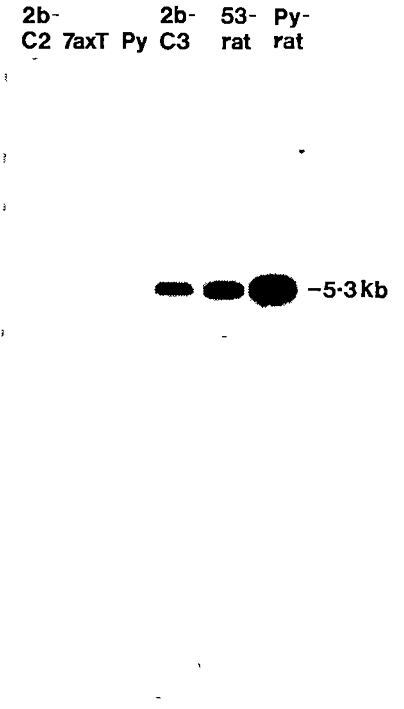

Fig 2 Detection of free viral DNA 24 h after fusion of the transformed cell lines with mouse cells Transformed cells from each of the five cell lines were fused with mouse cells as described in Table 1 legend The presence of free viral DNA was determined after fractionation of the cellular DNA using the SDS-salt precipitation method of Hirt[30] The Hirt supernatant DNAs were extracted with phenol, ethanol-precipitated, then treated with RNase (50 μg ml^{-1} for 3 h at 37 °C), extracted with phenol and ethanol-precipitated For each sample, 5 μg of Hirt supernatant DNA were cleaved with *Eco*RI and the resulting fragments analysed by electrophoresis through a 1% agarose gel The DNA in agarose gel was transferred to nitrocellulose paper according to the procedure of Southern[31] After transfer the filters were hybridized as described previously[7 20] with a polyoma DNA probe The polyoma DNA was labelled *in vitro* by nick-translation[32] to a specific activity of 2×10^8 c p m μg^{-1} After hybridization the filters were washed in 0 6% SSC, 0 1% SDS for 2–3 h at 68 °C The filters were then exposed to Fuji Rx film in the presence of intensifying screen Fuji Mach II at −80 °C for 16 h Lane Py contains 50 pg of the linear form (*Eco*RI cleaved) of polyoma DNA Long exposure (1 week) of the filter does not reveal any other bands When the *Eco*RI digestion was omitted, the Hirt supernatants of the heterokaryons of 2b-C3, 53-rat and Py–rat showed only the presence of free viral molecules as forms I and II kb, Kilobase

BOOK REVIEWS

Intellectual underworld

P.B. Medawar

Science: Good, Bad and Bogus. By Martin Gardner. Pp.408. ISBN 0-87975-144-4. (Prometheus: 1981.) $18.95.

Martin Gardner — urbane, amused and even-tempered.

THIS is a timely book for a number of reasons. Some simple people — canny, they imagine themselves to be — ever on their guard against being imposed upon by scientific and medical "establishments" are still willing to believe in those brilliant lone geniuses whose work was ridiculed by the establishment before being triumphantly vindicated. Such people have a natural taste for fringe medicine, spoon bending and such. A sharp corrective was needed and this book supplies it. Even if it will not be read by those most urgently in need of the lessons it teaches, it will be read delightedly by scientists. Gardner warns those with paranoid views on the establishment not to "forget that for every example of a crank who later became a hero there were thousands of cranks who forever remained cranks". He is rightly indignant at the way in which TV programmes have sometimes disparaged the establishment to support fringes: when a responsible watchdog committee reproached a number of NBC officials for that network's "outrageous pseudodocumentaries about the marvels of occultism one official shouted in anger 'I'll produce anything that gets high ratings!'."

Gardner's book is made specially readable by his deliberate avoidance of detailed analytic criticisms of the exhibits in his museum — believing it not worth while to explain just why he himself does not believe Venus to have been a rogue satellite of Jupiter that passed by the Earth en route to its present orbit — nor does he stoop to criticize the idea that the Earth is pancake shaped. No: Gardner's technique is to allow his subjects to speak for themselves and condemn themselves out of their own mouths. Thus of a work on *dianetics* ("the science of mental health") he simply invites us to share his consternation at its authors' having said "The creation of dianetics is a milestone for man comparable to his discovery of fire and superior to his invention of the wheel and arch". Examples then follow.

Perhaps because of President Reagan's well-known predilection for creationism, Gardner relaxes his self-imposed ordinance against analytic criticism when he turns to the opponents of evolution who hold the at one time popular view that existing fossils are relics of life before the flood. An old view, this (was it not Cuvier who named a fossil ichthyosaur as *Homo diluvii testis* — man-witness-of-the-flood?). We need not wonder that much of Gardner's copy comes from the United States because the USA is so enormous, and so numerous are its schools, colleges and religious seminaries, many devoted to special religious beliefs ranging from the unorthodox to the dotty, that we can hardly wonder at its yielding a more bounteous harvest of gobbledegook than the rest of the world put together. Gardner devotes special attention to the anti-evolutionary views of a retired professor of geology at the Walla Walla College in Washington who was cited as an authority by William Jennings Bryan during the famous Scopes trial.

Some of the best passages in the book deal with that genuinely sad figure, the hermit scientist, a paranoic who is driven into the occupation of a tiny little world of his own to protect himself from what he thinks of as the uncomprehending enmity of orthodox scientists who reject his views out of jealousy or frank ignorance. Sometimes

> around the Master will cluster a group of ardent admirers — either disciples whose own psychological demands find identification with those of the Master, or simply naive cultists who lack the knowledge to penetrate the Master's self deceptions.

Some of Martin Gardner's marvels of pseudoscience are effectively frauds, though they may have begun in good faith: thus of the discredited cancer cure Krebiozen he says that it consists of "nothing more than creatine" — an inexpensive chemical already present in the body. Though retailing at about 30 cents a gram, a dose containing a fraction of a milligram was meted out in return for a "donation" of $9.50 and its backers quoted the Government a price of $170,000 per gram. Another such bogus medicament was safflower oil prepared from the flowers of *Carthamus tinctorius* L. and sold in conjunction with a "worthless best-seller" *Calories Don't Count*; it provoked the FDA into impounding both book and capsules though the book still sells as a paperback, doubtless because of the welcome message its title brings. As Gardner says:

> It will be a long time until the average citizen is well enough informed about science to make the promotion of popularly written pseudo-scientific books unprofitable. And as long as they are profitable you can be sure they will be written and printed.

Gardner's book adds special weight to a distinction I myself am fond of drawing between natural science and unnatural science. The unnatural sciences ape the manners and the outward appearance of real science. They are especially distinguished by the belief that the use of the computer is a sign of scientific manhood and almost a guarantee of authenticity. The outward appearances to which I refer are the use of long and impressive-sounding words, the profligate invention of abstract concepts and above all the use of a literary style that obfuscates more often than it makes clear.

Generally speaking Gardner is urbane, amused and even-tempered in his condemnations of the bogus, but there is one subject that can be relied upon to bring him out of his corner with arms already flailing: this is occultism, written to pander to a public with a genuine predilection for the mysterious. Horoscopes for dogs, the infiltration of the human mind by thought waves from dolphins arouse his genuine indignation.

Not all scientific nonsense is written by cranks though: quite a lot of it is the work of scientists themselves, very often of scientists who, not content with the research upon which they can speak with some authority, asseverate upon difficult subjects of which they have no deep understanding. Such are electrician–eugenicists, astronomer–microbiologists and all scientists hungry for the recognition or applause their fellow scientists have so far withheld from them. Sometimes, too, to make a good story, inexperienced scientists are cajoled by interviewers into making presumptuous claims for their work, after which instead of withdrawing as gracefully as the situation allows they feel honour bound to stand by their ideas. ☐

Collected receptors

G.L.E. Koch

Towards Understanding Receptors. Current Reviews in Biomedicine, 1. Edited by John W. Lamble. Pp.233. ISBN 0-444-80339-4. (Elsevier/North-Holland Biomedical: 1981.) $25, £7.

RECEPTORS participate in a wide variety of cellular processes, ranging from intercellular communication to the absorption of nutrients from the environment. Indeed, the term "receptor" is used so widely that a universally acceptable definition is not possible, and perhaps the only necessary criterion is that the receptor should be a cellular constituent capable of binding a ligand and generating a response. However, even this leaves open the questions relating to natural and unnatural ligands and responses, and illustrates the importance of emphasizing the context in which the word is used.

In this book, it refers to the receptors which have interested pharmacologists for many decades, that is, those involved in the actions of hormones, transmitters, drugs and toxins. The book consists of over 30 relatively short articles which appeared originally in *Trends in Pharmacological Sciences*, and which relate to the role of receptors for such ligands as acetylcholine, noradrenaline, dopamine and opiates.

The brevity of the contributions permits a wide range of subjects to be covered, but it does mean that there is a tendency towards dogmatism and polemic. However, if one approaches the book as an introduction to the current status of a variety of subjects on receptors, one cannot fail to find it an enjoyable and profitable read. It is likely that with the ever-growing information explosion on specialized subjects, there will be an increasingly important role for books such as this, which serve as a halfway house between the popular *New Scientist* and the more weighty *Annual Reviews*. ☐

Gordon Koch is at the MRC Laboratory of Molecular Biology, Cambridge.

Soil chemistry: an open book

T.S. West

The Chemistry of Soil Processes. Edited by D.J. Greenland and M.H.B. Hayes. Pp.714. ISBN 0-471-27693-6. (Wiley: 1981.) £37.85, $89.85.

The Chemistry of Soil Processes is the companion volume to *The Chemistry of Soil Constituents*, published by Wiley in 1978 and edited by the same two distinguished soil scientists. These two volumes bear a close resemblance to Russell's definitive treatise, *Soil Conditions and Plant Growth* (10th Edn, Longmans, 1974), though as an edited work they cannot present the same comprehensive yet unified view. On the other hand I feel, like many others, that soil science is such a diverse subject and one that has expanded its boundaries to such an extent in recent years that no single author can really cover all of the topics involved. These days it is necessary to involve specialists who can treat each aspect in depth, as Greenland and Hayes have done.

A knowledge of the chemistry of soils is of importance to many scientists other than those entirely involved in soil work and, therefore, I find it particularly encouraging that the present volume is one that may readily be comprehended and appreciated by all chemists who have some knowledge of or interest in the biological sciences. The chemistry, too, is treated in such a way that it should be easily assimilated by specialists in other disciplines such as microbiology and geology. To most readers, therefore, this will be a fairly open book with easily recognized concepts and aims. It is well written and neatly illustrated, and I particularly applaud the avoidance of excessive use of mathematical manipulation by all of the authors.

The opening chapter — written, most appropriately, by the editors — is an excellent scene-setter for the following contributions. It traces the historical development of soil science through an overview of the subjects of pedology, soil chemistry, soil biology and soil physics. The following two chapters treat the movement of mobile components within the soil profile and precipitation phenomena, for example, the deposition of carbonates, sulphates, phosphates and aluminosilicates which all play an important role in most considerations of soil chemistry. Cation and anion exchange phenomena, which are so important in plant nutrition, and the fixation of added fertilizers are then considered separately by different authors, and this is followed by an extensive review of the adsorption of nutrients etc. by soil components such as clays and humic substances. A particularly well written account of redox phenomena describes the profound effect these have on soil chemistry and reactivity. These chapters lead on logically to four separate treatments of the translocation of metal ions in soils, the fate of plant and animal residues, fertilizers and heavy metals in soils; finally, there is an account of the behaviour of pesticides in soils. The book is provided with excellent indexes of subject matter and authors.

The 13 contributors are all recognizably expert in their individual subjects and, whether or not it has arisen by careful planning or by happy coincidence, a rather unique, synoptic view of soil chemistry has emerged which is most unusual in a book with so many authors. The depth and treatment is entirely satisfactory and there appear to be few if any serious inconsistencies.

There is no doubt in my mind that this well-written book will be of the utmost value to all junior, and senior, students of soil science, and an invaluable aid to all who have to refer periodically to matters relating to soil chemistry. ☐

T.S. West is Director of The Macaulay Institute for Soil Research, Aberdeen.

An animated Earth

John Sutton

The Earth Generated and Anatomized: An Early Eighteenth Century Theory of the Earth. **By William Hobbs. Edited by Roy Porter. Pp.158. ISBN 0-8014-1366-4. (British Museum (Natural History)/ Cornell University Press: 1981.) £24.50, $35. Paperback available from the BM(NH), £8.**

WHEN opening a university geology department, Stanley Baldwin once compared geological research with the writing of detective stories. Bow Street runners played little part in the development of geology, but excise men certainly did, the most famous being members of the Peach family whose watch over a whisky-filled wreck off northern Scotland led to the discovery of fossils which first demonstrated the Palaeozoic connection of Scotland and North America. That discovery was made in the nineteenth century. Now Dr Porter brings to light a geologically-minded excise man from the early eighteenth century. His name is William Hobbs. He recorded the tides

●A paperback edition of *Somatic Selection and Adaptive Evolution* by Ted Steele (reviewed in *Nature* **288**, 306; 1980) has recently become available in the USA. The book is published by the University of Chicago Press and costs $5.95.

around Weymouth and more remarkably noted the fossiliferous rocks of the Dorset coast None of his work has been previously published, who he was or what else he did still remains obscure despite Dr Porter's careful enquiry

The main part of this book, which forms a welcome addition to the Historical Series of the Natural History Museum, is a manuscript which Hobbs completed in 1715 Its history is obscure, it emerged in 1825 when it was sold in Southwark and surfaced again in a London sale room some 150 years later, when the Natural History Museum acquired it With his knowledge of eighteenth century geology, Dr Porter is just the person to edit it and he has done a thorough job He provides an introduction, identifying Hobbs as far as this is possible — a detective story in itself — and adds extensive notes on the milieu in which this solitary observer had to work With little formal education Hobbs appears to have spent years in observation along the Dorset coast in a singlehanded enterprise

He had the good judgement to pick on two phenomena which that coast shows well In recording the tides he was doing something that others had done before, but in understanding the significance of the stratification of the fossiliferous Mesozoic rocks he entered new territory Reflecting on his evidence, however, he came to a wholly erroneous explanation Hobbs himself describes his flash of inspiration "I had (at a place well remembered) clearly discovered the Body of the Earth to be an Animal" He supposed the tides were due to movements within the Earth and explained the fossiliferous sediments as dating from a time when the outer parts of the Earth were plastic He linked these two explanations and supposed that pulsations within the Earth could account for them Some years before he wrote the manuscript published here, he had sent a paper covering much the same ground to the Royal Society, which rejected it The referee's comments have survived

> I find him to have a Clear Head, and to be a person of great Diligence and pretty good Judgment considering his Want of Learning, but his Philosophy is much inferior to his Observations of Matters of Fact

That comment could equally be applied to what is now published Although the explanations are nonsensical one cannot help but admire Hobbs's ability to observe and record This manuscript was well worth bringing to light, not only does it show what a solitary individual was able to do, but it illuminates a wider question Dr Porter has considered on earlier occasions, the extent to which nineteenth century geologists drew on eighteenth century thinking, erroneous as that sometimes was □

John Sutton is Pro Rector and Professor of Geology at Imperial College, University of London

Symbiosis and the origin of cell organelles

T Cavalier-Smith

Symbiosis in Cell Evolution Life and its Environment on the Early Earth By Lynn Margulis ISBN hbk 0-7167-1255-5, ISBN pbk 0-7167-1256-3 (W H Freeman 1981) Hbk $24 50, £18 20, pbk $14 95, £10 40

Few sights are more fascinating than the teeming microbes from the hind-gut of termites and wood-eating cockroaches To Professor Margulis they also hold the clue to our own origins By 1960 electron microscopy had shown that the prokaryotic cells of bacteria and cyanophytes differ fundamentally from the eukaryotic cells of plants, animals, fungi and protozoa This, and the discovery of chloroplast and mitochondrial DNA, led Ris to revive Mereschkowsky's old idea that chloroplasts evolved from endosymbiotic cyanophytes and Margulis to revive Wallin's theory of mitochondrial origin from symbiotic bacteria. Stimulated by Cleveland's discovery that the termite-gut symbiont *Mixotricha* is propelled by thousands of ectosymbiotic spirochaetes, Margulis also suggested that cilia evolved from such ectosymbionts

The central thesis of her *Origin of Eukaryotic Cells* (Yale University Press, 1970) was that eukaryotic cells originated by the symbiotic uptake of an aerobic bacterium by a wall-less, mycoplasma-like prokaryote to form mitochondria, followed by the conversion of ectosymbiotic spirochaetes into cilia and of cilia into the mitotic spindle In that book she also discussed the symbiotic origin of plastids and the interplay between biological and geochemical evolution *Symbiosis in Cell Evolution* is very similar, but sadly takes little account of the extensive new electron microscopic and biochemical evidence accumulated over the past decade, or of published criticism of many of her ideas Written as a readable elementary textbook, it is avowedly a one-sided point of view which ignores conflicting evidence or arguments that might distract the reader from her message

The author has missed the opportunity to elaborate what should have been her strongest suit the symbiotic origins of plastids *Cyanophora*, the eukaryote possessing a blue-green plastid with peptidoglycan in its envelope but with DNA the same size as chloroplast DNA, is dismissed as a "unique, dead-end symbiotic complex" merely serving as a model of how plastids might have originated But if one compares the cell structure of *Cyanophora*, the other non-peptidoglycan-containing Glaucophyceae and the red algae, it is evident that they form a continuous spectrum which strongly suggests that the *Cyanophora* plastid is a "living fossil" directly descended from the same endosymbiotic cyanophyte that was ancestral to all eukaryote plastids

Margulis's entire treatment of the diversity of plastid types is minimal and inaccurate The origin of the three membranes of the plastid envelopes in *Euglena* and the dinoflagellates is not discussed (*Euglena* is incorrectly drawn with two membranes) Nor is the origin of the plastid endoplasmic reticulum, which others have well explained in terms of a second symbiotic event involving a eukaryotic symbiont (she incorrectly states that chrysophyte and phaeophyte envelopes are triple)

The author's diagram of eukaryote phylogeny shows 15 separate symbiotic origins for plastids, but no justification is given for this — it is not obviously deducible from her apparently unilinear scheme of mitotic evolution — or for the assertion that several independent symbiotic events produced the chlorophytes The scheme itself is essentially her 1967 one (*J Theor Biol* **14**, 225-275), based largely on half-a-century-old light microscopy and her symbiotic theory of ciliary origin, rather than modern ultrastructural data The latter enter the book only in the ten pages devoted to part of Heath's splendid tabulation of protist mitotic variation (fungi are oddly omitted as irrelevant)

Margulis's attachment to her five-step scheme of mitotic evolution makes her say (incorrectly) that "no animal cell that bears undulipodia [a cumbersome neologism for 9+2 cilia] can ever divide" And it is hard to see how her step II, the permanent loss of cilia, could lead to steps III - V which are ciliated Step I — organisms with cilia but lacking mitosis — is based on her theory that spindles evolved from cilia rather than on concrete evidence *Prorocentrum* does have mitosis, and *Pelomyxa palustris* has not been clearly shown to lack it, both contrary to what is stated She barely mentions the conventional view that spindles evolved from cytoplasmic microtubules, and erects as the sole alternative to her view the Aunt Sally that they originated as episomes, which no one has suggested It is also a mistake to call the autogenous origin of cilia "compartmentalization", or to tie their autogenous origin indissolubly to the autogenous origin of plastids She seems not to conceive that anyone could accept the symbiotic origin of plastids and reject the symbiotic origin of cilia, yet most biologists do just this

For mitochondria, Margulis assumes rather than debates a symbiotic origin A reasonably strong case for this theory can be made by supposing that the host was already fully eukaryotic and capable of phagocytosis (for example the mitochondrion-less flagellate protozoa) But she makes her task almost impossible by supposing that symbiotic uptake preceded the origin of the eukaryotic cell and phagocytosis Because prokaryotes lack phagocytosis and never contain cellular endosymbionts she supposes that the symbiont bored its way in, like a predatory *Bdellovibrio* The problem with this is that *Bdellovibrio* bores only through the cell wall, not the plasma membrane, and so never even enters the cell, which it also kills Moreover, the hypothetical wall-less host would have no wall to bore through[1] She now favours *Thermoplasma* rather than mycoplasmas as potential hosts, despite the fact that *Thermoplasma* have branched ether-linked membrane lipids, not phospholipids, and so could not be ancestors of eukaryotes Further, she fails to realize that the resemblances between the respiratory system of purple non-sulphur bacteria and eukaryotes could be explained non-symbiotically by the conversion of a purple non-sulphur bacterium autogenously into nucleus, cytoplasm and mitochondria, and gives only one out-of-date reference to Mahler's extensive arguments for such an origin Her description of which mitochondrial molecules are coded by mitochondrial DNA is inaccurate, incomplete and misleading

The treatment of mitochondrial origins is inadequate, split-genes and RNA splicing receive only three lines and the unique mitochondrial code but half a line The origin of the different cristal morphologies that some see as evidence for multiple symbiosis is totally ignored, as is the evolution of mechanisms to transfer nuclear gene products into mitochondria The problem of gene transfer to the nucleus is barely mentioned

Her classification of living organisms is better than most, but has several inconsistencies for example, acceptance in the text of the basic distinction between Archaebacteria and Eubacteria is not reflected in the appendix Her prokaryote phylogeny ignores the important data from 16S RNA sequences A major defect of the book is the absence of critical phylogenetic analysis, upon which the testing of symbiotic ideas largely depends

The book contains many errors, for example non-Mendelian heredity in *Chlamydomonas* is not a consequence of uniparental transmission of chloroplasts, the gene for the ribulose biphosphate carboxylase large subunit is in the chloroplast not the nucleus, and *Cyanophora* has a pellicle not a cell wall Such an important idea as the role of symbiosis in cell evolution, which Professor Margulis has done much to promote, deserves more thorough and more careful treatment than this □

Attractive rigour

D. Sherrington

The Theory of Magnetism I Statics and Dynamics By Daniel C Mattis Pp 295 ISBN 3-540-10611-1/0-387-10611-1 (Springer-Verlag 1981) DM 72, $32 80

THE study of magnetism has been one of the growth areas of the past decade It has interest not only in its own right, but also as a testing ground for the quantum-mechanical theory of interacting electrons and as a convenient example for illustrating and probing important questions in statistical mechanics Practical applications are legion, but mainly confined to ferro- and ferrimagnetism The fundamental interest lies more in the intellectual challenge which the subject offers to pure physicists, indeed, this challenge has even attracted the attention of elementary-particle theorists

There are two extreme approaches to the theory of magnetism, the phenomenological and the strictly fundamental At an intermediate level lies the study of idealized models, but with wide variations in emphasis on rigour or qualitative conception Most books on magnetism treat the basics in a fairly cavalier fashion and tend towards a semi-quantitive treatment of models Mattis is a welcome exception His inclinations are towards full rigour, eschewing sleights-of-hand or glossing-over of difficulties

The book is the first of a two-part set This volume is divided almost equally between a detailed analysis of the quantum-mechanical basis of magnetism and an incisive study of several of the intermediate models Subjects discussed include such modern ones as solitons, the Kondo effect, Bethe's ansatz and vortices in the XY model

Mattis's relentless approach will not be to everyone's taste, but his book will be a useful addition to the library of anyone deeply interested in the origins of magnetism and the careful study of mathematical models The statistical mechanician, or the particle theorist looking for hints on how to solve the lattice gauge theory problem, may, however, prefer to wait for the second volume which will cover thermodynamics and statistical mechanics

Finally, praise must be given for the introductory chapter, 38 pages long, which spells out the history of magnetism from the earliest days to the present, places it in the perspective of the general evolution of physics and the development of Western thought, and is backed up by marvellous quotations and an impressive bibliography This chapter can be strongly recommended to anyone interested in the history of science and, almost alone, would justify purchase of the book □

D Sherrington is Reader in Theoretical Solid State Physics at Imperial College, University of London

Receptor development

Eugene R. DeSombre

Ontogeny and Phylogeny of Hormone Receptors By G Csaba Pp 172 ISBN 3-8055-2174-X (Karger 1981) DM 172, $86 25

WHILE Professor Csaba does not entirely accomplish the awesome task of providing a synthesis and critical evaluation of our current knowledge of the ontogeny and phylogeny of hormone receptors, in this book he does provide a useful introduction to the subject Most valuable for those who may not have closely followed Csaba's work, the monograph includes extensive data (72 figures and 18 tables) from his contributions on the interactions and biological effects of various hormones of higher organisms in Tetrahymena and Planaria It starts from first principles on the basic concepts of cybernetics and information transfer related to hormone–receptor function and gives a general summary of our understanding of hormone–receptor interactions, paying especial attention to hormones active at the plasma membrane

The subject of the phylogeny of receptors is presented almost exclusively using examples from studies with Tetrahymena and Planaria, with only occasional reference to other species And while the section on ontogeny deals to a limited degree with higher animals — specifically, developmental aspects of receptors in the neonatal chick and rat — as well as with data from Tetrahymena and Planaria, neither of the two parts can be considered to be a definitive review of the topics

Nonetheless, because of the excellent documentation of a variety of studies in these lower species, the useful introductory comments and a substantial concluding discussion, the book is more than a simple summary of Csaba's own experiments His account of various possible developmental routes which could give rise to observed hormone and receptor patterns in different phyla is certainly valuable Unfortunately, the rich literature on steroid hormones, the action of which is mediated through cytosolic receptors, is less well integrated into the presentation The speculation that cytosolic receptors for steroid hormones may have evolved from membrane receptors, an interesting concept, is not well-developed in the book and the entire steroid hormone area is represented only by a few selected references

More appropriately entitled *Selected Topics on the Ontogeny and Phylogeny of Membrane Active Hormone Receptors*, this monograph provides an interesting, if limited, entree to the developmental aspects of hormone receptors □

Unemployment and the future

Most Western governments are seeking separate solutions for unemployment. They should do more to prove to the jobless that there will be a future, and should agree how to bring it about.

The long recession in the industrialized West has now brought its most daunting and predictable consequence: unemployment. In Britain, the total now out of work exceeds 3 million, or close on 10 per cent of the potential workforce. In West Germany, after several resilient years, the jobless rate is now pushing 7 per cent. In the United States, the growth of unemployment has been even sharper. Even Japan has not escaped unscathed. So it is inevitable that there should be great cries of protest at this state of affairs, and that governments everywhere should be under pressure to modify their monetary policies, devised with varying degrees of good sense to counter rapid inflation. (Reagonomics, devised in Washington with the different objective of unshackling industrial production, has had the same effect because the hard-headed New York money markets have agreed to let the Administration and others borrow money only at deflationary interest rates.) Politically, such pressures cannot indefinitely be resisted. In Britain, it is well remembered that the Heath government embarked in 1973 on its ultimately disastrous policy of reflation because unemployment had exceeded the daunting figure of one million. Although all governments except the French say they will continue to regard unemployment as a kind of lesser evil, the danger is that they will hurriedly change course for the wrong reasons, and at the wrong time.

Unemployment at the rates now customary is naturally hard for even those still at work to stomach. For those without jobs, a large proportion of the younger of whom have never worked, unemployment is a personal tragedy that is only inadequately offset by programmes of social security devised to avoid the improverishment of the 1930s. So much is commonly accepted, as is the proposition that a high degree of unemployment is a social waste of people's capacity and willingness to work. Yet the present plight of a substantial proportion of the working population in advanced societies is not merely an inevitable but an intended consequence of economic policies now in force, which have in turn been forced on governments by events in the past decade and in particular by the substantial increase of the international price of oil in 1973 and 1979. To pretend otherwise is to suppose that the rules of simple arithmetic can be suspended at will — which is not to say that there is nothing that can be done.

The first need, however, is to be clear where the present trouble has come from. Compared with the happy years before 1973, oil consumers are now paying more than $200 extra for each tonne of oil they use. For many, this entails a straight transfer of resources to the oil-producing states, which may either decide to convert their funds into a claim on the resources of the oil consumers or, alternatively, may choose to lend back the money through the banking system. Either way, customers for oil on the international markets can have hoped to weather these storms without impoverishment only by increasing their production and therefore their productivity. Japan and West Germany honourably followed that principle for several years. Elsewhere, governments chose to follow their voters' wish that the truth should be concealed from them, inflation gathered pace and had then to be countered by deflationary policies which reduced people's capacity to buy what they think they need and which in turn have now cast their shadow on the economic stalwarts of the West. This argument applies even to Britain, outwardly self-sufficient in oil, because the once cheap oil from the Middle East has been replaced by expensive oil from the North Sea, won only by capital and resources that might otherwise be used for more productive purposes.

For those who would cure unemployment quickly, the snag is that increased productivity is the enemy of job creation. The dilemma for Western governments is that the continuation of the recession will improve the former — even in Britain, productivity in manufacturing industry increased by more than 7 per cent last year — but will increase the unemployment queues. And the opposite is true — reflation would reduce the immediate misery of unemployment but jeopardize the long-term health of the economy. So are governments irretrievably boxed in? Not necessarily. Those most seriously afflicted are right to resist demands that jobs should be "created" in uneconomic pursuits but, on recent form, cruelly indifferent to the need to explain how the unemployment problem may eventually be solved. People who have just lost their jobs are understandably unwilling to accept that their misfortune must wait while inflation is contained. So what should governments attempt to do?

First, domestically, there is an urgent need that people displaced from jobs that have disappeared should be given a tangible and imaginative opportunity to prepare for the more productive world in which they may yet have the good fortune to live. Although the British government, for example, now plans to spend more generously on training programmes, and is in particular planning to offer every school-leaver who fails to find a job some structured opportunity for training at work, there is nothing to suggest that the results will generally be to make people more employable in the years ahead. By the same tests, all governments must recognize that the key to long-term prosperity — production, productivity and employment all high — is a more effective international division of labour than at present. Here too, unfortunately, the omens are not cheerful. Protectionist tendencies are increasing, with governments seeking to shield from overseas competitors industries that will never make economic sense. Is there a chance that the folly of these policies will be openly acknowledged, as it should be, at the "economic summit" advertised for June?

While they are about it, the governments in June should tackle the still more tricky question of how collectively to manage the transition from where we are to where we hope to be. What criteria will be used for telling when it will again be safe to let up in the battle against inflation? By what common criteria should governments decide that the time has come to invest in public works, or to allow commercial companies to borrow money at more modest interest rates? And by what agreed rules should the value of national currencies be determined and then adjusted? Putting these questions to many of the more orthodox turning up in June will be a little like asking a gathering of churchmen to define the circumstances in which sin is acceptable. In reality, the challenge is not so great. For the agreements negotiated towards the end of the Second World War at Bretton Woods in the United States, which were the basis of international financial relations until they collapsed between 1969 and 1971, were themselves an awkward adjustment between financial probity and an imperfect world. What is needed now is an open recognition that the world is far from perfect, that the governments that inhabit it are even less so and that, nevertheless, they must agree to act in concert.

Goodbye to guidelines

Recombinant DNA guidelines are on the way out. What should be learned from them?

This week's meeting of the Recombinant DNA Advisory Committee at the National Institutes of Health in the United States will be seen as not so much a landmark as a milestone in the brief but eventful history of the most elaborate attempt so far to regulate scientific research. After two years of agonizing in the wake of the Asilomar conference of 1974, government agencies produced rules for research with recombinant DNA which, once promulgated, were almost as quickly dismantled. Already, the guidelines in force are a pale shadow of the tough regulations that caused many professional people to protest that governments were planning to interfere with research — and many members of the lay public to complain that the controls were entirely inadequate. But on present form, the whole apparatus of regulation will have all but disappeared within a decade of being proposed. Has the whole exercise been a waste of busy people's time? What can be learned from it?

That busy people's time has been occupied is of course beyond dispute. People who might have been cloning some gene, or setting up some new biotechnology company, have instead been required to turn up at meetings of advisory and safety committees. There is probably also something in the complaint that important experiments were delayed by the lack of facilities necessary for compliance with the guidelines, or by the diversion of creative people's talents to the development of organisms even less capable of survival in the human gut than the standard laboratory strains of *E. coli* K12. So, now, there are two commonplace appraisals of the experience of the past few years. Some workers in the field claim that they have said from the beginning that the potential dangers of recombinant DNA research were exaggerated, and that the regulations were pointless and a needless interference with free research. Others, more circumspect but also more cynical, say that the guidelines were an unfortunate necessity, an exercise in public relations whose value is attested by the way in which the public clamour about the hazards of genetic manipulation has died down. The truth, however, lies with the smaller company of professionals who acknowledge that the guidelines were both necessary and valuable, that experience of their operation has been instructive and that the history of the recent past should be remembered well.

The argument is simple and straightforward. At Asilomar and in the months that followed, many people in a good position to know the truth held that the hazards for the general population of the construction of novel organisms could be serious. The hazards were always hypothetical, involving processes not then (or since) demonstrated in the real world. Those who claim to have known all along that the guidelines were unnecessary did at the time argue that organisms encumbered artificially with foreign genes were unlikely to be effective competitors in tissues which they happened to infect, but were too scornful of the now common difficulty of deciding how to assess a large danger which has only a very small probability. In the event, the erosion of the guidelines promulgated by the National Institutes of Health (and analogues elsewhere) has been made possible by scientific rather than philosophical developments — the discovery that the replication of genes in eukaryotic cells is more complicated than in bacteria for example. In 1976, the decision that there should be guidelines of some sort was not merely prudent but responsible. So, now, is the general agreement that the guidelines may be further attenuated without risk.

For the most part, the guidelines have also been well kept, even by the sceptics. The few know transgressions, in the United States and elsewhere, appear to have been engendered as much by frustration at the differences in guidelines applying to competing laboratories as to deliberate attempts at cheating. In the United States, the dominant role of the National Institutes of Health in supporting research must have been a powerful deterrent — which is why, in the history of this period, the failure of successive Administrations to apply to industrial laboratories the sanctions applicable to academic laboratories will seem odd, to say the least. Where guidelines have been backed by legislation, as in the United Kingdom, the courts have not been packed with recalcitrant molecular biologists. The scientific community can claim credit on this score.

So what should happen now? Should the guidelines simply be torn up, and the accompanying bureaucratic apparatus dismantled? That would be to go too far. To the extent that the foreseeable hazards of recombinant DNA research have become no more than coextensive with the risks of working with whatever naturally occurring organisms are involved, the existing rules for research with pathogenic organisms are sufficient. Separate rules for recombinant DNA research are therefore unnecessary, while voluntary compliance with further attenuated regulations will be meaningless. Yet the issues which have been raised in the past several years are interesting and have also made a mark on the public mind. What is needed, now, is a periodic and public reassessment of the risks, hypothetical though they may still be.

For laboratories, the most important procedural discovery since Asilomar is that local safety committees have not turned out to be the interfering busybodies they were feared to be. Even when (as required by the National Institutes of Health) lay members were appointed, the outcome has more often been public enlightenment than outside intrusion into the conduct of research. Indeed, the precedent of local safety committees including members from the nearby community is one that should be more widely adopted in other fields, for example where laboratories have an interest that they should be known to care for their experimental animals — and that the general public should be sensible of their dilemma. It would be no harm if this institution were the chief monument to the guidelines period.

Maths without teachers

British schoolteachers cannot teach mathematics properly, but nobody is surprised.

How should mathematics be taught? And by whom? These questions have perplexed the British educational system ever since it acknowledged, in the 1950s, that everybody profits from education, of which mathematics is an essential ingredient. In despair at not knowing how the questions should be answered, in September 1978, the then British government set up a committee under Dr W. H. Cockcroft, Vice-chancellor of the New University of Ulster in Coleraine, to suggest what might be done. The committee's report now published (*Mathematics Counts*, HMSO, £5.75) is as well polished as the time it has taken to prepare requires in decency that it should be. It is also full of sensible suggestions for the better organization of mathematics teaching in British schools. But on the main issues, the report is muffled.

The trouble with mathematics teaching is that the shortcomings of one part of the educational system are visited upon all others. University courses in mathematics, notoriously arid, are also the chief source of teachers in secondary schools who are saddled with responsibility for teaching mathematics to intending teachers in primary schools. Hitherto (and, indeed, until 1983) it has been possible for young people to embark on careers as teachers without having a formal qualification in mathematics at secondary school, even though they will be required to teach mathematics to young children. The result is that mathematics teaching is everywhere tentative — experts in graph theory teach elementary algebra to thirteen-year-olds, inexpert people wrestle with seven-year-olds on the conundrum of proportionality. The underlying fault, which Cockcroft does not tackle, is that the British educational system makes a fetish of specialization too early, and pays too little regard to general education at all levels. Paying some good mathematics teachers more, and the other stratagems he advocates, may help in the short run. Changing the way the British educate their young is the only long-term remedy.

Making private interests public

California may ask academics to declare all

Washington

Under new regulations proposed by the state's Fair Political Practices Committee (FPPC), research scientists at the University of California will no longer be given a blanket exemption from conflict-of-interest regulations covering other state employees

Until now, scientists have argued that academic freedom protects them from being required to disclose their personal stake in outside companies with which they may be involved These ground-rules are now being shifted, largely as the result of several well-publicized cases in which faculty members have profited substantially from such linkages

Last month, at a meeting in Sacramento, the state capital, the members of FPPC voted by three votes to two to require that any scientist who accepts a research contract from a private corporation must declare to the university whether he or she has a financial interest in that corporation

The University of California had previously volunteered to introduce an internal system requiring scientists to report potential conflicts of interest to their heads of department The regulations being proposed by FCCP would not only formalize this arrangement, giving the state the authority to check that such reporting is being carried out, but would also require the university to set up internal review panels at each campus to which conflict-of-interest problems would be referred

The commission's proposal has been published for public comment before its formal adoption, expected early next month It does not go as far as some of the university's critics would have liked, in particular, a legal aid group known as California Rural Legal Assistance, which has been leading a campaign against research into labour-saving agricultural machinery at the university's Davis campus, had petitioned the commission to require research scientists to declare all their interests in outside corporations

In their present form, the regulations would permit a scientist to keep confidential his or her stakes in a private company interested in the same area of research if the research were funded by a public agency The regulations would therefore be more liberal than the full disclosure required of other state officials

However, if the regulations are approved — and are subsequently accepted by the state's Office of Administrative Law — it would mean that faculty members on all nine campuses of the University of California could no longer use academic freedom as a reason for exemption from the conflict-of-interest rules

The law which covers the regulations was passed in the early 1970s as part of a nationwide movement to "clean up" the actions of state and federal officials in the wake of the Watergate scandals Its main purpose is to ensure that state officials are not in a position to gain financially through links with outside contractors and other corporations in which they may have a personal interest

Soon after the law was passed, its application to the state university was challenged by the university's board of regents on the grounds that it infringed the academic freedom of faculty members At the time FPPC, which was set up to administer the regulations, accepted this argument and allowed an exemption

Since then, pressure on research workers to establish closer links with the private sector has increased as both state and federal funding has decreased The consequent growth of linkages between faculty scientists and outside corporations has been particularly noteworthy in the development and exploitation of recombinant DNA techniques and genetic engineering Frequently, however, this has led to tensions between academic and commercial pressures

One campus of the university is already involved in a law suit over the ownership of a cell line passed to research workers in the private sector and subsequently patented, another has told an agricultural scientist working on nitrogen fixation that he cannot both remain principal investigator

Another French director resigns

Molecular biologists in France are sleeping a little less easily this week, following the spectacular resignation of one of their more important political friends, Professor Philippe Laudat, from his post as director-general of the Institut National de la Santé et de la Recherche Médicale (INSERM)

Laudat waited until after the National Colloquium on Science and Technology (see *Nature* 21 January, p 180) before sending his letter of resignation to the Minister of Health, M Jack Ralite, and the Minister of Science and Technology, M Jean-Pierre Chevènement It was against his own "personal ethics", he wrote, after working energetically for the policies of the previous government, to work now for "noticeably different policies"

The ministries appeared surprised Laudat's resignation was neither desired nor solicited, said a spokesman for the Minister of Health "All we did was to ask Laudat to take account of the conclusions of the National Colloquium and the regional assizes [which preceded it] "

INSERM will certainly do that now — for the new director-general will be M Philippe Lazar, who was chief rapporteur for the colloquium Lazar is 45, studied at the Ecole Polytechnique and is an epidemiologist interested in the social and economic aspects of health His star rose with the new government, and his appointment may shift INSERM away from its present strong emphasis on basic biology towards the clinical and softer sciences

The issues are complex, however Clinical science in France is generally thought to be weak Those who work in university hospital clinics are supposed to teach, care for patients and somehow also find time for research The research suffers Clinicians are sore that the last government increased INSERM's effort in molecular biology (with an eye on its application in industry) whilst neglecting sciences closer to medicine There is thus a battle for resources within INSERM between the clinical scientists and the pure scientists, a phenomenon not unknown elsewhere

However, the matter was complicated by Laudat's creation of international panels of experts, which doled out money for certain priority projects These panels were outside the normal semi-democratic control of INSERM's partially-elected review committees, and inevitably they tended to favour the successful (usually basic) laboratories, to the neglect of the ailing clinical research system

The strong French scientific trade unions have long demanded that the international committees should be advisory to, and vetted by, INSERM's elected committees — a procedure which Laudat clearly felt would destroy their effectiveness Since the unions now have much greater leverage on the government, the fear now is that this kind of democratic reform will go ahead — with the result that INSERM resources will be spread more evenly and thinly — exactly what Laudat was trying to avoid

But the government — and Lazar — are unlikely merely to capitulate to union pressure Chevenement, in particular, is well aware of the ineffectiveness of many university hospital clinics, but he puts it down to inefficient structures, in particular the overbearing power of the "grands patrons", the "gerontocracy" that rules French medical laboratories and — according to some — stifles research This view, together with the minister's determination to boost biotechnology and its base in molecular biology, may in the end refresh French biology rather than set it back **Robert Walgate**

0028-0836/82/050357-02$01 00

on a university project sponsored by a large fertilizer corporation and help run a private research company in which the same corporation has invested considerable capital (see *Nature* 8 October 1981, p. 417).

A representative of the university said last week that the new regulations proposed by FPPC represented an acknowledgement of some of the recent scientific developments affecting university–industry relations "particularly in genetic engineering, which were not foreseen when we went into this business".

The precise form in which scientists will be required to disclose either their own financial interests, or those of their spouse or children, in companies financing their research has still to be worked out by the university. Also under discussion is the way that the new reporting requirements would be policed. Here the conventional procedure at the university is that, although faculty members are under no legal obligation to make details of their outside interests available to the university, they can be barred from promotion or salary upgrading — both of which must be approved by the state — if they do not do as required.

So far, the university has reacted cautiously to the proposed regulations, recognizing that they have considerable support in the political community. One official on the Berkeley campus claimed that, although many faculty members felt they were being unnecessarily penalized for the excessive actions of a few, the general reaction was a reluctant acceptance.

But the debate may not be over. Some faculty members have apparently indicated informally that they may challenge the new regulations in court on the grounds that they constitute an infringement of constitutional rights. California Rural Legal Assistance in turn is suggesting that it, too, may sue the state if it feels that the regulations are not tight enough.

David Dickson

Polish higher education

Whose pigeon?

Academic freedom cannot be used to combat socialism and to reduce life to anarchy, General Wojciech Jaruzelski told the Sejm (Polish parliament) last week. This was the first meeting of the Sejm since the introduction of martial law. The two-hour speech was intended to justify the drastic measures of 13 December.

On the universities, he noted that the "political tensions" of the past year had involved most of the higher education system, and "weakened the pace" of academic work, creating "painful gaps" in study. The "reinstatement of law and order", however, was now creating conditions for normal work in the universities. "We want to continue the democratization of academic life, to ensure the self-government and autonomy of the colleges", he said. The new higher education bill should, he said, go ahead.

In spite of his professed support for autonomy, the general suggested that more government control over research would be necessary. In many institutes, he said, the practical results of research are nugatory, and the "discipline of scientific research" must be increased. In this respect he criticized all three sectors of Polish science — the universities, the Academy of Sciences and the "departmental" institutes belonging to the production ministries. Hitherto the "departmental" sector has been given financial priority and better fringe benefits. A main plank of Solidarity's programme for science and culture had been parity between the three sectors. Now, it appears, the three sectors may at least attain parity in the degree of government control. The state, said Jaruzelski, must reserve for itself the supervision of the cost-effectiveness of expensive research, and there should be no repetition in the future of "misguided specialist advice".

This last remark appears to refer to the grandiose investment projects envisaged by the Poland-2000 programme of the Gierek regime — although for the past 18 months the major criticism aimed by the scientists at Gierek was that he commissioned expert reports, and then went ahead with his plans for political reasons in spite of economic and technical indications to the contrary.

The form that the Polish research structure will now take is unclear from the general's speech, although clearly Solidarity's hopes of block-grants for academic research, with autonomy for the universities in the allocation of available resources seem unlikely to materialize. One possibility much discussed during the past 18 months had been the dissolution of the existing Ministry of Science, Higher Education and Technology, and the combination of the higher education sector with the Ministry of Education and Upbringing to form a single education ministry, as existed in Poland before 1972. In that event, a Ministry of Science and Technology would be created with responsibility for all the "departmental" institutes now belonging to the various production ministries, while the Academy of Sciences would continue with its present quasi-ministerial status.

It is not yet certain that these plans will be frustrated. The combination of science, higher education and technology in a single ministry has so far favoured the appointment of a scientist as minister. The new minister, however, appointed last week to replace Dr Jerzy Nawrocki who resigned soon after the declaration of martial law, is Professor Benon Miskiewicz, a military historian, who, until 1981, was rector of the Adam Mickiewicz University of Poznan. The appointment of a minister from the humanities could be the first step towards the eventual reorganization of the ministry. **Vera Rich**

Recombinant DNA guidelines

Only formality

Washington

The Recombinant DNA Advisory Committee (RAC) of the US National Institutes of Health (NIH) is to meet in Bethesda, Maryland, next Monday to decide whether to recommend the *coup de grâce* for federal regulations introduced six years ago to cover research using recombinant DNA techniques.

Many scientists are urging the committee to support a proposal that, as a final step in dismantling regulations initially introduced as protection against potential hazards from such research, would transform them into a voluntary code of practice. Several state and city legislatures, however — most recently the health committee of the California State Assembly — say that if this happens, they may adopt their own stringent regulations.

Judging by past experience, the most likely outcome is that a compromise formula will be worked out by NIH. While reducing the overall stringency of the regulations, this will probably stop short of making them voluntary in the hope of heading off local, more restrictive controls.

Two proposals have been put to RAC as possible major revisions to the NIH guidelines. The more radical suggestion was originally put forward by Dr David Baltimore of Massachusetts Institute of Technology and Dr Allan M. Campbell of Stanford University.

In its current form, which committee members agreed at their last meeting in October should be published for public comment, this revision would reduce the recommended containment level for almost all experiments to P1 physical containment, eliminate all current prohibitions on certain experiments (though retaining two as "admonishments") and abolish the mandatory aspects of the guidelines (see *Nature* 17 December 1981, p. 606, for full details).

A less severe revision has been proposed by RAC member Dr Susan Gottesman, of the National Cancer Institute's Laboratory of Molecular Biology. This would also revise and relax the containment requirements, but the guidelines would remain mandatory, and it would still be necessary for universities and research institutions to operate Institutional Biosafety Committees.

Officials at NIH report that, although both proposals have been widely distributed to the scientific community, the response has been much less than that to previous proposals to liberalize the guidelines made when the public debate about the safety of recombinant DNA techniques was at its height.

Some of those on both sides of the debate are clearly coming to an end of their stamina. "I cannot think of any letter that I

0028-0836/82/050358-02$01.00

A letter to Leonid Brezhnev. . .

Secretary General of the Communist Party
and President of the Council of the Supreme Soviet,
Leonid Brezhnev, Moscow, Kremlin

Sir,

We have followed with great interest your remarks in the press and on television, on the occasion of your latest visit to Bonn, expressing your concern for the maintenance of world peace This concern is shared by all responsible and thinking people throughout the world, independently of their ideological differences, and we stand with you in your desire to preserve humanity from destruction

At the time of your visit, however, we were shaken by the news that your country's Nobel Peace Prizewinner, Prof Andrei Sakharov, and his wife, Yelena Bonner, had embarked on a hunger strike of unlimited duration The ensuing response of the Soviet government, averting the danger to the Sakharovs' lives, was seen by the entire world as an act of humanitarianism Indeed, we recognize in your government's action an important contribution to detente, a regard for human rights being basic to and inseparable from the search for peace

The awarding of the Nobel Peace Prize to Andrei Sakharov acknowledges that he engaged himself unequivocally in the interests of world peace independently of his successes in physics This recognition of Prof Sakharov is a tribute also to all your countrymen who, like our own, are filled with the sincere desire for the peaceful coexistence of all nations following the dreadful sacrifices of the Second World War

In January 1980, Prof Sakharov was exiled to Gorky, without benefit of a court trial or having been sentenced

As members of the international scientific community, we feel we cannot ignore the circumstance that Prof Sakharov, in his two years of exile, has been unable to carry out his scientific work We see here a clear threat to the freedom of scientific endeavour, and indeed to the freedom of the human spirit

We therefore appeal to you to accede to Sakharov's repeated request for a full trial, or to allow him to return to his work at the Soviet Academy of Sciences

Prof Dr Gabriele Taugner

An English translation of a letter which was sent on 29 December last year to Soviet leader Leonid Brezhnev and signed by 136 scientists at the University of Heidelberg, West Germany

have written that has had any effect at all, those of us who think NIH has been dismantling the guidelines too fast still feel as strongly as ever, but we see no evidence that anyone listened to what we were saying", says Dr Susan Wright of the University of Michigan

Most of the letters received by NIH's Office of Recombinant DNA Activities from individual members of the scientific community, commenting on the two published proposals, support the more radical revision, which would make the guidelines voluntary This support, the apparent waning of public concern over the potential hazards of recombinant DNA research, legislative efforts to spur the commercial application of genetic engineering, and the anti-regulatory leaning of the Reagan Administration appear to favour a move towards less control

The single factor which could prevent this, however, is a resurgent militancy in communities in different parts of the country, particularly where new debates about the safety of the research have been triggered by the ambitious plans of the genetic engineering industry

Both the Boston Biohazards Committee and the Cambridge Biosafety Committee, for example, have written to NIH expressing their opposition to any move that would make the guidelines voluntary

In California, the state assembly's health committee has recently held two hearings on the growth of biotechnology companies in the state and the current status of federal safety regulations The chairman of the committee, Mr Art Torres, says he would consider introducing legislation enforcing the guidelines if NIH made them voluntary

With a large proportion of the nation's genetic engineering research taking place in California, threats of state legislation are not being treated idly by NIH In the past, university scientists have made strenuous efforts to prevent Congress from enacting legislation that would turn the NIH guidelines into broad legal requirements, indeed, this has frequently been the motivation behind NIH's agreement to accept tougher restrictions on the research than it would have liked **David Dickson**

Lead additives in petrol

New offensive

A well-organized campaign to persuade the British government to ban lead in petrol was launched in London last week The Campaign for Lead-free Air, or CLEAR, claims already to have 130 Members of Parliament, 8 national organizations concerned with environmental and health matters and 21 scientists and clinicians who are convinced by epidemiological studies or their own clinical experience that low blood lead levels harm the mental health of children The chairman of the campaign, Mr Des Wilson, is a seasoned campaigner whose organization to put forward the case of homeless people, SHELTER, was prominent in the late 1960s

Lead in petrol has been in and out of British politics since 1980 when a working party under Professor Patrick Lawther found no conclusive evidence that low concentrations of lead in the blood are detrimental to health or that lead in air is a major contributor to increased blood lead concentrations In the light of the Lawther report, the government's decision last May to reduce the lead content of petrol from 0 4 to 0 15 grammes per litre by 1985 was a surprise

CLEAR's objectives are to persuade the government to introduce the reduction earlier than planned and to pass legislation requiring all new cars sold in Britain after 1985 to run on lead-free petrol The pressure group will also be pressing for a lower excise tax on lead-free petrol and for it to be on general sale by 1985 at the latest

The campaign, which has received some money from its trustees, hopes to raise £250,000 mainly from public donations Some of the money will be spent on public education and monitoring the government's programme to reduce lead pollution The plan is to send out teams to investigate, for example, the effectiveness of the government's programme to increase public awareness of the hazards of lead in old paint and whether can manufacturers are following government instructions to reduce the amount of lead in solder CLEAR also hopes to support academic research on the effects of low lead levels in the body and to monitor the level of lead in air

At the launch last week, the organizers described two recent studies implicating low levels of lead in the body as harmful to health D A Otto and colleagues in California, whose study was published in *Electroencephalography and Clinical Neurophysiology* **52**, pp 229–239, claim to have found a link between abnormalities in the electroencephalograms of sensory stimulated children aged 1-6 years with blood lead levels as low as 150 microgrammes per litre Dr Fraser Alexander, a paediatrician from Newcastle and a member of CLEAR's scientific and medical advisory committee, reported his as yet unpublished study implicating low blood lead levels in pregnant women with malformation of the fetus **Judy Redfearn**

Up for grabs

Washington

It seemed a good idea at the time, the RCA Corporation, besieged by more than 50 potential customers eager to lease space on its latest telecommunications satellite, Satcom-IV, successfully launched last month, had previously held a public auction for bids to lease seven separate transponders (frequency-shifted radio relays) The response was even better this time With the auction being held in the Manhattan Galleries of Sotheby Parke Bernet, it attracted a flood of national publicity, the transponders were sold at between $10 7 and 14 4 million for leases that run until 1988, resulting in a total sale of more than $90 million dollars

It was a bit too good to last On Thursday the Federal Communications Commission (FCC) ruled that the auction was illegal, since it resulted in different prices for leases being paid by different buyers, in violation of federal regulations which require no discrimination As a result, negotiations with the seven successful bidders have been suspended

0028-0836/82/050359-02$01 00

until a new way of allocating the leases has been worked out

However, FCC did not rule out the auction idea completely, and has invited the company to make alternative proposals for selecting bidders that would not contravene federal regulations One is that sealed bids should be invited, and leases awarded to the seven highest bidders at the price offered by the lowest of the seven

The dispute between RCA and FCC over how to allocate the leases reflects a gradual shift in attitudes towards the regulation of access to telecommunications satellites In the early 1970s, when the satellites were first coming into service, the federal government introduced strict regulations to prevent manipulation of the market

In practice, this goal has been achieved through classifying companies such as RCA which launch the satellites as "common carriers" which are required to offer leases on their transponders on a first-come, first-served basis at prices that are strictly regulated by FCC The procedure has been effective in protecting smaller users from being squeezed out of the satellite communications market, it has also made it difficult for companies to stockpile transponders, even if they have no immediate need for them, in order to exclude their competitors

Recently, however, concern has been growing about speculators who have bought leases at the regulated prices and resold them at a considerable profit In addition, the growth of available space on satellites has lead the industry to argue that tight federal regulation is no longer needed The cause of deregulation of the telecommunications satellite industry has also been embraced by the members of FCC, which in a 7–0 vote last week agreed to publish for public comment new rules which would allow companies operating satellites to negotiate sales directly with private customers

Satcom IIIR, launched successfully from Kennedy Space Center in November, contains 24 transponders, eight of which were reserved for those who had bought space on the ill-fated Satcom III which failed to go into orbit after its launch in December 1979

Both Satcom IIIR and Satcom IV are dedicated to use by cable television companies The satellites are intended to transmit programmes to local television operators, which would then distribute them to individual homes Since an antenna can only pick up signals from a single satellite at any one time, the companies have been keen to band together rather than lease space on other commercial satellites, such as Westar 1 and Comstar D2

Among the companies which will have to renegotiate the transponder leases with RCA is RCTV, a joint venture of RCA and the Rockefeller Center Inc , which has announced ambitious plans to distribute entertainment programmes through cable television The company has already agreed to buy the first rights of British Broadcasting Corporation programmes for transmission in the United States

Meanwhile, in a separate move illustrating the social and political possibilities being opened up by satellite telecommunications technology, four labour unions have joined with the American Federation of Labor/Council of Industrial Organizations to arrange for the broadcast over public television of two films on safety and health whose distribution had been suspended by the Department of Labor's Occupational Safety and Health Administration The unions have made use of a 1978 amendment to the 1934 Communications Act which allows groups outside public broadcasting to rent time on one of the four transponders which the Public Broadcasting Station (PBS) leases on the satellite **David Dickson**

Cashing in now

British Telecom, exercising its right under last year's Telecommunications Act to form partnerships with commercial enterprises, has launched a company to exploit spin-off from research at its laboratories at Martlesham Heath, Suffolk

The plan is to set up small venture companies to exploit ideas, although patents may be available under licence to existing manufacturers The new company, Martlesham Enterprises, has been set up with £250,000 of issued ordinary share capital, the shareholders being British Telecom (30 per cent), Electra Investment Trust (25 per cent), Lazard Brothers (20 per cent), Raeburn Investment Trust (managed by Lazards) (20 per cent) and Thompson Clive and Partners (5 per cent)

Research at the Martlesham Heath laboratories covers optical fibres, semiconductors, video-phones, slow-scan TV, speech synthesis and public viewdata systems Martlesham Enterprises has already identified five ideas which could form the basis for new manufacturing companies, but so far only one of them, a new materials process for semiconductors, has been developed to any significant extent

Martlesham Enterprises plans to hold a financial interest in new operating companies, giving its shareholders first option to put up new capital Attractive terms are to be offered to inventors who leave the laboratories to help set up new companies Interest on profits will, as normal, return to the shareholders It is hoped that the operating companies will grow to the point where they can be launched publicly, when Martlesham Enterprises will decide whether to retain a financial interest or dispose of them

Technical change in France

Central theme

The French government is to set up a centre for social and systems research on science and technology, inspired to some extent by the Brookings Institution of Washington and, in Britain, the Technical Change Centre in London and the Science Policy Research Unit (SPRU) in Sussex But in the Paris institution there will be a difference it will be strictly linked to, and under the direction of, the Ministry for Research and Technology, and will thus lack the political independence of its models

The Center for Advanced Technological Systems Study (CATSS), to use its Americanized name, (CESTA, Centre d'etudes des systemes et des technologies avancées, in French) should be in full swing by 1984 with a budget of around 40 million francs and a staff of 40 "scientists and engineers"

The creation of CATSS is the immediate result of a report to Prime Minister Pierre Mauroy by Dr Joel de Rosnay, director for research applications at the Institut Pasteur (where François Gros, science adviser to the Prime Minister, was until recently director) De Rosnay recommended that a centre like CATSS be established "to study the industrial, social and cultural change induced by advanced technological systems (such as microelectronics, biotechnology, robotics and solar energy)"

The questions are political and involved, the report notes, and it claims that in France "there are traditional difficulties" in thinking in terms of complex systems and networks CATSS must overcome these difficulties

As a government agency in a government devoted to industrial development through technology, CATSS may find its emphasis lying more frequently on innovation strategy in key industries than on social impact *per se* The emphasis of the report is on missed, or botched, industrial opportunities Concorde, an "indisputable technical success" marred by a failure to anticipate economics, competition and environmental impact, microelectronics, insufficient in France because opportunities to develop liquid crystals and integrated circuits were not taken up, and biotechnology, limited by the lack of researchers and engineers trained in the life sciences

Despite its government links, the centre will be open to scientists, industrialists, union leaders, parliamentarians and local politicians It will also collaborate with outside institutions (including, perhaps, Brookings SPRU and the Technical Change Centre)

CATSS will have a strong training function as well as undertaking research, experimenting with new educational technology and communications systems,

0028-0836/82/050360-02$01 00

and helping to "diffuse" new technology Thus the concept appears to be of an intellectually and politically sophisticated institution to assist the country's technological development one which will be able to help industry to make its forecasts and plans, but will, at the same time, take into account likely social impacts and obstacles CATSS's first programmes begin next month — training programmes in biotechnology and microelectronics A director for the centre is expected to be appointed before the summer **Robert Walgate**

Fluoridation in Scotland

Days in court

A legal trial that will decide whether Strathclyde Regional Council becomes the first Scottish water authority to add fluoride to its water supply has now passed its 130th day, making the record books as the longest ever court case to be heard in Scotland The Edinburgh Court of Session, Scotland's High Court, has become a battleground for fluoridation and anti-fluoridation interests

The case, *McColl v Strathclyde Regional Council*, opened on 23 September 1980, and was originally expected to last twelve weeks The eventual cost is estimated at £1 million, which would make it the most expensive civil case in Scottish legal history The costs of Strathclyde Regional Council will be met by its four area health boards The expense of an expert witness can be as much as £450 a day and many have come from as far away as the United States and Australia If the case lasts for 150 days, as it may well do, lawyers' costs alone could exceed £60,000

The issue at stake is twofold — the legal right of the council to add a trace of fluoride to the water supply and the medical effects of fluoride In 1977, the council voted by a majority of 43 to 42 to build a £2 million plant to introduce fluoride into the water supply Mrs Catherine McColl is contesting the decision, claiming the right of herself and her grandchildren to drink unfluoridated water on the grounds that fluoride is not only useless but can cause cancer and other diseases The hearing is before Lord Jauncey

The evidence has been intricate and technical Mrs McColl appeared in the box only on the first day The medical issues have focused on the contention that fluoride can cause cancer Sir Richard Doll for example, has so far given evidence for two weeks It is expected that Lord Jauncey will take months to reach a judgement

Evidence against fluoridation has been given by Dr John Yiamouyiannis, formerly of the National Health Federation organization and a member of the US National Health Action Committee, and Dr Dean Burk, a retired National Cancer Institute laboratory scientist In some ways the Scottish trial is a re-run of the hearing in West View, Pennsylvania in November 1978, when Drs Yiamouyiannis and Burk also argued that there is a link between fluoride and increased cancer mortality rate Dr Burk has separately told the US House of Representatives that fluoridation is "socially imposed murder"

In Pennsylvania, Judge Flaherty, then a lower court judge, issued an injunction ordering West View Water Authority to cease water fluoridation His decision, however, was appealed against on grounds of jurisdiction In January 1979, after a review of the evidence by the Department of Environmental Resources, the water authority was ordered to continue to fluoridate The Minnesota Governor's Commission, appointed in 1978 to study the health effects of water fluoridation, examined the same body of evidence as Judge Flaherty and concluded that "an association between fluoridation and cancer has not yet been shown"

Fluoride has been added to water supplies in Britain since 1957, and 10 per cent of the population drinks artificially fluoridated water (in the United States 44 per cent of the population drinks treated water) The 1972 Water Act enjoins the water authorities to provide "wholesome water", but although 87 out of 90 area health authorities are in favour of fluoridation, in the past 7 years few schemes have been implemented The water authorities seem reluctant to proceed in the absence of parliamentary legislation

The decision in Scotland could thus be influential, particularly as a similar case is being prepared in Calderdale, Yorkshire If Lord Jauncey decides in favour of Strathclyde, the issue of further legal aid for an appeal will arise If the case goes to the House of Lords, it may take several years for a final decision And neither side may be able to claim a victory — if, for example, the judgement is that fluoride is beneficial to dental health but that water authorities do not have full jurisdiction to determine what goes into the water supply

In Strathclyde, the irony is that local elections early this year could render any judgement nugatory a new council could vote to reverse the fluoridation policy

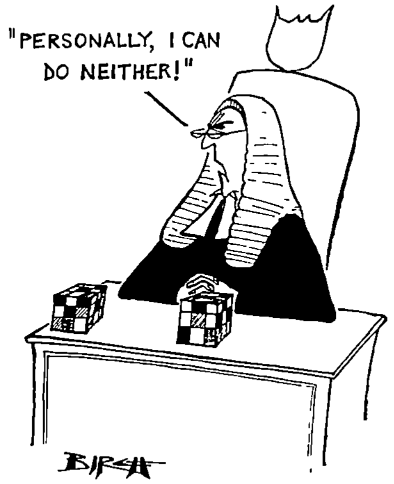
Rubik's cube

Puzzles galore

A decision is expected this week from the British high court hearing of a copyright and passing-off suit brought by the Politehnika Industrial Corporation of Budapest, manufacturers of the original Rubik's cube, against Dallas Print Transfers of London, importers of an alleged copy known as the "Wonderful Puzzler", produced in Taiwan

The case, initiated by an injunction from Politehnika last March, has turned on two main issues As far as copyright is concerned, the emphasis has been on the internal structure of the cube, involving comparison of production blueprints, while the passing-off charge is based on claims that the puzzler has on occasion been marketed as the Rubik cube

The dual nature of the case corresponds appropriately to Dr Erno Rubik's own dual interest in the cube — structure and concept A lecturer in architecture at the Budapest Academy of Applied Arts, he was, he says, originally interested primarily in the internal mechanism of the cube which allows each face, consisting of a 3 × 3 array of cubelets, freely to rotate either clockwise or anticlockwise Only later did he decide to communicate his pleasure in the new device to others by offering it for commercial construction



"PERSONALLY, I CAN DO NEITHER!"

Rubik says that other international contributions to the booming market in logic toys — pyramids, spheres and the like — embody essentially the same principle as the cube, since the various sections are displaced without changing the over-all shape of the assemblage The one major exception, known as the "tower", which exists in two contending Hungarian versions, is, in his opinion, simply the old "15 puzzle" invented in the 1880s, rolled up into cylindrical form, since it incorporates a vacant parking spot into which an element can be moved during the transfer process

The popularity of the cube, which Rubik himself cannot adequately explain, has made him reputedly the seventh richest man in Hungary and won for him a "Gold Medal of Labour" for his services to Hungarian industry, and has had a number of unexpected spin-offs The possible and impossible configurations of the cube, Rubik said last December, were attracting attention from physicists as a means of modelling the properties of quarks

In Hungary, the unprecedented boom in the toy industry generated by the cube has highlighted a number of defects in the New Economic Mechanism, and seems to have been in part responsible for the recent relaxation of the rules governing small enterprises **Vera Rich**

CORRESPONDENCE

Soviet sanctions

Sir — I welcome your leading article of 7 January (p 1) and in particular your criticism of the suspension of the exchange agreement between the United States and the Soviet Union

Such a suspension must surely weaken world peace The merits and demerits of unilateral nuclear disarmament are much debated but the prior need is for a better understanding between peoples of different cultures — in this case the United States/United Kingdom and the Soviet Union The risk of scientists "having their brains picked" surely matters less than the potential benefits from better knowledge of human beings of the "other" culture — their hopes, fears and hang-ups

As a first line of defence for international understanding and peace, scientific and other exchanges can be good investments and should be fostered, not reduced Their costs, if prohibitive to self-financing individuals, are infinitesimal compared with those of armaments

Abingdon, UK

Ethnic journal

Sir — H H Hirschhorn (*Nature* 14 January, p 92) appears to have misunderstood the "small niche" to which *Journal of Ethnopharmacology* is trying to lay claim, even though my review quoted the aims of the journal in full Rather than being another journal of pharmacognosy, which I would accept could appear to be of greater importance than all the drugs for the cardiovascular system, *J Ethnopharmacology* specializes in the use of drugs by ethnic cultures How does the importance of "ceramic use for prehistoric Datura use in N America" compare with a typical paper from *Journal of Cardiovascular Pharmacology*?

The number of reprint requests might reflect more accurately the obscurity of the journal and difficulty in finding it in a library, than the importance of the subject

Anthrax island

Sir — The paper by Manchee *et al* [1] provides the first published quantitative information about the the contamination of Gruinard Island with anthrax spores In view of the public interest and concern that have been expressed, this is welcome Nevertheless, the information given is meagre and the main tentative conclusion questionable

Since no accurate viable counts of spores were made on samples taken before those reported on in the paper, it is impossible to estimate the time course of the contamination The authors consider that its present extent warrants their taking seriously van Ness's assumption[2] that significant multiplication of anthrax bacilli may occur in the soil However, neither in that paper, nor in a series of earlier papers, does van Ness cite experimental evidence to justify this assumption In support, he quotes a paper by Minett and Dhanda[3] But those authors actually come to the *opposite* conclusion — that the anthrax bacillus does *not* behave as a saprophyte in nature

In the past, I have exhumed and examined cadavers of cattle that have died of anthrax, but I failed to isolate anthax from any, even from one buried as little as three months previously The conditions — high ambient temperatures and the availability of blood and tissues from the cadavers for the nutrition of the anthrax bacilli — resembled those postulated by Manchee *et al* [1] as being likely to promote an increase of bacilli and spores in the soil However, those familiar with the epizootiology of anthrax tend rather to regard such conditions as favourable to the increase of soil microflora inimical to anthrax organisms, a view which practical experience reinforces

There is little experimental evidence to support either van Ness's view or the more conventional opinion that anthrax does not behave as a saprophyte Unfortunately, incentives to investigate the ecology of the anthrax bacillus have diminished — despite its intrinsic interest — because of the ease with which anthrax can be controlled by the vaccine I developed[4]

Attention should be paid to studying factors which could be responsible for the exceptionally long survival of the contamination of Gruinard Island Is this related, for example, to the form in which the spores were distributed, to their number, to the character of the soil or of the soil microflora, to the lack of husbandry, or to climatic conditions? It would be deplorable if the special circumstances on Gruinard Island were not used to provide answers to these neglected ecological questions, and particularly to the question as to whether the anthrax bacillus can multiply sufficiently in the soil for this to be a significant factor in the epizootiology of anthrax Practical experience in the control of anthrax does not support this view

No change in RE

Sir — D B Jack and M R Gregg (*Nature* 22 October 1981, p 602) have used Flesch's index of reading ease (RE) to suggest that letters to *Nature* became harder to read at some time between 1940 and 1950 Using the first hundred words in each letter as the criterion, the papers analysed from the years 1950 to 1980 were, on average, 15 44 index points more difficult (the harder to read the lower the index)

This conclusion obscures a difference of style between earlier and more recent letters to *Nature*, that of the way in which the opening paragraph is used by authors Current practice demands that the opening paragraph shall serve two functions, both as introduction and as a summary of the main conclusions In its latter function it must often be laden with a burden of latinate technical terms and exactitudes, for those readers who choose to go further The earlier style demanded simply that the opening paragraph served to whet the appetite and to lead the reader gently to the nub of the matter, eschewing difficulties at first

I have therefore computed Flesch's RE for the first and second paragraphs of two samples of 20 letters each, culled from *Nature* of October 1981 and of October 1931 If the second paragraph contained less than a hundred words the third paragraph was lumped with it

	Reading ease		
	Para 1	Para 2	Total text
1931	29 8 ± 4 3	23 7 ± 4 1	26 3
1981	15 1 ± 2 1	21 0 ± 2 4	18 5

This analysis confirms Jack and Gregg's conclusion that the opening sentences today are more difficult than they were 50 years ago In my sample the difference is 14 7 RE points The 50 year difference for the second paragraph, however, is a mere 2 7 points which is not statistically significant In 1931 the second paragraph was on average 6 1 points more difficult than the introduction, today it is 5 9 points easier

Authors today seem not to be cloaking their findings in obscure language significantly more than they did 50 years ago, except in the introduction

More repeats

Sir — There appear to be two homologous sequences in a single exon of the collagen $\alpha2(1)$ sequences reported by Wozney *et al* in *Nature* of 12 November 1981[1]

The sequences occur in a single polypeptide and are apparent in the nucleotide sequence but not the amino acid sequence A span of 36 nucleotides is repeated with six differences (marked with ×)

```
1242                                1278
GlyAlaAlaGlyProProGlyProProGlyProSer
GGTGCTGCTGGCCCCCCTGGCCCTCCTGGTCCAAGT
  XX     X                X     X   X
GGCTCTGCTGGTCCCCCTGGCCCTGCTGGTCTAAGA
GlySerAlaGlyProProGlyProAlaGlyLeuArg
1315                                1351
```

The differences are probably due to post duplication mutations

The sequences lie 4 collagen units, $(\mathrm{Gly}\text{-}X_1\text{-}Y)_4$, from each other and contain 4 collagen units each, which makes a 54 base pair (bp) repeat hard to credit I cannot think of a plausible scheme to yield 36 bp repeats from 54 bp units Apparently 36 bp were extracted by double unequal crossover and re-appended 36 bp further down the molecule leading to the internal homology

Michael P Finerty

Mantle heterogeneity and isotopes in oceanic basalts

from W M. White and A W Hofmann

THE chemistry of volcanic rocks is strongly influenced by processes which occur during magma genesis and evolution and it is generally difficult to relate it to the chemistry of the rocks' sources One exception is the isotopic composition of radiogenic elements such as Sr, Pb and Nd, which are thought to be unaffected by most magmatic processes and provide a means of 'fingerprinting' volumes of source materials in the Earth's mantle It has been known for nearly two decades that the mantle is isotopically and chemically heterogeneous but the interpretation of the geochemical data is not easy because the kinematics of mantle convection remains elusive Now isotope geochemists and mantle convectionists are beginning to interact and collaborate in order to overcome this difficulty Two issues remain unresolved — the size of the domains of mantle heterogeneity and their spatial arrangement — is the mantle layered or irregularly heterogeneous?

On the geochemical side, it is well established that volcanic rocks erupted on oceanic islands are apparently derived from a type of mantle fundamentally different from that which supplies magma to most of the mid-ocean ridge system Second, all of the mantle now involved in mid-ocean ridge volcanism has previously been depleted in incompatible elements (that is, elements having a strong affinity for a melt phase as opposed to the solid) Further, heterogeneity in the mantle is long-lived Pb isotope data suggest that the various reservoirs have remained separate for a time of the order of 2×10^9 yr, demonstrating that mantle convection does not stir the mantle sufficiently to eliminate the heterogeneity Thus, and because of the hope that the isotopic data will somehow give clues about mantle kinematics and dynamics, geochemists continue to gather isotopic data on mantle-derived volcanic rocks

Systematic studies of basalts from the Mid-Atlantic Ridge in the 1970s revealed that, as islands such as Iceland and the Azores are approached, isotopic compositions of Sr and Pb change gradually from those typical of mid-ocean ridge basalts to compositions characteristic of island basalts, providing evidence of geographically correlated variation in mantle chemistry on a scale of the order of 100–1,000 km Two recent papers in *Nature* deal with mantle heterogeneity on a local scale Dupré and co-workers (*Nature* **294**, 552, 1981) report Pb and Sr isotopic data for two well studied areas of the mid-ocean ridge system the FAMOUS area in the North Atlantic and the CYAMEX area of the East Pacific Rise Basalts erupted in these two areas have nearly uniform Sr isotopic compositions and though Pb isotope variations exist, they are much smaller than variations observed on larger scales Earlier studies of Sr and Nd isotopes in basalts from the FAMOUS region also revealed virtual isotopic uniformity

Machado and his colleagues (*Nature* **295**, 226, 1982) report Sr and Nd data on basalts from the vicinity of the Kane Fracture in the North Atlantic, some 200 km from the ridge Measurable variations occur in both Sr and Nd, with basalts from the western ridge segment having systematically higher ^{87}Sr/^{86}Sr and lower ^{143}Nd/^{144}Nd ratios than those from the eastern ridge segment The total range of Sr isotopic compositions (^{87}Sr/^{86}Sr = 0 7022–0 7025) is small compared with what is normally found in mid-ocean ridge basalts, but the range of Nd isotope ratio is relatively large (^{143}Nd/^{144}ND = 0 51337–0 51313) The Fracture Zone apparently forms a boundary between two geochemical domains in the mantle

Yet another recent study bearing on the question of the scale of mantle heterogeneity has been reported by Zindler and co-workers (*EOS* **62**, 424, 1981) They find that seamounts in the vicinity of the East Pacific Rise have ^{87}Sr/^{86}Sr and ^{143}Nd/^{144}Nd ratios varying between 0 7027 and 0 7032 and 0 5132 and 0 5130 respectively, and basalts from a single small seamount span this entire range

Local isotopic variations have been reported from oceanic islands in earlier studies For example, on the island of Sao Miguel (Azores), 60 km in its longest dimension, reported ^{87}Sr/^{86}Sr ratios range from 0 703 to 0 705, while ^{143}Nd/^{144}Nd ranges from 0 51300 to 0 51276 On Iceland's Rekjanes Peninsula, ^{143}Nd/^{144}Nd ratios vary from 0 51317 to 0 51299 on a scale of a few tens of kilometres and less, although ^{87}Sr/^{86}Sr is nearly uniform Although it is often assumed that Sr and Nd isotopic variations are closely related, these studies, and that of Machado and his colleagues, demonstrate that these ratios, and by inference variations in Rb/Sr and Sm/Nd, may occasionally become decoupled

The conclusions that may be drawn from the data accumulated so far are (1) in most regions, especially along the mid-ocean ridge but also on many oceanic islands, isotopic compositions can be mapped, and it is found that the regional variations are larger than the local ones (2) Nevertheless a few regions, such as 45°N on the Mid-Atlantic Ridge, the island of Sao Miguel and the small seamounts off the East Pacific Rise, do show significant local variability and cannot be characterized by a single isotopic ratio (3) The local variations generally have greater amplitudes on oceanic islands than on the mid-ocean ridge (4) The regional variations are also larger for oceanic islands than for ocean floor basalts

The question of scale is intimately related to the question of origin A view widely held by geochemists and geophysicists, but by no means universally accepted, is that oceanic islands result from mantle plumes arising from the deeper mantle, while the upper mantle, depleted in incompatible elements through repeated episodes of melt extraction, is the source of mid-ocean ridge basalts The lower mantle source of mantle plumes may be either primitive, undepleted mantle or subducted oceanic crust An alternative view is that mantle heterogeneity is created by fluids rich in incompatible elements percolating upwards and metasomatizing the upper mantle, this is supported by evidence from mantle xenoliths in alkali basalts and kimberlites In this model there is a large potential for creating small-scale heterogeneity if fluid pathways are not uniformly distributed The plume

---

W M White is in the Geochemistry Department, Max-Planck-Institut fur Chemie, D 6500 Mainz, FRG, of which A W Hofmann is Director

0028-0836/82/050363-02$01 00

hypothesis predicts that oceanic islands are created at quasi-stationary locations and that large quantities of material are advected to the surface in excess of the volume needed to create normal oceanic crust. The existence of isotopic anomalies of large wavelengths and large amplitudes is certainly consistent with this hypothesis, and we have long favoured this idea. However, the hypothesis that isotopic variations are produced by more local phenomena possibly involving metasomatism does not really conflict with this view, rather, it may be the appropriate explanation for many or all of the small-scale isotopic variations observed. Indeed, it seems unlikely that the mantle plumes can explain everything. Surely not all seamounts are former or present sites of mantle plumes, nor is it clear, for example, how the isotopic variations near the Kane Fracture Zone could be related to a mantle plume.

We believe, perhaps unimaginatively, that in order to improve our understanding of mantle heterogeneity we do need to accumulate a lot more isotopic data on more oceanic basalts rather than wait until evidence of a different kind or insight provides a new impetus. Further study of the mid-ocean ridge system will be essential if the questions about the chemical structure of the mantle are to be resolved. Is the well studied North Atlantic Ocean anomalous because of the presence of the very large Iceland and Azores anomalies? Do other areas similar to 45°N exist or is the mid-ocean ridge system more nearly uniform away from oceanic islands? What is the total volume of isotopically anomalous basalts? Do all postulated plumes have large-scale isotopic gradients associated with them? Can the apparently randomly distributed small-scale variations also be mapped with improved coverage? Do major fracture zones, such as the Kane, form boundaries between geochemical domains in the mantle? To reconstruct the distribution of source materials and their movement in the mantle, we still need much more complete isotopic maps of the ocean floor and the oceanic islands than those so far compiled.

What is required is a programme of intensive mid-ocean ridge 'geochemical mapping' similar to that already carried out in the North Atlantic. We believe this would most profitably be accomplished through dredging rather than drilling because of the higher sample quality and the substantially lower costs. Drilling of seamounts and similar anomalous features, already begun by the International Phase of Ocean Drilling (IPOD), should continue. We think of this 'fingerprinting' of source materials in the Earth's mantle using isotopes as perhaps being similar to fingerprinting the oceanic crust using magnetic anomalies, the meaning of which remained obscure until there were enough data for them to be interpreted by simple visual inspection. ☐

New measurements near the Gulf Stream

from W J Gould

THE Gulf Stream is, to the layman, a well known ocean circulation feature responsible for the temperate climate of Western Europe. It would therefore seem surprising that oceanographers should be in any doubt about the structure and dynamics of the Gulf Stream in view of studies that have been made over many years[1–3]. However, until recently, progress in the field has been restricted by the difficulty of measuring directly the current in the strongest parts of the Gulf Stream. Now this problem has been overcome and a recent paper[4] sheds light on the relationship of the Stream to its recirculation and on the Gulf Stream's inherent variability.

The Gulf Stream is the intense (surface currents of 3 knots (150 cm s^{-1}) or more) narrow current that flows northwards along the eastern seaboard of the North American continent from the Florida Straits to south of the Newfoundland Grand Banks. North of Cape Hatteras the Stream begins to meander, with the envelope of the stream tracks spreading like a fan as it turns eastwards away from the continental slope and past the New England seamounts. The intense current is associated with the boundary of the warm Sargasso Sea water, which fills much of the western North Atlantic, and the colder 'slope water' adjacent to the continental slope. (The current axis is often defined as the locus of positions at which the temperature at 200 m depth is 15°C.)

East of the Grand Banks the current and its associated temperature structure rapidly lose their identity and the course of the Gulf Stream becomes diffuse. It is at this point that the current is considered to form two main branches, the North Atlantic current which heads northeastwards towards Europe, and the Gulf Stream recirculation which turns south and eventually westwards to rejoin the Gulf Stream and complete the subtropical Gulf Stream gyre.

Until comparatively recently the view of the Gulf Stream system (Gulf Stream, North Atlantic current and recirculation) has been derived solely from observations of the density field (from temperature and salinity observations) which are then used to derive the geostrophic flow field (based by definition on the assumption of a balance between the horizontal pressure gradients and the Coriolis force). A typical view[5] shows a Gulf Stream system confined almost entirely west of the Mid-Atlantic Ridge and characterized by two anticyclonic (clockwise) gyres penetrating throughout the entire water column. The main gyre is that of the Gulf Stream and its recirculation and the secondary one lies to the east of the Newfoundland Grand Banks. But the interpretation of the temperature and salinity data in terms of two gyres is controversial[6]. The calculation of geostrophic currents provides only a current profile relative to some arbitrary reference level, usually at depth, and thus while the near-surface circulation may be adequately described the deep current field may not.

A possible explanation of the exact nature of the circulation may come from direct observations of currents either by moored current meters (eulerian measurements) or by the tracking of drifters (lagrangian measurements) at the surface or at depth. The strength of the Gulf Stream has so far precluded the use of moored current meters in the upper part of the water column near the Gulf Stream axis although they have been used extensively north and south of the Stream and in the deep ocean below it. Lagrangian measurements do not have the same restriction and recent technology presents new possibilities for investigating the Gulf Stream system.

Neutrally buoyant floats are instrument packages designed to be less compressible than seawater. Thus, as they sink, they gain buoyancy relative to the surrounding water until by suitable ballasting they may be made neutrally buoyant at some pressure level. For many years since their development in the 1950s these floats were tracked acoustically from attendant ships[7,8] but their use was restricted to the duration of a typical research cruise (a few tens of days). In the late sixties and early seventies a series of neutrally buoyant floats with lifetimes of two or three years were tracked in the southern Sargasso Sea[9,10] using low-frequency sound signals (400 Hz) received at shore-based listening stations in the Caribbean. The necessary acoustic propagation over distances of the order of 1,000 km is achieved by means of a minimum near 1,000 m depth in the vertical profile of sound speed in the ocean which acts as a wave guide. This is known as the SOFAR (SOund Fixing And Ranging) channel and the long-range floats as SOFAR floats.

The technique was initially restricted to areas within range of the fixed receivers but the development of moored autonomous listening stations (ALS) in which signals from the SOFAR floats are received, processed and stored has raised the possibility of deploying SOFAR floats almost anywhere in the ocean.

A recent paper by Schmitz *et al*[4] provides some of the first direct measurements of currents in the strongest parts of the Gulf Stream and helps explain the nature of its circulation. The float tracks described are from depths of

0028-0836/82/050364-02$01 00

700–2,000 m and have been considered to provide eulerian estimates of current from the areas through which they passed These have been compared with eulerian measurements of currents from either side of the Gulf Stream (There are some fundamental difficulties in the interpretation of the float tracks Since they depend for their neutral buoyancy on the ambient pressure they tend to follow isobaric surfaces and so do not stay with a particular body of water, that is, they are not truly lagrangian)

The float tracks reported exhibit similar complexity in space and time to synoptic views of the Gulf Stream from temperature field maps and from previous current meter records The kinetic energy of the floats is consistent with an extrapolation of known meridional variations of kinetic energy[11] into the region of the Gulf Stream axis The deeper float tracks do not, however, support the view of a vertically coherent Gulf Stream, floats close to the Gulf Stream axis exhibiting both westward and eastward motions The tracks of floats in and above the thermocline (depth of greatest current shear) support previously held views of the circulation

New measurements in the vicinity of the Gulf Stream at both thermocline and abyssal depths raise the possibility of connecting the known (from eulerian measurements) time scales of variability south of the Gulf Steam in the Sargasso Sea recirculation and north of it on the continental slope[12] Subject to the only quasi-lagrangian nature of the float tracks there may also be evidence of the geographical distribution of the recirculation of the Gulf Stream system and a possible resolution of the two gyre controversy

There are now plans for a wider use of SOFAR float technology In particular, the next two years should see measurements taken by US, UK and French laboratories near and to the east of the Mid-Atlantic Ridge in an effort to study the paths taken by the North Atlantic current on its eastward path and long-term dispersion in the deep ocean These projects will use SOFAR floats in areas of more complex sound velocity structure than are found in the western North Atlantic and at much greater depths than previously explored ☐

Substorms and the growth phase problem

from S W H Cowley

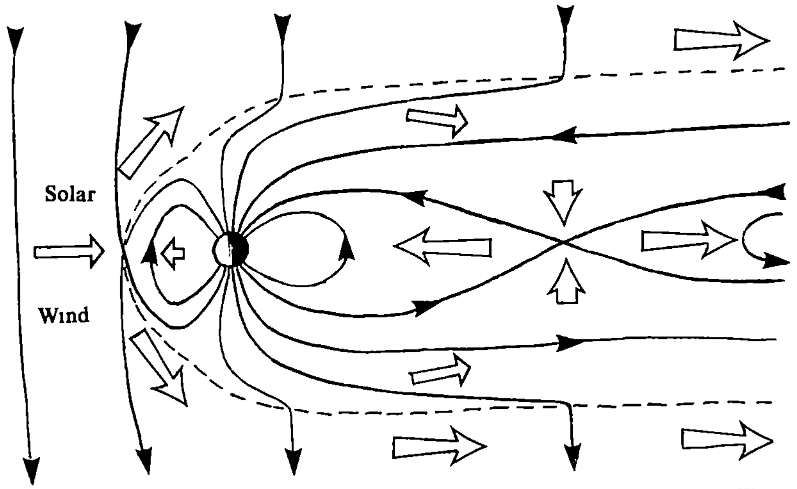
SPACECRAFT observations over the past decade have clearly demonstrated that large-scale dynamic changes in the magnetic field and plasma populations take place periodically inside the Earth's magnetosphere These disturbances are termed magnetospheric substorms They last for 1–2 hours and it is not unusual for several to occur in one day At the Earth, substorms are associated with brilliant auroral displays resulting from bombardment of the upper atmosphere by kilo-electron volt magnetospheric electrons, and with intense ionospheric electric currents flowing at high latitudes

It is generally agreed that substorms tend to occur when the coupling between the magnetosphere and the surrounding solar wind is strong Magnetospheric coupling to the solar wind causes a large-scale circulation of plasma and embedded magnetic field lines within it (see the figure) When the solar wind magnetic field points south, as shown, magnetic 'reconnection' can occur across the dayside boundary so that the solar wind magnetic field becomes directly connected into the Earth's polar magnetic field These terrestrial 'open' field lines are then swept downstream by the solar wind flow and are stretched out into a long magnetic tail typically extending to ~ 1,000 Earth radii (R_E) on the nightside of the Earth A similar 'reconnection' process then occurs (at least eventually) in the tail, returning 'closed' field lines to the Earth and thence to the dayside boundary where the process can repeat, as originally described by Dungey in 1961 The important point is that the strength of the cyclic flow depends primarily on the direction of the solar wind magnetic field Magnetospheric substorms occur preferentially when the field points south and dayside reconnection and the flows reach a maximum As the solar wind field turns northwards, both the flows and the occurrence of substorms decrease

There is broad agreement that once a substorm begins it can be described in terms of auroral brightening and 'break-up', the sharp intensification of ionospheric currents and the disturbances which occur in the magnetic field and plasma in the nightside magnetosphere However, there are two important and opposing views on the events which lead up to substorms the 'growth phase' model of McPherron[1] and the 'directly driven' model discussed most recently by Akasofu[2]

The 'growth phase' picture assumes that the increased magnetic flux transfer from the dayside to the tail which follows a southward turning of the solar wind magnetic field is not immediately matched by increased flux return from the tail to the dayside As a result, magnetic energy is stored in the increasing field in the tail for perhaps 1 hour or more before substorm onset (the 'growth phase') At a certain point, however, an instability occurs (substorm onset), resulting in the formation of a new reconnection region about 15 R_E down-tail from the Earth The rapid tail reconnection which then occurs dissipates the stored magnetic energy, feeding it over periods of about 1 hour into plasma energy (the substorm expansion phase) The substorm subsides when the reservoir of available magnetic energy in the tail is depleted, but a new substorm cycle can then start if the solar wind field remains southerly directed

The 'directly driven' substorm model is based primarily on the close correlation



Cross-section of the Earth's magnetosphere in the noon–midnight meridian plane The solid lines are magnetic field lines, and the dashed line is the magnetosphere–solar wind boundary which on the dayside of the Earth lies typically at a geocentric distance of 10 R_E Solid arrows indicate the flow of plasma and embedded magnetic field lines, and snow the convection system set up inside the magnetosphere by the magnetic 'reconnection' which occurs between the Earth's field and the solar wind magnetic field across the dayside magnetopause when the latter is southerly directed observed between substorm and solar wind conditions and postulates that the state of the magnetosphere is determined solely by the solar wind, with a magnetospheric response delay of perhaps a few tens of minutes The correlation is described in terms of a function of solar wind variables termed the 'ε parameter', whose value depends principally on the solar wind field direction, being maximum for southward fields and zero for northwards Substorms are postulated to begin whenever ε exceeds a certain critical value such that an instability occurs in the magnetosphere, and to be continuously maintained so long as ε remains above this value Akasofu suggests that the instability occurs in the current system connecting the magnetic tail with the nightside auroral ionosphere

One important difference between the 'growth phase' and the 'direct' models is the expected magnetospheric response to intervals of steady southward solar wind magnetic fields The 'direct' model would predict steady substorm-like conditions, while the 'growth phase' model suggests that a sequence of substorms would occur, whose time scale is determined by magnetospheric time constants Another important difference concerns the expected behaviour of the tail field at substorm onset In the 'direct' model the tail field may indeed often increase in strength before substorm onset, due to increasing ε and increasing solar wind ionosphere coupling However, onset is not associated with dissipation of the increased tail energy as in the 'growth phase' model Rather, since ε will generally continue to increase as it passes the critical value the tail field strength may also be expected to continue to increase Thus in the 'direct' model the tail field is expected to develop and decay in concert with ε and with the expansion and recovery of substorms, while in the 'growth phase' model the tail field is expected to grow before the substorm and generally to decay after the onset

Recently, Baker *et al*[3] have assembled a variety of observations of a large isolated substorm whose expansion phase onset occurred at about 0100 UT on 29 December 1976, which bears directly on the above question The nightside magnetosphere was monitored by two spacecraft, one directly measuring the tail magnetic field at a distance of $\sim 30 R_E$, the other detecting the changes in the energetic charged particle environment at $\sim 6\ 6\ R_E$ which directly result from the growth and decay of the tail field These data show that for ~ 1 5 hours before the substorm (determined from ground magnetic records) the tail field continuously increased in strength In itself this result is compatible with both substorm models — it can be regarded as a good example of a 'growth phase' or, in terms of the 'direct' model, it can be argued that ε was increasing during this period but remained below the critical value required for substorm onset Unfortunately, solar wind magnetic field data are not available during this interval to test this interpretation The critical observation, however, is that shortly after substorm onset the tail field started to decline, reaching initial values ~ 40 min after onset This result argues strongly in favour of the 'growth phase' model in which stored tail energy is dissipated after onset

An important objection to this conclusion may be made by asserting that while the tail field was increasing, substorms could indeed have been occurring (with ε above critical value), but at sufficiently high latitude that they were not observed at standard auroral zone observatories (about 65°–70° magnetic latitude) Baker *et al* rule out this possibility by examining data obtained from a widespread network of riometers The riometers indicate when energetic electrons are precipitating into the upper atmosphere by measuring the attenuation of cosmic radio noise at 20–40 MHz resulting from the production of D region ionization They gave no indication of substorm-associated precipitation for at least 7 hours before the observed substorm onset The result is confirmed by a 'snapshot' taken of the aurorae ~ 10 min before substorm onset near the height of the growth of the tail field by a US Air Force DMSP weather satellite, which shows the presence of quiet nightside auroral arcs, but no dynamic substorm features such as are plainly evident in the subsequent 'snapshot' taken by the same spacecraft ~ 100 min (one orbit) later

Taken together, the data presented by Baker *et al* clearly argue strongly for the 'growth phase' model of substorm onset One feature of the data does, however, strike a somewhat discordant note It is found that while the decline in the tail field is essentially complete ~ 40 min after substorm onset, the ground data and DMSP observations clearly indicate that intense substorm activity continued for at least another hour This behaviour is reminiscent of Akasofu's 'direct' model, although the suggestion cannot be directly tested in this case due to the lack of simultaneous solar wind magnetic field data It seems reasonable to suggest that, in future, thought might be given to an intermediate substorm picture in which the expansion onset is as described by the 'growth phase' model, as demonstrated by Baker *et al* 's results, but where substorm-like conditions may be maintained after the stored energy has been largely dissipated by a sufficiently large direct energy input from the solar wind □

T cell function: Ly phenotype and the MHC

from Elizabeth Simpson

THE lymphocytes of the immune system comprise a heterogeneous collection of subpopulations of cells performing different functions The main distinction is between B cells, which produce antibodies and can be recognized by the antibody molecules on their surfaces, and T cells, which subserve almost all the other functions of the immune system and can be distinguished from B cells by the Thy-1 antigen on their surfaces T cells themselves, however, are functionally heterogeneous, and cell surface markers reliably identifying different functional subsets have been more difficult to find

One of the earliest T lymphocyte marker systems to be described was that of the Ly markers, Ly 1, Ly 2 and Ly 3, first described by Boyse *et al*[1] The importance of these markers lay in their differential expression on T cell subsets[2,3] and it was soon shown that they could be used to distinguish between helper T cells (Ly 1^+ 2^-) and cytotoxic T cells (Ly $1^\pm$ 2^+)[4,5]

At about the same time it became evident that T cells used self major histocompatability (MHC) antigens as guides during recognition of extrinsic antigens[6] For cytotoxic T cells, the self-restricting or guiding elements were class I MHC antigens H–2 K and D in the mouse, HLA-B and -C in man, whilst for helper cells the appropriate self determinants were class II MHC antigens H–2 I in mouse, HLA-D in man[7]

Thus two sets of correlations seemed to be apparent first, cytotoxic T cell function was attributable to Ly $1^\pm$ 2^+ cells and directed towards class I and class I-associated antigens Second, helper cells were Ly 1^+ 2^- and directed towards class II or class II-associated antigens As a result of some recent experiments by Swain, however, the correlation between help and class II antigens and cytotoxicity and class I antigens has now broken down Instead, she proposes that Ly phenotype correlates primarily with the class of MHC antigen rather than with function The basis for this proposition is that, under certain con-

Elizabeth Simpson is in the Transplantation Biology section of the Clinical Research Centre, Watford Road, Harrow, Middlesex HA1 3UJ ditions, (1) T help can be found in populations of T cells responding to class I allo-H-2 antigens, and this help is mediated by Ly 1^+ 2^+ cells, and (2) cytotoxic T cells directed towards class II allo-H-2 antigens can have the Ly 1^+ $2^{\pm}$ phenotype This analysis was made using monoclonal anti-Ly 2 antibodies so that the ambiguities inherent in results from polyclonal antisera were eliminated

It had previously been reported that Ly 2 antibodies would block killing by cytotoxic T cells Swain therefore added anti-Ly 2 antibody to cultures in which T cell help was generated by an allogeneic response against allo-MHC antigens, either class I alone, class II alone or class I plus class II The induction of helper cells against class I antigen alone was blocked by anti-Ly 2 antibody In all other cases, anti-Ly 2 antibody failed to block help This result is concordant with a previous report[10] that helper T cells stimulated with class I allo-MHC antigens had the phenotype Ly 1^+ 2^+ In a second series of experiments Swain tested the effect of anti-Ly 2 antibodies on cytotoxic cells generated against either class I plus class II, class I alone or class II alone MHC alloantigens Cytotoxicity directed against class I alloantigens was inhibited whilst that against class II alloantigens was unaffected This finding is consistent with recent results of both Glasebrook and Pierres[11], using cytotoxic T cell clones directed against class II MHC antigens These clones were phenotypically Ly 1^+ 2^+ or Ly 1^+ $2^{\pm}$ (Swain's bulk culture activity was mediated by Ly 1^+ $2^{\pm}$ cells cells with a reduced expression of Ly 2 surface antigen) but the cytotoxic activity of these cloned lines could not be abrogated by Ly 2 antiserum in the assay Swain's conclusions are that T cells directed towards class II MHC antigens express Ly 1 and (at low levels) Ly 2 and can have helper or cytotoxic function neither of which is blocked by anti-Ly 2 antibody However the presence of at least some Ly 2 antigen on the surface of the cytotoxic cells distinguishes them from the normal Ly 1^+ 2^- helper cells generated in response to class II antigens She also concludes that the helper cells directed against class I antigens have a Ly 1^+ 2^+ phenotype and can be blocked by anti-Ly 2 antibody This last conclusion, however, is perhaps open to one objection it is possible that the helper activity could be mediated by cytotoxic cells making lymphokines — in particular, interleukin-2 which could substitute for helper T cells in the culture This possibility is suggested by the recent discovery of cytotoxic T cell clones directed against class I antigens and producing interleukin-2[11,12] It is also in line with recent evidence that T cell clones with either helper or cytotoxic function can elicit delayed-type hypersensitivity — a T cell-mediated response — when injected into the footpad of a mouse[13,14]

Nevertheless the unifying hypothesis put forward by Swain, that the Ly phenotype of a T cell and its MHC guiding antigen are the primary correlates, while function depends on the nature of the stimulation, is an attractive one, which puts into perspective a certain amount of apparently conflicting data recently accumulated □

Great voids in the Universe

from Joseph Silk

ONCE astronomers were content to point to the distribution of galaxies in the sky and infer that the Universe is relatively uniform in appearance More recently, the cosmic microwave background radiation, which samples the Universe at great depth, has provided dramatic confirmation of this homogeneity It is uniform to at least three-hundredths of a per cent, apart from the dipole anisotropy over 180 degrees that is associated with the motion of our Galaxy Our local region of space is obviously inhomogeneous, but this can easily be accounted for because the microwave background radiation is seen as being emitted from a very early phase in the history of the cosmos before structure fully developed One can think of this epoch as corresponding to a cosmic 'surface' or photosphere where the radiation was last scattered, somewhat analogous to the photosphere layer of the Sun below which we cannot see Before this moment of last scattering, which also coincides with the epoch of 'decoupling' of matter and radiation, the radiation was strongly scattered by ionized particles As the Universe expanded, the electrons and protons cooled eventually to combine into hydrogen atoms, which are highly transparent to the radiation, and little scattering subsequently occurred

Since then, small density fluctuations have grown, unimpeded by the drag of the radiation and driven by their own slight increase in gravitational attraction, and have gradually accreted more and more surrounding matter Such primordial fluctuations eventually formed galaxies, clusters and even superclusters of galaxies The smoothness of the radiation provides a measure of the degree of inhomogeneity of the Universe at the decoupling epoch, and a strong constraint on theories of galaxy formation

The larger the structure that is observed, the greater is the challenge to any theory for the origin of large-scale structure The recent discovery of a great void extending over some 10^6 cubic megaparsecs in the direction of the constellation Boötes has therefore attracted considerable attention (R P Kirshner, A Oemler, P L Schechter and S A Schectman *Astrophys J. Lett* **248**, L57, 1981) Several smaller regions containing no luminous galaxies were discovered during the course of galaxy surveys in the vicinities of great clusters, but the Bootes void is considerably greater than these regions It had previously been noted that galaxies surrounding the Coma cluster formed a great supercluster But if galaxies were sprinkled at random locations in space, many of them should have possessed redshifts appropriate to distances intermediate between the Coma cluster and the Virgo supercluster, of which our own Galaxy is an outlying member Instead, great gaps were found in the redshift distribution, and as redshift is a direct measure of distance, this was indicative of an almost complete absence of bright galaxies in the vast space between Coma and Virgo

The void in Boötes was discovered by looking deep into three small regions of sky separated by up to 30 degrees, and measuring the redshifts (and hence the distances) of all galaxies brighter than 16th magnitude In this way, a region of the Universe extending well beyond the Coma cluster was probed When Kirshner and his colleagues analysed the data in each of the three windows, they found a surprising coincidence — there was a similar gap in the redshift distribution in all three data sets In effect, they had surveyed three cone-shaped regions that passed through the same great hole in the distribution of galaxies The only plausible explanation was that the width of the hole spanned at least the 30 degrees they had sampled, and this led to the estimate that it encompassed a roughly cubical volume some 100 Mpc on the side

The absence of bright galaxies in such a volume can be interpreted in several ways Perhaps the region is truly devoid of matter, and is a genuine void in space Galaxy clustering permits the formation of holes, just as in some regions, great aggregations develop This explanation runs into one possible difficulty, since small inhomogeneities should have been

---

Joseph Silk is Professor of Astronomy at the University of California, Berkeley, California 94720

0028-0836/82/050367-02$01 00

present in the matter at the epoch of last scattering of the radiation The inferred amplitude of the associated radiation fluctuations from which this hole and other similar structures grew must have been at least one part in 10^3, and the fluctuations would extend over an angle of about 2° One would expect to see traces of these fluctuations in the microwave background radiation, however recent observations suggest that they are probably absent These primordial fluctuations could, in principle, be smoothed out if the intergalactic medium stayed ionized because of heating from some unknown process, which would rescatter the radiation However, the scale on which such smoothing effects could operate is limited by the distance travelled by light at a time when the density was high enough to permit rescattering of the radiation and amounts to few degrees If the implied radiation fluctuations are definitely not seen, the great void in Bootes cannot be a true hole but must contain matter in some form

This leads to the intriguing implication that there is an underlying dark component of the matter distribution One could imagine it to be distributed uniformly on scales of tens of megaparsecs Only a modest fraction need be clumped to account for the galaxy haloes and clusters which most astronomers believe are bound by such dark matter It is a sobering reflection on our role in the Universe that most of its contents are hidden from view The nature of the pervasive dark matter may, however, soon be resolved Two experiments tentatively reported in 1980 that the neutrino has a finite rest mass Neutrinos are predicted by the big bang theory to fill space in numbers comparable with those of the photons of the microwave background, and several experiments are underway to confirm this result If the neutrino mass ultimately is found to exceed even one-millionth of an electron mass, neutrinos would dominate the mass density of the Universe

Why should the voids contain neutrinos but lack the atoms from which galaxies formed? Adjacent to the voids are huge superclusters of galaxies Evidently galaxies accumulated in great sheet-like or filamentary structures, occupying a small fraction of the volume of space The galaxies could not have simply participated in the collapse of the superclusters, otherwise they would have acquired extremely high random velocities that would grossly violate observational constraints A more plausible possibility is that the matter originally collapsed while still in gaseous form into great sheet-like condensations that subsequently fragmented into galaxies Gaseous matter can radiate away the kinetic energy acquired during free-fall collapse, and so the newly formed galaxies need not develop large random motions This idea is the basis of the pancake (or blini) theory of galaxy formation advanced by Ya B Zel'dovich and his colleagues in Moscow A serious but not necessarily fatal objection to the blini theory is that all galaxies are predicted to form at a relatively late epoch Astronomers have been searching for the luminous protogalaxies predicted by this scenario, but have had little success

A final possibility is that the galaxy formation process has somehow been modified or even suppressed in the great voids between the luminous galaxies Perhaps the voids simply lack bright galaxies but contain vast numbers of faint, low luminosity galaxies or, alternatively, enormous amounts of very diffuse hot gas that has failed to condense into galaxies Existing searches have not been sufficiently sensitive to test either of these hypotheses One can only conclude, as with so many other astronomical problems, that improved observations are urgently needed □

How the malarial parasite enters the red blood cell

from R J Wilson

MALARIOLOGISTS have been thrown into a state of excitement by the expectation that the question of how the malarial parasite interacts with and deforms the erythrocyte membrane in order to gain entry may soon be answered The excitement stems from the rapid accumulation of information about the composition and structure of the erythrocyte membrane and its associated cytoskeleton, as well as the experimental identification of separate stages in the parasite's (merozoite) invasion sequence The stages can be categorized simply as recognition, attachment, junction formation and entry

Recognition

Both the resistance and the susceptibility of animal species to particular malarial parasites correlate with surface interactions between the parasite and the host red cell More specifically, Miller and his colleagues have shown there is an association between 'receptors' for malarial parasites and red cell surface antigens[1] Human erythrocytes lacking the Duffy blood group antigens are resistant to invasion by merozoites of the simian parasite *Plasmodium knowlesi* — an observation which may explain the striking absence of *P vivax* (a human malarial parasite) in West Africa where most of the population is Duffy negative Unfortunately, continuous cultivation of *P vivax* has not been accomplished *in vitro*, so it is not possible to test this hypothesis directly Nevertheless, much data has been gathered to support the hypothesis, culminating in the observation that although *P knowlesi* is, after all, able to recognize and attach to Duffy-negative human red cells, it is not able to enter them. It is the internalization process rather than recognition of an appropriate red cell that is defective

A good case can be made that on human red cells glycophorin acts as a receptor for the major human malarial parasite *P falciparum*[2] Erythrocytes (so-called En(a-) cells) deficient in glycophorin A, the main sialoglycoprotein of the human red cell membrane, are less susceptible to parasite invasion *in vitro* Furthermore, antibodies to glycophorin A block invasion, and the addition of purified glycophorin A to cultures can inhibit parasite invasion *in vitro* Erythrocytes deficient in glycophorin B (S-s-u cells), which are relatively resistant to invasion, become almost completely resistant when trypsinized so as to remove the oligosaccharide-rich N-terminal region of glycophorin A Interestingly, merozoites of *P falciparum* are unable to distinguish between erythrocytes bearing MM, NN or MN antigens As these antigenic structures are determined by the configuration of the five N-terminal amino acids of glycophorin A and the three associated oligosaccharides, the terminal region of glycophorin A seems not to be specifically involved in recognition and attachment

Attachment

Adhesion of a merozoite to an appropriate erythrocyte has no immediate consequences unless the merozoite is oriented with its apical end (which contains various micro-organelles) to the erythrocyte membrane This orientation results in a rapid spasmodic 'flinching' movement involving as much as one-third of the erythrocyte membrane[3] The membrane then appears to relax with the merozoite still attached but largely external to it Next, the parasite is drawn relatively slowly into a tightly localized invagination of the host cell membrane After entry, sealing of the pore is accompanied by irregular but widespread movements of the erythrocyte membrane and slight swelling of the host cell

The changes involved in this dynamic process take about 20 seconds to complete and can be deciphered by drawing on the static structural evidence of transmission electron microscope and freeze-fracture

R J Wilson is at the National Institute for Medical Research, The Ridgeway, Mill Hill, London NW7 1AA

studies, as well as models of the structure of the erythrocyte membrane and its associated cytoskeleton. Transmission electron micrographs indicate that the plasma membranes of the host erythrocyte and parasite do not fuse but the merozoite seems to be attached by its apical tip to the red cell membrane and contents discharged from the merozoite's rhoptry organelles may be implicated in adhesion.

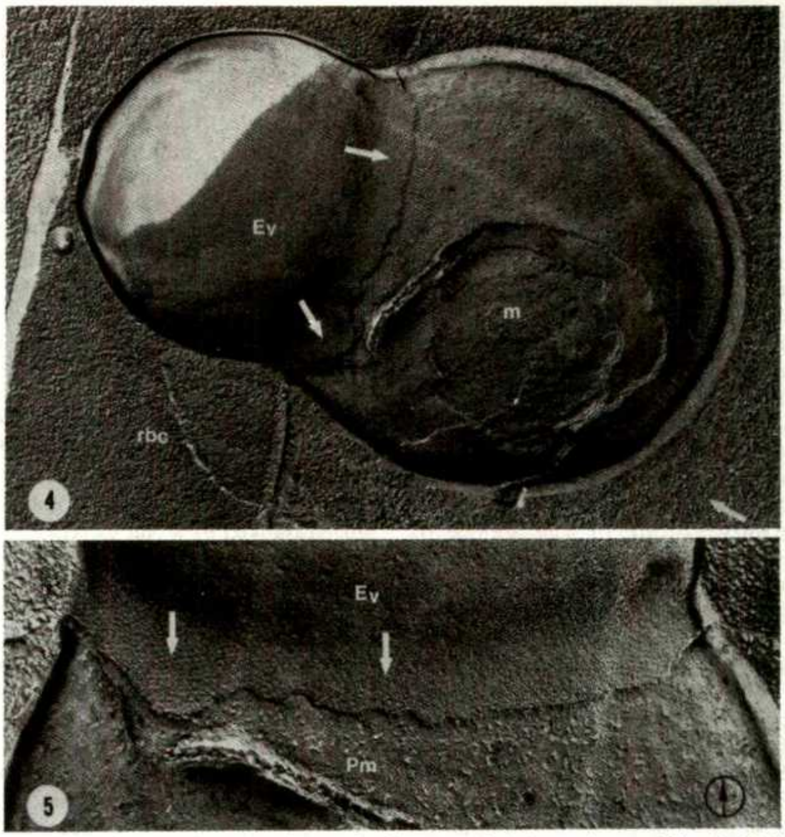
Junction formation

The subsequent invasion process is characterized by the development of a discrete junctional zone — an electron-dense thickening of the erythrocyte membrane closely applied (10 nm) to the parasite's surface coat in the apical region[4]. Electron micrographs indicate that the inner leaflet of the red cell membrane bilayer is thickened and Aikawa and his colleagues[5] have demonstrated by freeze-fracture that in this zone in the protoplasmic or P-face of the membrane, there is an array of tightly packed intramembranous particles (IMPs). Both this and an earlier freeze-fracture study by McLaren *et al.*[6] concur in describing IMP-free vesicles (or sections through a tortuous membranous channel) extending from the parasite's point of attachment deep into the erythrocyte's interior. All the changes just described still occur when merozoites treated with cytochalasin B interact with erythrocytes, even though the merozoites cannot complete the invasion process. Clearly attachment, which may involve recognition sites (receptors) and the formation of an IMP-rich junction area of host cell membrane, needs to be followed by further steps to allow invasion.

One of these is the translocation of the junctional zone as a narrow ring-like structure along the longitudinal axis of the merozoite until it encloses it and forms part of the parasitophorous vacuole surrounding the internalized parasite. Aikawa *et al.*[5] have confirmed the earlier important observation by McLaren *et al.* that the P-face of the invaginated membrane, which ultimately forms the parasitophorous vacuole, has a grossly reduced number of IMPs compared with the intact membrane. Unlike Aikawa, McLaren *et al.* reported few particles in the external or E-face of the invaginated membrane.

Entry into the red cell

During internalization, the surface coat of the merozoite is modified and can no longer be detected within the invagination by electron microscopy. Earlier suggestions that the surface coat accumulates outside the invagination and is eventually sloughed off have been challenged. Aikawa *et al.* maintain that the surface coat is unaltered external to the invagination and that a process akin to capping cannot be invoked to explain the parasite's internalization.



Above, freeze-fracture electron micrograph of a merozoite(m) entering a red blood cell (rbc). The arrows indicate the E-face of the erythrocyte membrane. Ev is the E-face of the vacuole membrane. x37,000. Below, high-power electron micrograph of the neck of the invagination. The E-face of the vacuole (Ev) shows few IMPs. Pm, P-face of the merozoite membrane. x68,700. (From ref. 5.)

The motive forces responsible for invagination of the parasitophorous vacuole membrane and internalization of the attached parasite can only be guessed. Membrane flow past the junctional zone might cause its apparent lateral displacement. The formation of an IMP-rich patch around the initial attachment site and the subsequent invagination of a large IMP-depleted vacuole (commensurate with about 3 per cent of the erythrocyte's surface area) suggest that peripheral membrane proteins such as spectrin and actin are dissociated from the cytosol surface of the erythrocyte membrane to allow lateral redistribution of IMPs. In intact erythrocytes there is evidence that IMPs represent the integral membrane proteins, band 3 and glycophorin. These have restricted lateral movement because of interaction with the cytoskeletal network[7]. It is still unclear whether a histidine-rich (73 per cent) parasite protein is released during invasion and acts like other polyanionic substances to disrupt the cytoskeletal network[8], and whether the IMPs aggregated in the junction zone by the malarial parasite actually correspond to erythrocyte proteins.

So far there have been few studies of the invasion of erythrocytes with modified cytoskeletons. Recently, it was reported that ovalocytic erythrocytes from Melanesions are resistant to invasion by *P. falciparum*[9]. This could be due to an alteration in the erythrocyte's cytoskeleton that reduces the physical deformability of the membrane or prevents the redistribution of IMPs required for junction formation. Alternatively, there may be a defect in the distribution of surface receptor sites. Access to the cytoskeleton for specific reactions with antibodies and other reagents has been achieved by the formation of resealed erythrocyte ghosts which retain their susceptibility to parasite invasion[10]. Preliminary studies (Dluzewski, personal communication) with resealed erythrocyte ghosts containing antibodies to spectrin indicate that parasite invasion is markedly reduced. This approach promises to help clarify the rearrangement of peripheral and integral erythrocyte membrane proteins during invasion. Clearly, many challenging problems remain to be solved at the molecular level before we can claim to understand how the major haemotropic pathogen of man makes its temporary escape from the extracellular environment by invading red cells. □

The mystery of the mouse α-globin pseudogene

from R.A. Flavell

THE chromosomes of multicellular organisms seem to be full of a wide variety of DNA sequences which are of no apparent use to their hosts. Some of these sequences, termed pseudogenes, are defective copies of functional genes. The laboratory mouse has two such crippled genes — the α-globin pseudogenes. However, one of them, $\alpha\psi3$, is different from other pseudogenes described to date. It has precisely (to the nucleotide) lost the intervening sequences (or introns) which are present in the functional α-globin genes[1,2]. It is not known why introns are commonly found in the genes of vertebrates — they are removed from the primary RNA transcript during production of a functional messenger RNA and it seems a complicated method of encoding genetic information when intronless genes work well in prokaryotes (for speculations on this subject see ref.3). But whatever the reasons why the insertions are present in the normal α-globin genes; the question of how $\alpha\psi3$ lost its introns is a riddle of great interest.

One possible origin of $\alpha\psi3$ is that an intronless α-globin mRNA altered a duplicated normal α-globin gene to an exact copy of itself by gene conversion[1]. However, although gene conversion between homologous DNA sequences is well characterized, gene conversion by a RNA has not been seen. Another, perhaps more plausible possibility is that $\alpha\psi3$ somehow derived from the copying of an α-globin mRNA into a DNA molecule by the retrovirus-encoded enzyme reverse transcriptase. Such a DNA might also alter a duplicate α-globin gene by gene conversion.

The most exciting proposal is, however, that an α-globin mRNA actually became incorporated into the RNA genome of a retrovirus. Retroviruses are equally at home as either RNA-containing viruses or DNA copies of this RNA (called proviruses) which are integrated into the host cell DNA. Therefore, provided that one accepts that an α-globin mRNA could gain entry into the retrovirus genome, it is only necessary to invoke the normal infectious cycle of the virus to explain the presence of $\alpha\psi3$. Retroviruses are certainly capable of incorporating cellular genes into their RNA genomes[4] and, significantly, comparisons between the cellular and viral genes show that the RNA copies of these cellular genes have sometimes lost the introns which characterize the parent genes[5]. So far the only genes known to have been 'captured' by a retrovirus are those conferring an easily scored phenotype on infected cells (tumorigenic transformation), but it is reasonable to suppose that a retrovirus might incorporate any piece of the cells' transcribed DNA, such as the α-globin gene. Of course, such an event would have to occur in the germ line of the mouse to survive the eventual death of its host.

Such a model demands that the newly integrated α-globin gene be accompanied by a retrovirus provirus. In this issue of *Nature* (p.426), Lueders *et al.* describe their analysis of the flanking DNA of both α-globin pseudogenes and the α-globin genes of mouse. They show that $\alpha\psi3$ is indeed flanked by a pair of retrovirus-like elements whereas the other α-globin genes are not. The elements, which are present in about 1,000 copies per mouse genome, encode a class of virus-like entities called intracisternal type A particles (IAPs) which share close similarities with the commonly studied type B and type C retroviruses. Unfortunately, it is by no means clear whether IAP elements are responsible for the creation of $\alpha\psi3$, as the pseudogene is flanked on either side by about 4 kilobases of cellular DNA before the IAP elements are reached, whereas the model demands that $\alpha\psi3$ be actually connected to the retroviral sequences. It is at this point that the real problem in determining the origin of this pseudogene raises its head.

The pseudogene emerged roughly 20 million years ago, since when there may have been numerous alterations to the gene and its immediate environment, perhaps because $\alpha\psi3$ was probably superfluous to the metabolic requirements of its host. Deletion or insertion of other DNA sequences may have masked its original configuration. The authors point out that a way around this problem may be to study the same pseudogene in related mouse species and in the rat. By looking for alterations which have cropped up during the evolution of these species, the original configuration of $\alpha\psi3$ may be revealed. Two of the authors are accumulating more data on mouse genes flanked by other IAP elements which should show whether the $\alpha\psi3$–IAP complex is particularly unusual. Doubtless, the sequences between the pseudogene and the IAP elements are also being scrutinized for clues to the origin of the arrangement.

If IAPs do turn out to have a role in the creation of the α-globin pseudogene, could such a phenomenon affect genome evolution by inducing the migration of functional DNA sequences to new sites? Or are we looking at a way of creating merely new 'junk' DNA? □

THE INDIAN DARTER

The Darters form a very peculiar type of birds of the order Steganopodes, allied to the Cormorants in structure, but very Heron-like in gait and gesture. The Darter in its normal position sits erect upon a branch or stump overlooking the water. When proceeding to fish it dives head foremost into the stream, and swimming entirely under water, transfixes its finny prey with the rapidity of lightning. Emerging from the water with the fish speared upon its long slender beak, the Darter chucks the fish into the air, and catching it head foremost with unerring aim, swallows it whole.

The Indian Darter

The Darters usually exhibited in the Royal Society's Gardens are of the South American species (*Plotus anhinga*), but in 1878 an example of the African form Le Vaillant's Darter (*Plotus levaillanti*)[1] was received. In April last an example of a third species of this genus — the Indian Darter (*Plotus melangaster*) was obtained in exchange from the Zoological Gardens of Calcutta.

"In a state of nature," as Dr. Jerden tells us, "this beautiful diver is found throughout all India, Ceylon, Burmah, and Malayana. It is exceedingly numerous in some parts of the country, especially in Bengal; hundreds are often to be seen on a single jheel. They hunt singly in general, or in scattered parties, but often roost in company, both at night and in the middle of the day, when numbers may be seen perched on the trees overhanging some tank or river. They float low on the water, often with nothing but the head and neck visible, and swim and dive with rapidity. After feeding for some time they perch on the bough of a tree or on a pole or stone, and spread their wings out to dry as the Cormorants do."

REVIEW ARTICLE

Grain alignment in the galactic magnetic field

Paul E. Johnson

Wyoming Infrared Observatory, Department of Physics and Astronomy, University of Wyoming, Laramie, Wyoming 82071, USA

The linear polarization of light observed in many distant stars, presumably an effect of absorption of starlight by elongated interstellar dust grains, provides a means of mapping the magnetic field lines in our own Galaxy as well as probing the properties of the intervening dust. Processes for grain alignment in the galactic magnetic field are reviewed: evidence is examined for grains being spun up to extremely high (10^9 Hz) angular frequencies by the recoil of hydrogen recombination on grains, as an essential part of the alignment process. Grain alignment would then be inhibited in regions of grain growth and would be most effective where grain growth is inhibited or reaches saturation.

WHEN the light from stars close to the galactic plane is analysed, it is found to be both reddened and polarized, with the angle of polarization most often lying in the galactic plane. Both are presumed to be effects of absorption of starlight by a medium containing clouds of elongated dust grains (accompanied by neutral hydrogen), spinning so that their major axes tend to be transverse to the plane of the galaxy. The starlight transmitted through such a medium would appear reddened and linearly polarized in a direction parallel to the galactic plane.

The typical interstellar grain is usually found in diffuse clouds composed of a relatively high density of dust ($\sim 8\times10^{-11}$ grains cm^{-3}) and neutral hydrogen gas ($\sim$20 atoms cm^{-3})[1]. Inside such denser clouds grains are shielded from the destructive effects of stellar UV radiation and can therefore grow by the accretion of volatiles such as H_2O, CH_4 and NH_3. Grain cores are expected to be composed of more refractory materials, such as silicates, SiC and graphite. The observed optical properties of grains indicate overall grain diameters of 0.02 to 0.15 μm (ref. 2).

Martin[3] pointed out that a rotating, charged grain will precess about a magnetic field, regardless of the mechanism aligning the grain. The result of such a precession is that, on a time average, the distribution of grain axes will be symmetric about the magnetic field, if the period of precession is adequately short. Dolginov and Mytrophanov[4] suggested that the Barnett effect, the spontaneous alignment of atomic dipoles in a rotating body, will produce a rapid precession in a magnetic field, even for an uncharged grain. For physical conditions in the interstellar medium the period of either type of precession is much shorter than the time constant for any previously proposed alignment mechanism. Therefore, the polarization of starlight should either be parallel or perpendicular to the magnetic field.

Figure 1 shows that the most orderly regions of polarization are those near the galactic plane exhibiting a polarization parallel to that plane. Therefore, it is reasonable to conclude that the general galactic magnetic field probably runs either parallel or perpendicular to the galactic plane[5].

The increase in the amount of Faraday rotation (which gives $n_e B_\parallel$ integrated along the line of sight, where n_e is the electron number density in the interstellar medium and $B_\parallel$ is the component of the magnetic field directed along the line of sight) with decrease in galactic latitude, as measured in several hundred extragalactic radio sources, is consistent with radiative transfer through a general galactic magnetic field[6]. Uncertain-

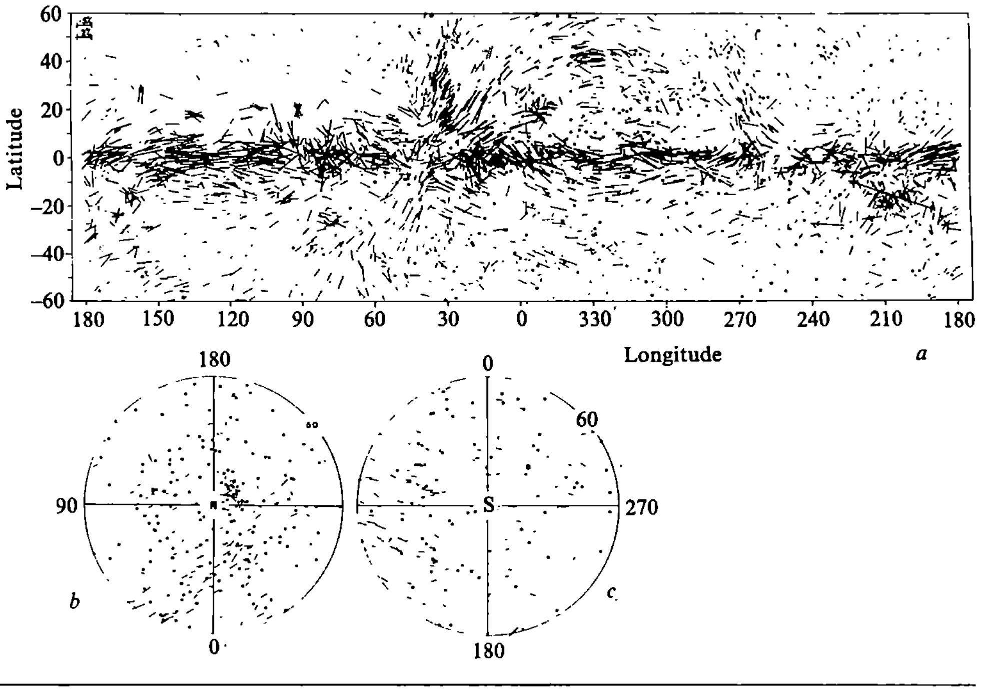

Fig. 1 Interstellar polarization. The direction and degree of linear polarization of nearly 7,000 stars is shown with respect to galactic coordinates. The length of each line is proportional to the linear polarization. Stars with a polarization <0.08% are represented by small circles. (After ref. 5. With the permission of the Royal Astronomical Society.)

ties in the electron density and variations in the magnetic field, B, over long pathlengths prevent an accurate determination of the galactic magnetic field from these data[1]. Measurement of the dispersion of pulsar signals (which gives n_e integrated along the line of sight) and their Faraday rotation allows an accurate determination of both the electron density and magnetic field in the solar neighbourhood. The uniform component of the magnetic field in the solar neighbourhood has been measured at $2.2 \pm 0.4 \times 10^{-6}$ G in this way[7]. The variation of the magnetic field with galactic longitude indicates that B runs roughly parallel to the galactic plane. The polarization of starlight has been one of the chief tools with which to investigate the large-scale structure of the galactic magnetic field. I review here the two most viable theories of grain alignment and assess the evidence bearing on them.

Davis–Greenstein grain alignment

It has been generally assumed that interstellar grains are aligned with respect to the interstellar magnetic field by paramagnetic relaxation of thermally rotating grains, as originally proposed by Davis and Greenstein[8] (DG alignment). In this process a paramagnetic grain is set spinning by impacts with the interstellar gas. When such a grain is immersed in an external magnetic field an internal field is induced such that its direction is coincident with the external field. It is impossible for the alignment of the internal and external fields to be achieved instantaneously. Because the grain is spinning there is always a slight misalignment between the two fields. The external field attempts to enforce alignment with a drag torque opposing the angular velocity of the grain about an axis perpendicular to the direction of the magnetic field. This results in grain alignment. DG alignment of aspherical particles was modelled by Purcell[9] and Purcell and Spitzer[10] using a Monte Carlo analysis of the entire process. Their analyses confirmed the theoretical results of Jones and Spitzer[11] that alignment of grains adequate to explain the interstellar polarization of starlight would require a magnetic field $>10^{-5}$ G, much larger than what has been found empirically.

To achieve effective DG alignment, the collisional damping time of grains (due to gas–grain collisions) t_d, must be less than or equal to the paramagnetic relaxation time (the time scale for alignment) t_r (refs 10–12). In a H I cloud one must have

$$\delta \equiv \frac{t_d}{t_r} \approx \frac{B^2 \chi''}{\omega n_H m_H \bar{v}_H a} \leqslant 1 \qquad (1)$$

where χ'' is the complex part of the magnetic susceptibility of the grain material, ω the angular frequency of the grain, n_H the number density of hydrogen atoms, $\bar{v}_H$ the r.m.s. velocity of hydrogen atoms, and a the mean radius of an interstellar grain. For the conditions in a 'typical' H I cloud (the neutral hydrogen density, $n_H = 20$ cm^{-3}, $T_g = 80$ K, $T_d = 15$ K, and paramagnetic grains with $a = 0.3$ μm (ref. 1)) B must be greater than 8×10^{-6} G. So large a magnetic field in H I clouds is inconsistent with the upper limit of 3×10^{-6} G from Zeeman measurements[13].

This problem can be circumvented by assuming that the grains responsible for interstellar polarization are weakly ferromagnetic or superparamagnetic. The latter occurs when isolated clusters of iron atoms, less than 100 Å in size, behave as single, giant magnetic moments[14]. Duley[15] has suggested the existence of weak ferromagnetism or superparamagnetism in grains of mixed MgO FeO SiO. According to this theory, if the cores (100–200 Å in size) of 0.1–0.3 μm grains are composed of such material and covered with ice, then they can be aligned in a field of only 1×10^{-6} G. If the cores are weakly ferromagnetic, relaxation is caused by the spin-lattice relaxation of paramagnetic spins in a mantle of icy material. If, on the other hand, the grains are superparamagnetic, relaxation proceeds as in the case of paramagnetic relaxation, but with fields $<1 \times 10^{-6}$ G. However, it is not certain that this latter process is effective in cores 100–200 Å in size.

In any case, such mixed oxide grains would reproduce the spectral resonances at 3.1 μm and 10 μm seen in such sources as the Becklin–Neugebauer Object (BN) in Orion[16]. Other ferromagnetic materials, such as magnetite[17], used in explaining interstellar polarization cannot easily reproduce these spectral features.

Most other alignment mechanisms are greatly inferior to DG in explaining grain alignment in the galactic magnetic field[14]. For example, Gold's streaming mechanism (in which grains present their smallest cross-section to a stream of rapidly moving gas) falls short of DG by an order of magnitude in explaining the general interstellar polarization[9].

Purcell pinwheel alignment

Purcell's[18,19] pinwheel alignment mechanism seems to be viable for the physical conditions in the interstellar medium. In this theory, a grain spins-up to high angular velocities when inhomogeneities on the surface of the grain result in a mean torque with respect to an axis fixed in the grain. Such torques arise, for example, when hydrogen atoms collide with a grain and stick to it, diffusing over the surface of the grain until they combine with another hydrogen atom at an 'active' site. Hollenbach and Salpeter[20] suggest that a limited number of active sites exist on a grain and are simple impurities or surface defects that serve to catalyse the formation of molecular hydrogen. Such a molecule is subsequently ejected with a linear momentum p_0, resulting in a relatively large torque being imparted to the grain. For ν active sites randomly distributed over the surface of a grain, the mean torque applied by such a collision is about $ap_0/\nu^{1/2}$. A torque can also be the result of a variation in the photoelectric emissivity or the accommodation coefficient (the fraction of gas atom kinetic energy transferred to the grain in a gas–grain collision) over the surface of a grain.

All of these processes will produce relatively strong systematic torques, leading to rotational frequencies as high as 10^9 s^{-1}, corresponding to a rotational velocity, (ωa), of 10^4 cm s^{-1} for a grain of radius 0.1 μm. In comparison, the mean velocity of a gas atom for $T_g = 80$ K is 1.3×10^5 cm s^{-1}. Purcell[19] shows that in the presence of dissipative processes, such as anisotropic elasticity, the grain's angular momentum direction will lie along the principal moment of inertia. Note that almost nothing is known about the shape of grains other than that elongated grains are required to generate the observed polarization of starlight.

Of the above processes, the hydrogen recombination pinwheel should be the most effective in the interstellar medium by several orders of magnitude where hydrogen is mainly in the atomic form.

Effect of grain resurfacing on alignment

The Purcell pinwheel mechanism possesses quantitative difficulties in explaining grain alignment[1,19,21]. These problems arise because we previously assumed that the net torque due to anisotropies on the surface of a grain does not change with time. Here only the case of hydrogen recombination driving the grains suprathermally, the strongest of the processes suggested by Purcell, will be considered, although the results are quite general. Both the theory of grain growth and the measurement of the increase of λ_{max}, the wavelength of maximum linear polarization, with distance into a dark cloud indicate that grains are growing[1]. Therefore, over a period of time, t_L, old active sites will be covered up, leaving new ones. Whether or not the locations of the new sites are correlated with those of the old sites is unknown. It is reasonable to assume that the new torque on a grain would be entirely altered when the radius of a grain is increased by a single monomolecular layer.

Spitzer[1] gives the rate of increase of the radius of a grain due to the accretion of atoms, excluding H and the noble gases, with cosmic composition as

$$\frac{da}{dt} \cong 2 \times 10^{-13} \xi \text{ cm yr}^{-1} \qquad (2)$$

where ξ is the effective sticking coefficient, $T_g = 80$ K, and

$n_H = 20\ \text{cm}^{-3}$. Most growth in dust clouds should be due to the accretion of oxygen and the resulting formation of ice. In 2.4×10^5 yr, the collisional damping time in these conditions, the radius of a grain changes by about 6×10^{-8} cm, exceeding the thickness of a monomolecular layer.

Just as serious as grain growth is the constraint put on Purcell alignment by grain denudation due to UV radiation in unshielded nebulae as well as in dust clouds where there has been a burst of UV radiation during star formation. Such denudation would resurface grains just as effectively as grain growth.

Purcell[19] and Spitzer and McGlynn[21] treat the effect of the alteration of a grain surface on pinwheel alignment in some detail. Let us assume that after a time t_L the torque on a grain, in body coordinates, will have been completely altered. Unfortunately, the effectiveness of paramagnetic relaxation on grain alignment depends critically on t_L, which is uncertain at best. If $t_L \gg t_r$ grains will spin-up to an equilibrium angular velocity in a time t_d, and will then become aligned. However, if t_L is small, the torque about the principal moment of inertia will occasionally change sign and the angular velocity of the grain about the axis will 'cross-over' through zero. The extent to which alignment is affected depends on the magnitude of the change in grain orientation during cross-over and the cross-over frequency. Purcell[19] shows that the mean time between cross-overs is t_x, where

$$t_x = 1.3(t_L + 0.6t_m) \qquad (3)$$

t_m is the time required for a grain to collide with a mass of gas equal to its own mass. If $t_x \sim t_m$ and a grain loses all memory of its orientation during a cross-over, then the Purcell mechanism falls short by at least an order of magnitude in explaining the observed polarization of starlight.

Spitzer and McGlynn[21] used a Monte-Carlo analysis to determine how much orientation a grain loses during cross-over. They were only able to strengthen marginally the ability of the Purcell mechanism to align grains. Some of the physical parameters affecting their model (such as grain size and density) are rather poorly known, however, so that the outcome is not certain.

There are at least two sets of conditions in which pinwheel alignment is still viable. If the grains are superparamagnetic or ferromagnetic χ'' can be larger by up to a factor of 10^5 (ref. 1). Then (t_m/t_r) is small enough so that appreciable alignment is likely, even with fields of 10^{-7} G. Another possibility is the inhibition of grain resurfacing.

Grain growth and destruction in the interstellar medium

Observations of the wavelength dependence of the polarization of the stars obscured by the R Coronae Australis dark cloud has led Vrba *et al.*[22] to conclude that there is an evolution of grain size distribution with age and changing environment (Fig. 2). R CrA is a young cloud ($\leq 10^6$ yr)[23] with its high density and low internal stellar luminosity favouring the formation of large grains. The large variation in grain size (as reflected in the large dispersion in λ_{max}) is likely to be caused by individual grains being formed and growing in different conditions in different parts of the cloud. Stars near the edge of the cloud, for example, would be less shielded than grains in the interior and would therefore experience a slower rate of growth and a smaller mean size.

The α Persei cluster (an analogue of the R CrA cloud with an age of 2×10^7 yr) has a smaller mean grain size, close to that of the general interstellar medium[22]. Coyne *et al.*[24] show that in $\sim 10^7$ yr large grains can be destroyed by photodesorption during a phase of extremely luminous pre-main-sequence evolution, which the α Per cluster has apparently experienced and to which the R CrA cloud has not yet evolved. Stellar winds and radiation pressure may have dispersed large grains, and, of course, UV radiation would be expected to dissipate the mantles of grains, thus reducing their size.

We will assume that grains in the diffuse interstellar medium are cores denuded of their mantles and are strongly growth inhibited by UV desorption. Such grains, almost regardless of their composition, will experience efficient alignment by the Purcell pinwheel alignment process due to the non-existence of an efficient grain resurfacing mechanism in these conditions.

The rate at which an interstellar grain accretes material by gas–grain collisions is given by $\pi a^2 n_a \bar{v}_a \xi$, where n_a is the number density of atoms in the gas other than hydrogen and the noble gases and $\bar{v}_a$ is the r.m.s. velocity of these atoms. The rate at which atoms are desorbed from a grain is given by $\pi a^2 Y_{pd} G_0 \exp(-\tau_{uv})$, where Y_{pd} is the photodesorption yield of a grain, G_0 is the integrated diffuse interstellar photon flux between 912 (the Lyman limit) and 1,900 Å (longward of which photodesorption is rather ineffective[25]), and τ_{uv} is the effective extinction in the UV to the region under consideration[25]. One would expect that even if there is no net grain growth, accretion and photodesorption will redistribute active sites more rapidly

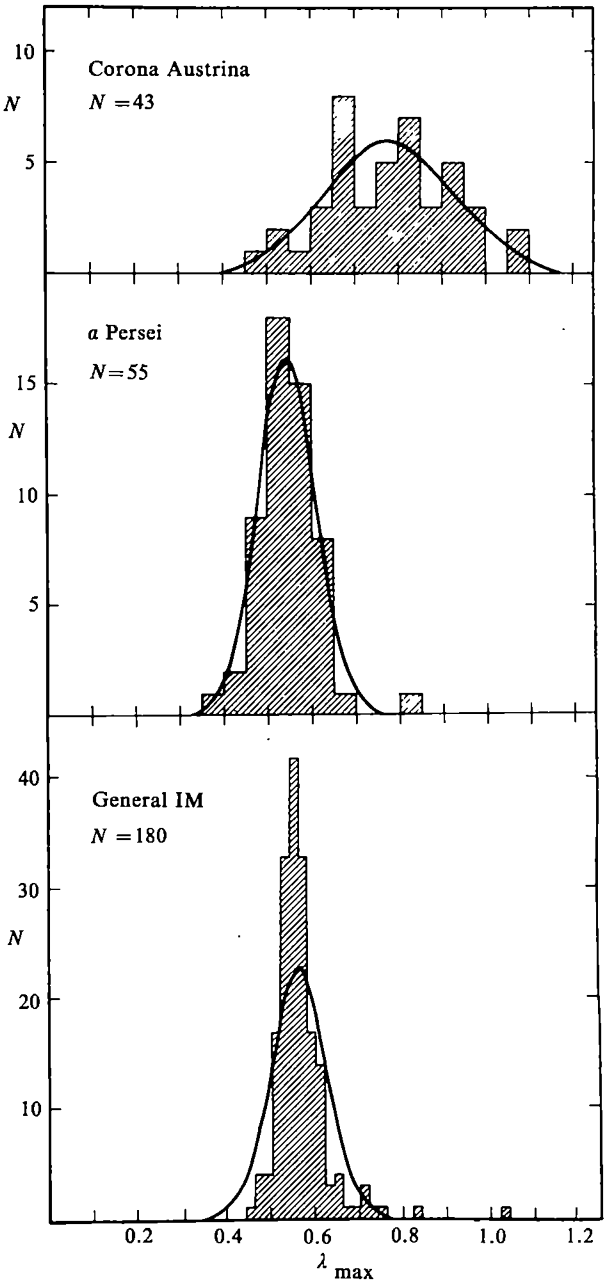

Fig. 2 Histograms of the grain size distribution (as measured by the wavelength of maximum polarization, λ_{max}, for an obscured source) for the diffuse interstellar medium (IM) and the α Per and R CrA dark clouds. The solid curves represent normal distributions fitted to the data. (After ref. 22. With the permission of the University of Chicago Press.)

than accretion alone. For the activation of the Purcell pinwheel mechanism by photodesorption it is then necessary that grains are completely stripped of volatiles, or

$$n_a \bar{v}_a \xi < Y_{pd} G_0 \exp(-\tau_{uv}) \qquad (4)$$

In the interstellar medium nominally we have $\xi \cong 1$, $Y_{pd} \sim 5 \times 10^{-3}$, $G_0 \sim 1.7 \times 10^8$ cm^{-2} s^{-1}, and $\bar{v}_a \sim 8.0 \times 10^3$ cm s^{-1} (corresponding to the r.m.s. velocity of oxygen atoms at 80 K)[25]. Therefore $n_a \exp(\tau_{uv}) \leqslant 8 \times 10^4$ cm^{-3} in order for grain resurfacing to be effectively halted[25]. This criterion would in general be met in the diffuse interstellar medium, but not necessarily in the interiors of dense molecular clouds.

In the above model, grains shielded from photodesorption in the dense interiors of dark clouds would be less susceptible to alignment than unshielded grains. Indeed, it has been observed in both the ρ Ophiuchus dark cloud[26] and in R CrA (ref. 22) that the polarization efficiency of grains (as measured by p/A_v where p is the linear polarization of an obscured object and A_v is its visual extinction) decreases dramatically with the mean size of grains in a particular region (as measured by λ_{max} and the ratio of total to selective extinction, R). This may be due to the anti-correlation between grain alignment and rate of growth in the Purcell model. Such results are also consistent with DG alignment, which is most effective with small particles.

The major difficulty with our model is the efficient grain alignment in regions of dense clouds having large λ_{max}, such as the Orion Molecular Cloud (OMC-1) (ref. 27) and M17 (ref. 28). I suggest that the solution to this apparent dilemma is to dissociate large λ_{max} from a high growth rate. The rate at which the radii of grains can grow due to atomic accretion, in the absence of photodesorption, is given by equation (2). It then follows that the time scale for the adsorption of a molecule or atom by a grain is $5 \times 10^{15}\ a/T_g^{1/2} n_a$ yr (refs 22 and 29), for a in cm, T in K, and n_a in cm^{-3}. The shortness of this time scale (of the order of 10^6 yr for a typical dark cloud) implies two things:

(1) In the regions of dark clouds adequately shielded from UV radiation, grain growth due to molecular accretion will rapidly saturate. The saturation of R in the ρ Oph cloud with $A_v \gtrsim 3.5$ has been shown to be consistent with all heavy elements having been accreted onto grain mantles[30–32]. The correlation between the column density of ^{13}CO versus A_v in the dark cloud L134 up to $A_v \sim 3$–5 can be interpreted as being caused by all C and O being deposited on grain mantles when $A_v \gtrsim 4$ (refs 30, 33).

(2) Grain growth in dense clouds, as indicated by the increase in λ_{max} with extinction is probably caused by coagulation of individual grains and not by accretion of atoms and molecules onto grain surfaces[34]. Accretion can only increase the mean grain size by a factor of ~2, corresponding to the exhaustion of all condensable species in the gas[35].

In these conditions, I suggest that the time scale for grain–grain coagulation from systematic collisions between grains, when acted on by an external force such as gravity or radiation pressure[22,29] is, the limit to spin-up (due to resurfacing) through the Purcell pinwheel alignment mechanism. This is given by

$$t_{gg} \cong 8 \times 10^{17}\ a/n_d V_d\ (\text{yr}) \qquad (5)$$

V_d is the drift velocity of grains with respect to the gas and n_d is the number density of dust grains. V_d, a and n_d are in cgs units. For the inner regions of OMC-1 we estimate t_{gg} (using the formulae in refs 22, 29) at ~10^9 yr. This limit is weak enough to place no constraint whatsoever on Purcell alignment. For Purcell alignment to be effective the alignment time, t_r, must be significantly smaller than the time scale for resurfacing, t_{gg} in this case, or

$$\left(\frac{t_r}{t_{gg}}\right) = 4 \times 10^{-14} \frac{a \rho T_d n_d V_d}{B^2} \ll 1 \qquad (6)$$

with ρ the grain density. For our typical H I cloud with $\rho = 1$ g cm^{-3}, $n_d = 7.6 \times 10^{-11}$ cm^{-3}, and $B = 2.5 \times 10^{-6}$ G we have $t_r/t_{gg} \cong 4 \times 10^{-11}\ V_d$ which is much less than unity for any reasonable choice of V_d.

Grain alignment in star formation regions

Until recently there has been no empirical evidence for pinwheel alignment. Johnson *et al.*[27] have demonstrated the quantitative inadequacies of DG alignment in the OMC-1 quite independent of grain composition. The high density of the nebula means that the temperatures of the dust and molecular gas are expected to be tightly coupled. This has been seen in H$_2$CO maps[36] and 91-μm photometry[37] of the nebula (indicating the temperature of the gas and dust, respectively). DG alignment is driven by differences in the dust and gas temperatures and therefore cannot operate in a region where $T_d \cong T_g$ (ref. 38). Johnson *et al.* hypothesize that grain alignment in OMC-1 is due to pinwheeling, the only viable alternative to DG alignment. The atomic hydrogen abundance necessary to excite hydrogen recombination pinwheeling would be provided by atomic hydrogen left in the wake of a shock propagating through the nebula. Evidence for a shock in OMC-1 has been found[39] from a broad velocity feature ($\Delta v \cong 49$ km s^{-1}) in CO and detection of H$_2$ vibrational emission. Alignment would occur in OMC-1 with a relatively weak (milligauss) magnetic field.

Dyck and Capps[40] have measured the IR linear polarization of 15 compact sources associated with H II regions and molecular clouds. They find a clear correlation such that strong interstellar polarization is associated with the youngest prestellar objects. Dyck and Capps hypothesize that as these objects evolve, the conditions for producing polarization can no longer be maintained. This is the situation that shock-induced grain alignment would predict. Strong shocks in molecular clouds, due to stellar winds accompanying star formation, would produce grain alignment (and thus linear polarization) in the same way that Johnson *et al.*[27] suggest for OMC-1. As prestellar objects evolve onto the main sequence and produce H II regions, shocks in the surrounding molecular cloud will dissipate resulting in the decay of linear polarization of sources embedded in the cloud as all of the atomic hydrogen is consumed. Another possibility is that as a number of luminous pre-main-sequence stars 'turn-on' in the dust cloud, resurfacing of grains by photodesorption begins, thus inhibiting grain alignment.

Conclusions

Both the Purcell alignment mechanism and DG alignment can quantitatively explain interstellar polarization. However, both theories have apparent drawbacks. DG alignment requires invoking ferromagnetic or superparamagnetic grains, thus placing rather stringent requirements on grain composition. DG alignment also seems to fail to explain grain alignment in OMC-1. Although the Purcell theory seems to be equally viable for almost any grain composition, it does require rather small grain resurfacing rates.

In any case, it seems that the typical interstellar grain is suprathermally rotating, and any grain alignment theory must deal with this. The Purcell mechanism would predict that grain alignment is most effective where: (1) grain growth has been inhibited either due to UV photodesorption or depletion of accretable material; and (2) there is a significant atomic hydrogen abundance or an adequate ambient radiation field.

These two conditions seem to be met not only in the unshielded regions exterior to dark clouds but also in regions where pre-main-sequence stars are undergoing a burst of luminosity. Significant progress can be made in this field by checking the predictions above against a detailed set of measurements of the polarization of sources found in or behind a number of clouds exhibiting a wide variety of conditions.

Roger N. Anderson

Lamont-Doherty Geological Observatory, and Department of Geological Sciences, Columbia University, Palisades, New York 10964, USA

In situ *lithostratigraphy and the distribution of fracture and void zones in oceanic layer 2A were examined with an ultrasonic borehole televiewer at IPOD sites 501 and 504B on the south flank of the Costa Rica Rift. These records indicate a decrease in the size of basalt pillows with depth and a corresponding increase in fracture and void density. The observed increase in P-wave velocity with depth in this hole, as layer 2A merges into 2B, is best explained by an increase in the degree to which clays and zeolites fill fractures and voids. This also explains the order-of-magnitude drop in permeability observed in hole 504B. An increase in alteration-filling with age could explain the transition from convective to conductive heat flow and the correlative disappearance of layer 2A on the flanks of oceanic spreading centres.*

HEAT flow measurements on the flanks of mid-ocean ridges show a transition from primarily convective heat flow near ridge axes to predominantly conductive heat flow in old ocean basins[1]. Coinciding with the change in heat transfer mechanism, oceanic crustal layer 2A essentially 'disappears' with age on the flanks of mid-ocean ridges (Fig. 1; ref. 2). Layer 2A is defined as a seismic transition zone in which a section with anomalously low P-wave velocity ($V_P \sim 2$–$3\ \mathrm{km\ s^{-1}}$) overlies high-velocity layer 2 basalts ($V_P \geq 5\ \mathrm{km\ s^{-1}}$). This transition occurs within the interlayered pillow, flow and rubble zones of the upper 1 km of oceanic crust. To investigate the interrelationship between these thermal and acoustic phenomena and other physical properties of the oceanic crust, we participated in an integrated suite of *in situ* downhole experiments at IPOD sites 501–504B on the south flank of the Costa Rica Rift of the Galapagos Spreading Centre (Fig. 2). The experiments included *in situ* permeability and pore-pressure measurements[3], sonic velocity logging[4] and formation fluid sampling[5]. Here we describe ultrasonic borehole televiewer imagery that was conducted to examine in detail the lithostratigraphy and fracture and void variation with depth, and compare these data with the change in P-wave velocity with depth.

A primary difficulty with interpreting lithostratigraphy of the oceanic crust from core samples recovered by the DV *Glomar Challenger* has been the low percentage of core recovery. Drilling operations crush and wash away an average of 70% of all oceanic crust drilled through. The only measurements capable of recording information over the entire wellbore are geophysical logs, but it has been extremely difficult to interpret these logs in detail because of a lack of comparable examples on land for cross-correlations (see ref. 6).

A borehole televiewer (BHTV) was used to provide the type of continuous data needed to interpret more fully the structure and stratigraphy of the ocean crust. The BHTV is a seldom-used oil-field logging tool developed by the Mobil Oil Corporation for the study of fractures in wellbores and casing (see ref. 7). The downhole tool contains an ultrasonic transducer which rotates three times per second and emits a 1 mHz pulse 180 times per second as the tool is moving vertically in the hole at a speed of $1.5\ \mathrm{m\ min^{-1}}$. By displaying the amplitude of the acoustic pulse that is reflected off the borehole wall as brightness on a three-axis oscilloscope, the BHTV produces an image of the reflectivity and smoothness of the wellbore referenced to magnetic north. Hard, smooth surfaces produce strong reflections (or 'bright zones' on photographs of the data displayed on the oscilloscope) whereas fractures and voids greatly diminish the reflected signal and produce 'dark zones' on the records. Similarly, where the hole reaches great width, or very soft clays are encountered, no appreciable reflection is returned, and dark zones again appear. The result is a complete

north–east–south–west–north 'picture' of the reflectivity of the wellbore.

The setting

We deployed a borehole televiewer at sites 501 and 504B on IPOD Legs 68A and 69 in 6-Myr-old crust on the south flank of the Costa Rica Rift, the easternmost segment of the Galapagos Spreading Centre (Fig. 2). The sites were chosen to penetrate into young oceanic crust with high surface heat flow. The two sites are only about 1 km apart. Because they lie near the Equator where there is rapid productivity of pelagic sediment, a 280 m sedimentary section has formed a thick impermeable lid over a hydrothermal circulation system active in the oceanic crust[3]. Pore pressure measurements[3] and temperature logs[8] indicate oceanic bottom water being drawn naturally into an underpressured aquifer with a permeability of about 200 millidarcies (md) located 50–100 m below the top of layer 2A [8]. Flow tests in hole 504B show that the average permeability of layer 2A drops from 20–40 md in the upper 100 m to 2–4 md about 200 m below the sediment–basalt contact[3]. Sonic logs indicate an increase in velocity of layer 2A from 2.5 to >5 km s^{-1} in the upper 200 m of the oceanic crust.

The BHTV tests conducted in these wells have contributed to our understanding of why the sedimentary layer forms a hydraulic lid, why the permeability drops by an order of magnitude with depth and why the seismic velocity increases with depth. It also gave the first complete glimpse of the lithostratigraphy of the upper oceanic crust.

Structure at site 501

Using the BHTV we logged the entire sedimentary column and 25 m below the sediment–basalt contact in hole 501 of DSDP Leg 68A (Fig. 3). In much of the sedimentary section the record is quite dark (that is, there is no significant reflection from much of the circumferential sweep of the trace). This is due to pronounced 'washing out' and ellipticity of the hole; the problem is most severe at ~3,710 m depth (Fig. 3).

The youngest chert yet encountered by the *Glomar Challenger*[9] was found over the lower 30 m of the sediment column of hole 501. The BHTV records show that the first chert encountered is a solid layer ~5 m thick. Drilling results indicated that within this layer there are interlayered lenses of chert and silicified limestone. The chert, being harder and more resistant to 'washing out', shows up as bright, high-reflectance bands between the darker limestone layers. Although we do not know the horizontal extent of these chert layers, all holes drilled at the 501–504B sites encountered chert over the lower 30 m of the sedimentary section.

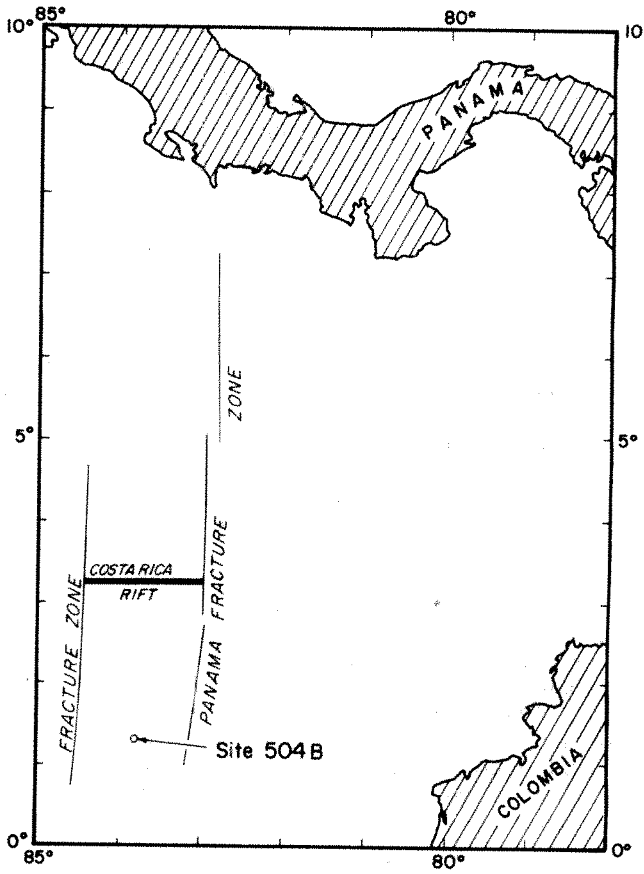

Fig. 2 Index map showing location of DSDP site 504B. 501 is 1 km to the west of 504B. The Costa Rica Rift is the easternmost segment of the Galapagos Spreading Centre.

Pillow basalts recorded by the BHTV appear as bright spots within dark ellipses. These dark ellipses probably represent the pillow's glass and alteration rims that are fractured and washed-out during drilling (Fig. 3). The pillow units as seen in the wellbore also seem to contain large voids where virtually no signal is reflected back to the transducer (for example, at 3,735 m in Fig. 3). Several massive flow units are seen at the top of the oceanic crust interlayered with the pillow basalt units. Because of the poor core recovery, the interrelationship between these stratigraphical units was not previously known. Note the 8 m thick massive flow unit that extends from 3,747 to 3,755 m.

Structure at site 504B

At site 504B on Leg 69, a BHTV was used to log 196 m below the casing which was set 2 m into basalt. Unfortunately, the factory-equipped transducer was destroyed on the first lowering of the tool by a pressure-compensation failure. The hole was then logged using a 600 kHz transducer array taken from an acoustic reentry tool as a replacement televiewer transducer. Sixty-cycle noise (apparently caused by a faulty logging cable) further obscured the BHTV image. Because the noise has proved difficult to remove from the data, we present only line drawings (Fig. 4) rather than the original records. Nevertheless, distinct pillow and flow units were discernible and contacts between distinct eruptive events were often seen (for example, 3,855 m, Fig. 4). Fracture resolution is several millimetres and several fractures this small were seen (for example, 3,860 m, Fig. 4).

The interpretative line drawing of the BHTV records allows us to reconstruct the lithostratigraphy of hole 504B (Fig. 4). We observe that thick flow units dominate the upper 50 m of layer 2A. These flows have numerous fractures which are predominantly horizontal to subhorizontal. Thin interlayers (~1 m thick) of large diameter pillow units are seen at 3,757, 3,765, 3,773–3,778 and 3,782 m. The 8 m thick massive flow unit of hole 501 (at 3,747–3,755 m of Fig. 3) may be correlative with a thick flow encountered at 504B at depths of 3,753–3,758 where it is more broken-up. Another thick massive flow is in 504B seen at 3,785–3,795 m depth.

The percentage of pillow units gradually increases down-section and the average size of the pillows decreases from 20 to 30 cm near the basalt–sediment contact to only a few centimetres (Fig. 4). For example, from 3,838 to 3,851 m a suite of pillow units has a range in sizes up to ~30 cm whereas the pillow units from 3,890 to 3,897 are all <10 cm in size. In addition, the massive flow units become thinner down-section. The entire lower 55 m of the recorded section appears as discrete pillow units <1 m in thickness. Fractures often seem to be concentrated at the borders of separate pillow flows but some zones are uniformly fractured. As in hole 501, most of the fractures observed in hole 504B are horizontal to subhorizontal.

From 3,805 to 3,825 m an anomalously low reflectance zone exists. While some structure can be seen within this zone, the amplitude of reflectance is much lower than zones directly above and below it. The general level of reflectance also drops from flows to pillows and towards the bottom of the hole. The lowered reflectance may be due to the increased occurrence of clay and zeolite which was clearly observed in the cores[9].

Increase in seismic velocity with depth

A primary aim of this project is to interpret the BHTV records in terms of the change in the physical properties of the ocean crust. Specifically, we wish to relate variations observed in the sonic velocity log over the BHTV-logged section of 504B to the stratigraphic variations seen with the BHTV. Although the velocity log from hole 504B is extremely noisy, a marked increase in average P-wave velocity with depth can still be clearly seen (Fig. 5*a*, after ref. 4). The average basement velocity just below the casing begins at ~2.5 km^{-1} and increases over the next 200 m to ~5 km s^{-1} (values typical of layer 2A). Although most of the large-amplitude high-frequency velocity variations in Fig. 5*a* are spurious and due to the effect that changes in the shape of the hole have on the seismic waveforms being transmitted by the velocity tool, the high-velocity interval from 3,785 to 3,795 m correlates with a massive flow unit which contains few fractures or voids at that depth.

Fracture and void counts

The BHTV record of hole 504B allows us to test various hypotheses for the increase in seismic velocity with depth within layer 2A because we can correlate the observed change in character and structure of fracture and void zones down the hole

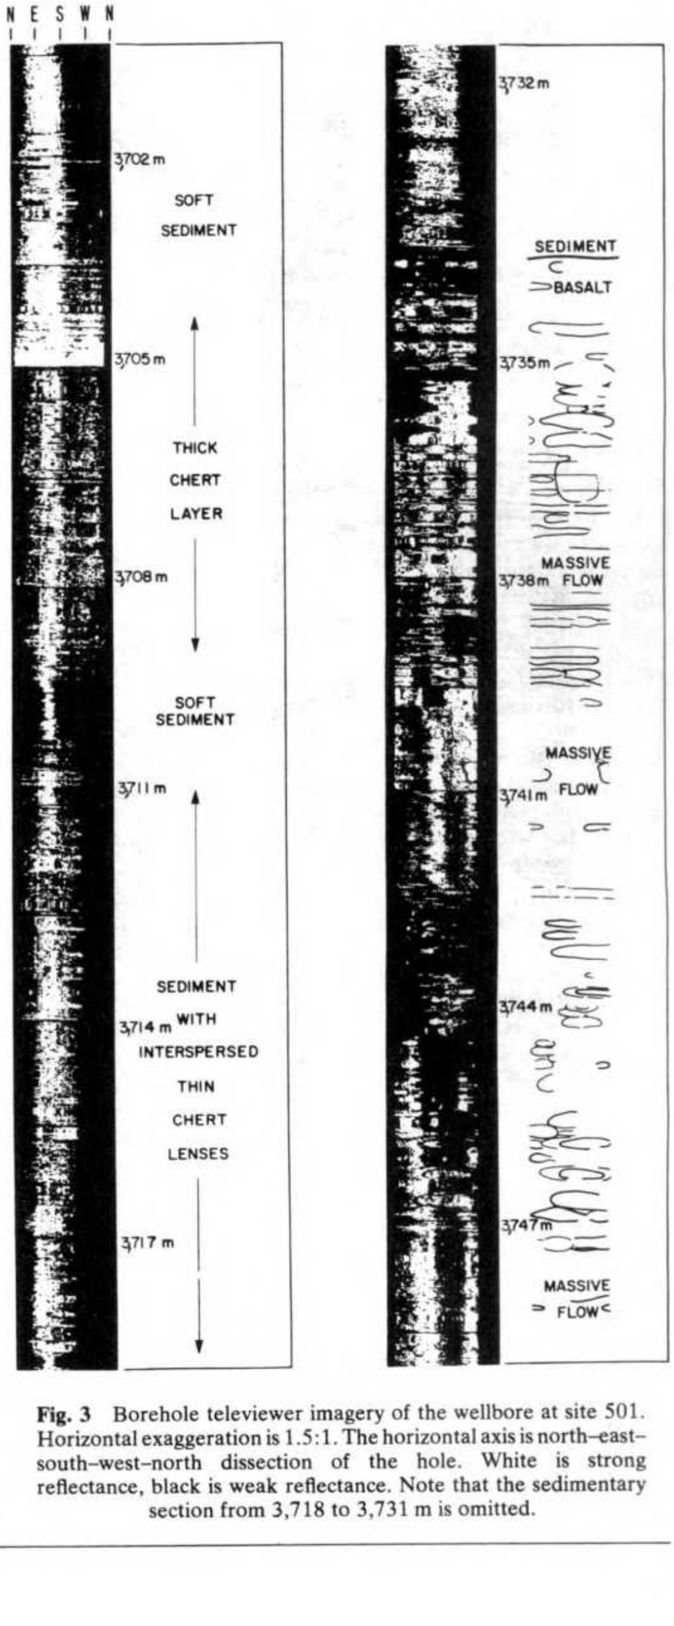

Fig. 3 Borehole televiewer imagery of the wellbore at site 501. Horizontal exaggeration is 1.5:1. The horizontal axis is north–east–south–west–north dissection of the hole. White is strong reflectance, black is weak reflectance. Note that the sedimentary section from 3,718 to 3,731 m is omitted.

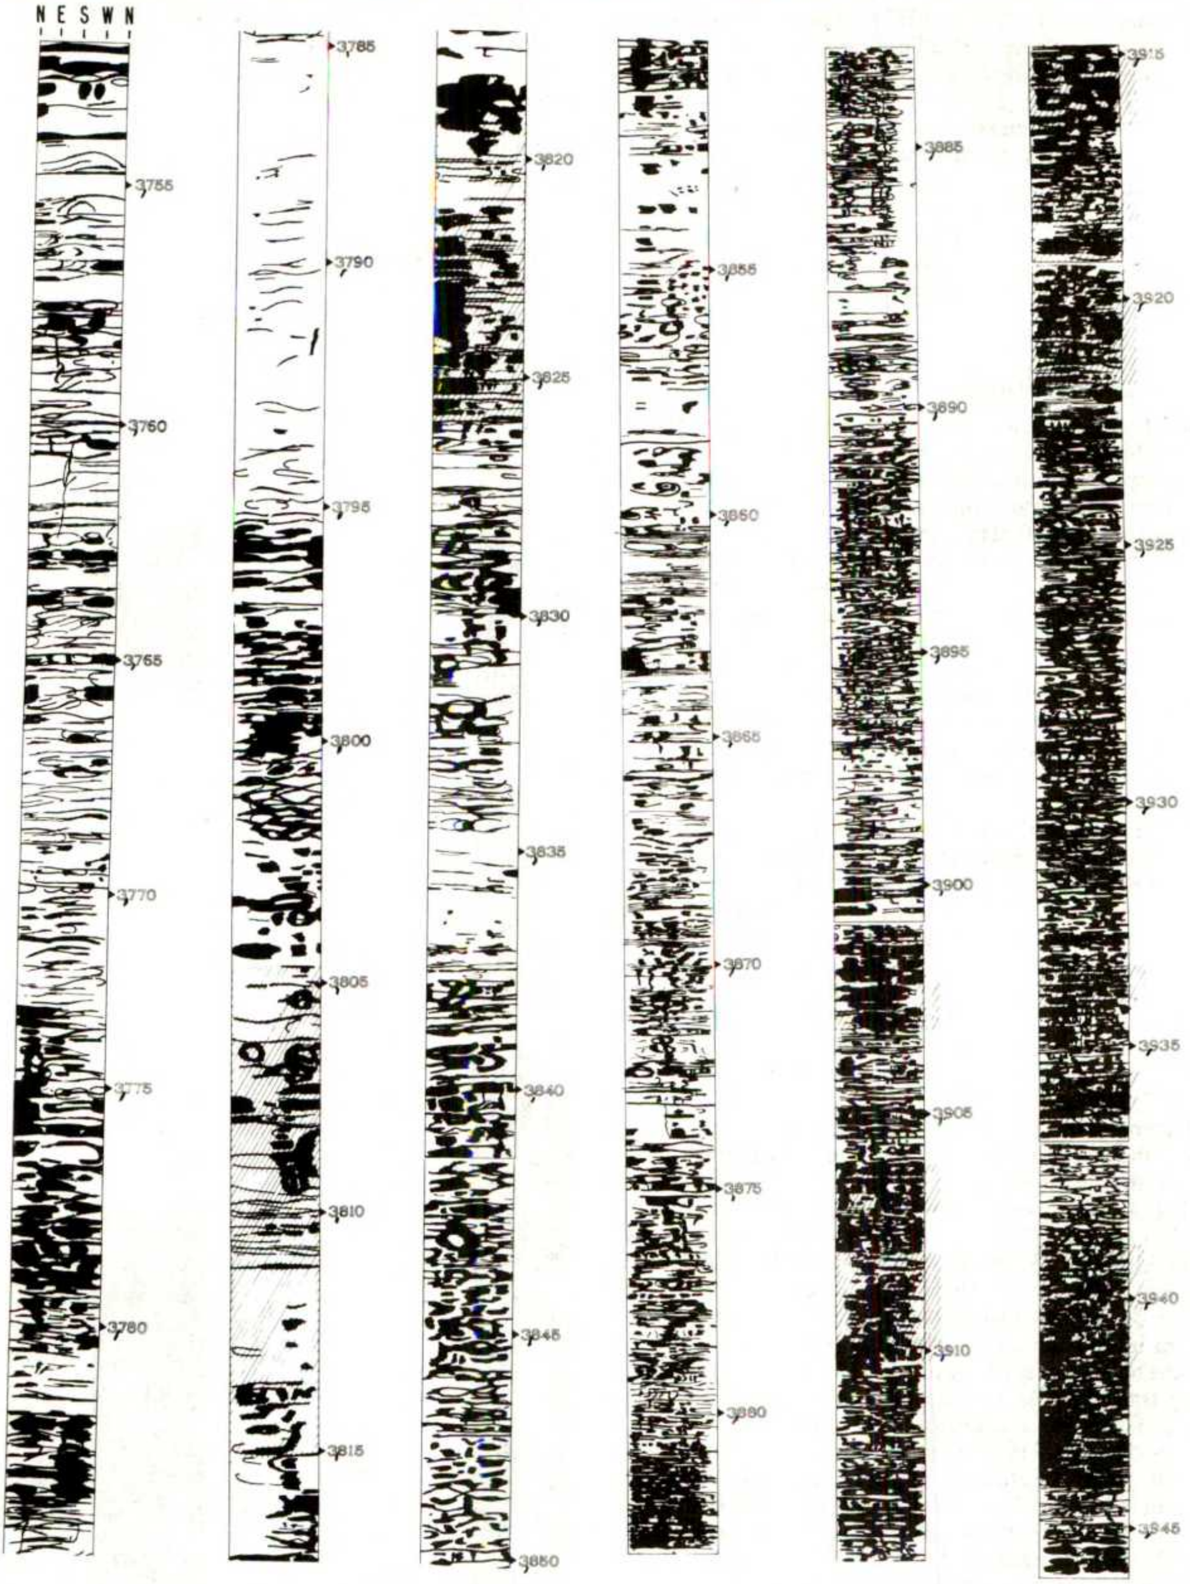

Fig. 4 Line drawing of borehole televiewer imagery of site 504B drillhole. Horizontal exaggeration is 1.5:1. Black-rimmed elliptical images are pillow lavas. Solid white segments are massive flow basalts. Thin lines are cracks and fractures. Hatched areas are of anomalously low reflectance. Depths in metres below sea level. Casing ends at 3,753 m.

with changes in seismic velocity. To this end, we counted the number of fractures observed on the BHTV records from hole 504B (Fig. 5*b*). As can be seen in both Figs 4 and 5*b*, the fracture density actually increases with depth in hole 504B. As laboratory studies show, this would be expected to decrease the velocity if the degree of fracturing alone were controlling V_P in layer 2A. Instead, a marked velocity increase with depth is observed in hole 504B that is typical of layer 2A (Fig. 5*a*).

As voids between pillows might be expected to have a similar effect on velocity as fractures, a plot of the percentage of voids in the wellbore (percentage of black versus white in Fig. 4) is presented in Fig. 5*c*. In the pillow units, this 'void ratio' (Fig. 5*c*) measured the per cent of pillow rims, glassy rind and rubble surrounding the solid basaltic core of each pillow. We observe an increase of voids with depth in the hole because of the decrease in the diameter of the individual pillows with depth. Presumably,

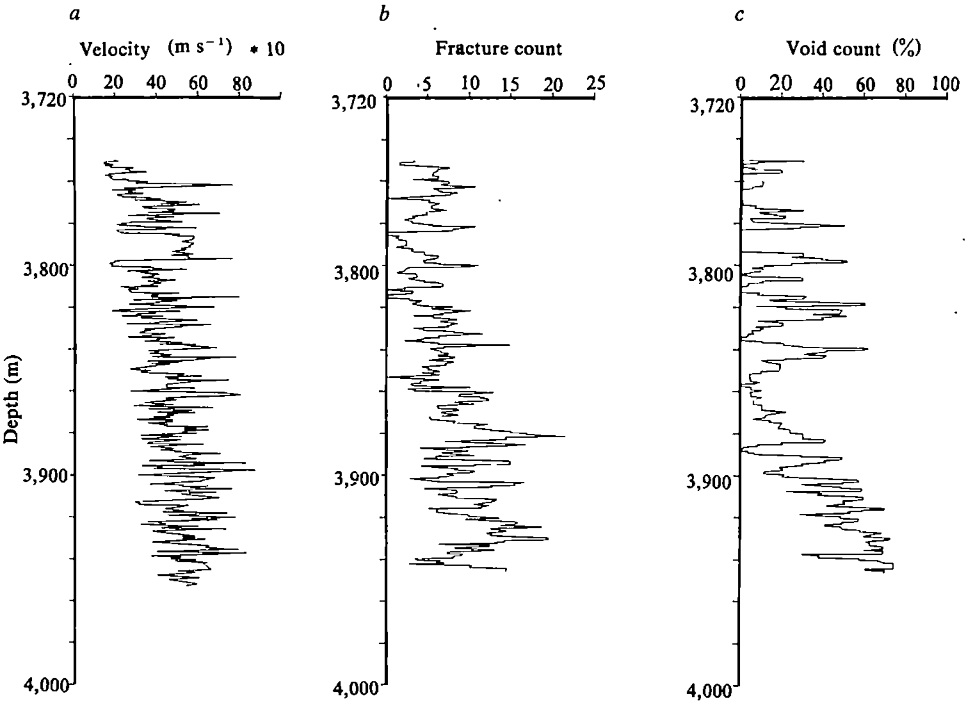

Fig. 5 *a*, Sonic velocity logs of site 504B upper 200 m of basalt corresponding to interval of BHTV log in Fig. 4. Spurious data points with $V_P < 1.5$ and >8 km s^{-1} were excluded from digitization of original analog record. Note that despite the noisy character of the log a clear increase in V_P with depth can be observed in hole. *b*, Histogram of the number of fractures per 50 cm of hole. *c*, Void percentage based on an estimation of the per cent black versus white in Fig. 4 per 50 cm of hole.

a lower seismic velocity might be expected to correlate with the higher void count, but again, an inverse correlation is seen in hole 504B.

Discussion

To explain the variation of velocity in the upper oceanic crust three basic questions must be answered. Why is the velocity of the upper portion of layer 2A so low? Why does the velocity increase so rapidly with depth within layer 2A? And why does layer 2A disappear with age at about the time of the transition in the mode of heat transfer along ridge flanks? It has been argued[10-13] that the low seismic velocity of the upper portion of layer 2A results from the highly fractured and porous nature of the shallow oceanic crust. This explanation seems quite reasonable from the nature of the basalt encountered in holes 501 and 504B. However, what causes the velocity to increase so rapidly with depth? Velocity is expected to increase with depth due to the closure of fractures with pressure, but the increase in effective pressure over only a few hundred metres depth is quite small (only about 15–20 bar per 100 m), and mechanically closing enough fractures and voids to account for the velocity increase over the depth range of interest is highly unlikely[12]. Spudich and Orcutt[14] suggested that the increase in velocity is caused by a decrease in porosity with depth. But why should a decrease in porosity occur in a regular manner on the flanks of many ridges, and how could this account for the disappearance of layer 2A with age?

Schreiber and Fox[12] have proposed a model that seems to explain the seemingly inconsistent seismic velocity and borehole televiewer data in holes 501 and 504B, as well as several of the questions posed above. They suggested that as voids and fractures are filled by alteration minerals like chlorite, zeolite and smectite (with characteristic seismic velocities of ~4 km s^{-1}) the alteration minerals replace seawater (with a seismic velocity of ~1.5 km s^{-1}). Thus, the seismic velocity of layer 2A would be expected to rise rapidly as the degree of alteration increased. Increased alteration in layer 2A would be expected with both depth (due to increased temperature) and age. Geophysical logging data[6] also suggests that an increase in alteration-filling occurs with age on ridge flanks. The alteration-filling hypothesis seems capable of explaining the rapid increase of layer 2A velocity with depth despite an apparent increase in fractures and voids and the eventual disappearance of layer 2A with age. The increased occurrence of clays and zeolites with depth was well noted in the core descriptions of holes 501 and 504B [9] and the rapid decrease in permeability with depth in hole 504B [3] also indicates the filling of fractures and voids with alteration minerals. We do not now understand the cause of the decrease in the size of the pillows encountered in 504B and the related increase in the number of voids. This may be a localized phenomena which is of no general significance. However, the observation of a marked increase in velocity despite an apparent increase in fractures and voids demonstrates that the replacement of seawater by alteration minerals is more important in controlling the increase in velocity than the change in fracture or void density. If this is correct, it suggests that on the flanks of oceanic spreading centres a marked decrease in the permeability of the 'crustal plumbing system' can be expected to correspond to the change in seismic velocity. This would explain the correlation between the transition from conductive to convective heat flow and the disappearance of layer 2A with age.

We thank Bob Broding and the Amoco Oil Field Research Co. of Tulsa, Oklahoma, for loaning us the borehole televiewer used on Leg 68 (hole 501) and for invaluable support, Joseph Svitek Jr, Larry May and the Global Marine drilling crew for making this project successful, and Robin Newmark for help in the preparation of Fig. 4. This work was supported by the NSF under grant OCE-78-27026 and the US Geological Survey.

Resolving the functions of overlapping viral genes by site-specific mutagenesis at a mRNA splice site

Craig Montell*, Eric F. Fisher†, Marvin H. Caruthers† & Arnold J. Berk*

* Department of Microbiology and Molecular Biology Institute, University of California, Los Angeles, California 90024, USA
† Department of Chemistry, Campus Box 215, University of Colorado, Boulder, Colorado 80309, USA

Early region IA of human adenoviruses encodes a function required for normal induction of early viral genes and virus-induced cell transformation. The region is expressed at early times as two overlapping spliced mRNAs, 12S and 13S, which encode closely related proteins. To distinguish between the functions of these proteins, a single T → G transversion was constructed which prevents splicing of the 12S mRNA. This transversion, in the second base of the 12S mRNA intron, does not alter the protein encoded by the 13S mRNA due to degeneracy in the genetic code. Studies with this mutant demonstrated that only the 13S mRNA encodes the regulatory protein required for normal early gene expression.

MANY eukaryotic genes are interrupted by introns removed from mRNA precursors by RNA splicing. Sequences encompassing splice sites share considerable homology and variants of the following sequence are found at the 5′ end of every intron analysed: 5′-(exon)-AG/GUAAGUA-(intron)-3′ (refs 1–3). Although specific 5′ splice sites differ from this consensus sequence to a greater or lesser degree, the underlined GU dinucleotide which begins the intron is virtually invariant. To determine whether the integrity of this dinucleotide is required for efficient RNA splicing, we constructed an adenovirus mutant with a T → G transversion in the second base of the intron in an early region IA (EIA) gene. We believed that this transversion would eliminate RNA splicing, allowing us to ascribe specific functions to the two overlapping early adenovirus mRNAs transcribed from this region[4]. Animal viruses frequently encode overlapping spliced mRNAs in a common region of the viral genome. Such compact gene organization enables the small viral genomes to encode several related proteins in the same region by splicing a single mRNA precursor in two or more alternative ways.

EIA of adenovirus 2 (Ad2) has attracted considerable interest because it encodes a function required for both normal expression of the other early viral genes[5,6] and virus-induced cell transformation[7,8]. The two overlapping early mRNAs transcribed from this region, 12S and 13S, share identical 5′ and 3′ termini and vary by 138 nucleotides due to the differing sizes of the introns removed by RNA splicing (refs 9, 10; Fig. 1). Assuming translation is initiated at the first AUG, the 12S and 13S messages encode proteins of 243 and 289 amino acids respectively. The 12S and 13S mRNAs are spliced such that they continue in the same reading frame[9]; therefore, the larger protein has the same amino acid sequence as the smaller protein except for an additional internal 46 amino acids encoded by the 138 nucleotides unique to the 13S mRNA. One EIA mutant, Ad5 hr1 (ref. 11), has a single base deletion in the portion of viral genome encoding the unique region of the 13S mRNA[12]. This mutation leads to premature chain termination during translation of the 13S mRNA, but does not affect translation of the 12S mRNA[12]. Ad5 hr1 is deficient in both early viral gene expression[5] and inducing cell transformation[7], demonstrating that the 289 amino acid protein at least is required for these processes.

The question of the role of the 243 amino acid protein in regulating early viral gene expression or virus-induced cell transformation has not previously been addressed. It cannot be investigated using mutants of the 243 amino acid protein as random or directed mutagenesis intended specifically to alter the 243 amino acid protein encoded by the 12S mRNA, without affecting the 289 amino acid protein specified by the 13S mRNA, would be futile since every amino acid in the smaller polypeptide is included in the larger one. To overcome this

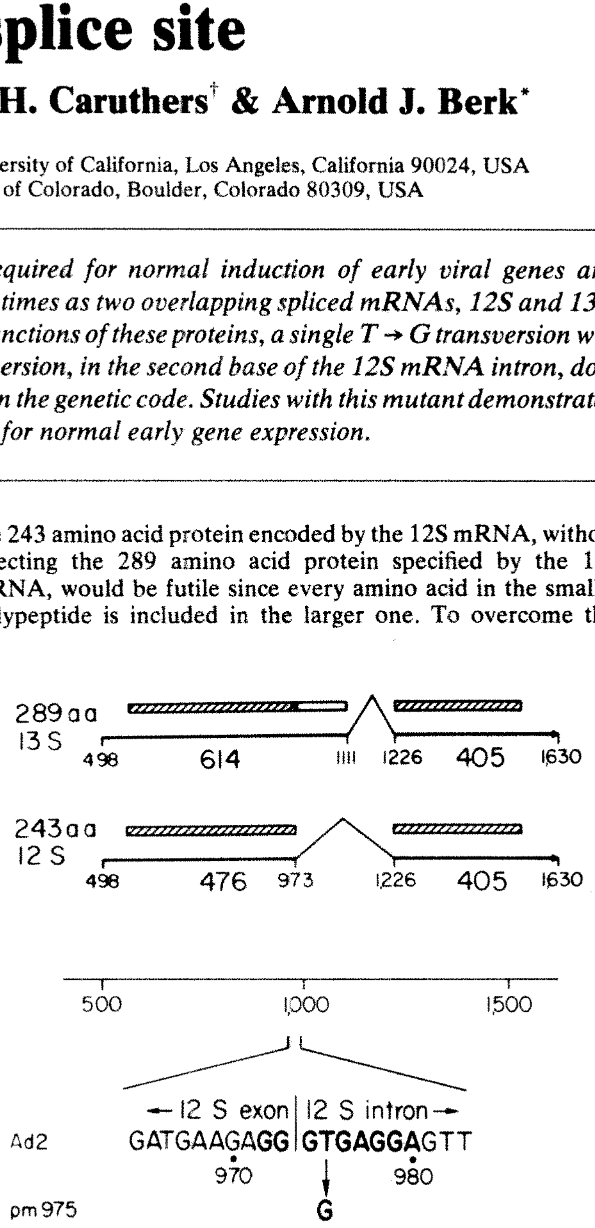

Fig. 1 Structures of EIA gene products at early times. The EIA portion of the Ad2 genome is represented as a line at the centre of the figure marked off in base pairs from the left end of the genome. The horizontal lines joined by carot symbols represent exons of the 12S and 13S mRNAs; the total lengths of exons are indicated in nucleotides below the lines with the end points identified in the Ad2 sequence; arrowheads indicate the 3′ ends of the mRNAs. Boxes above the exons demarcate the translated regions. The lengths of the polypeptides are given as the number of amino acids (aa). The portions of the 289 and 243 amino acid proteins with identical sequences are indicated with hatches; the open box refers to the 46 amino acids unique to the larger polypeptide. The sequence of the L strand of Ad2 in the vicinity of the 12S mRNA 5′ splice site between nucleotides 964 and 983 is shown below the line representing the genome. Those nucleotides included in the 5′ consensus sequence are highlighted. The vertical line identifies the splice junction separating the 5′ 12S exon from the intron and the T → G transversion at nucleotide 975 is indicated. The Ad2 EIA sequence is >99% homologous with the corresponding region in Ad5 (ref. 36). To align the Ad2 with the Ad5 EIA sequence, add one to the Ad2 sequence to account for an additional base pair in the Ad5 inverted terminal repeat.

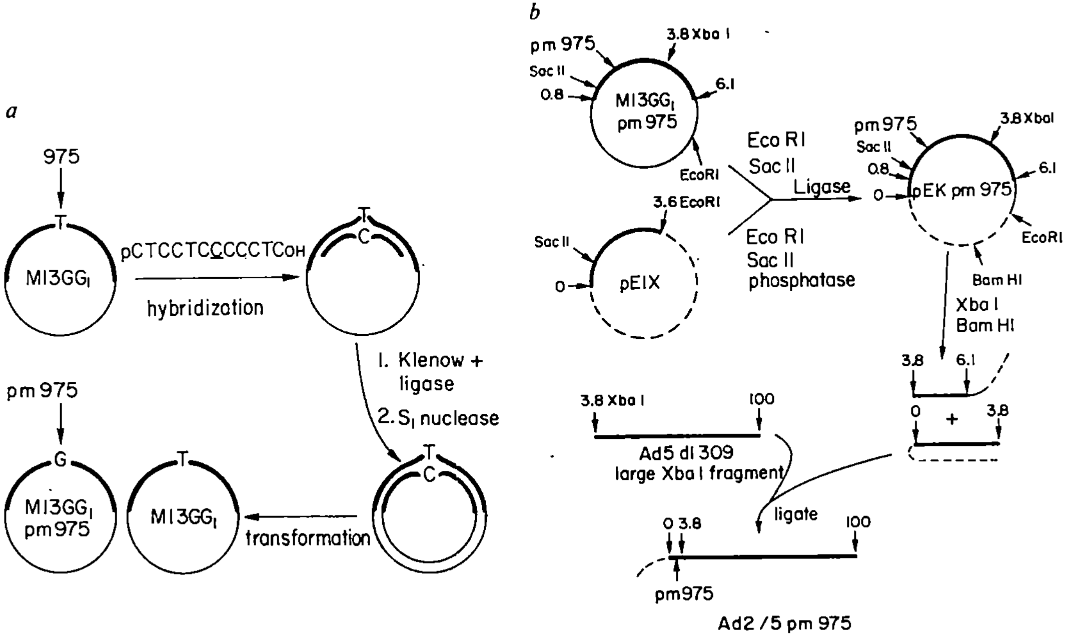

Fig. 2 Construction of Ad2/5 pm975. *a*, Oligonucleotide-directed mutagenesis. The bold portion of the circles represents the Ad2 component. T refers to nucleotide 975 in the Ad2 sequence and the underlined C to the corresponding mismatch in the dodecanucleotide. M13GG1 was constructed (by R. Gaynor) by transferring the Ad2 *Kpn*I fragment from pSB2 (ref. 37) into the *Kpn*I site of M13G*ori*1 (ref. 38) producing a clone of the Ad2 L strand extending from nucleotides 269 to 2,049. Oligonucleotide-directed mutagenesis was performed as described elsewhere[15] with M13GG1 as the single-stranded template and *E. coli* K12 JM101 (ref. 39) as host, except for the following modification. After 4 h of DNA synthesis, the specified amounts[15] of DNA polymerase I large fragment (Klenow) and T4 DNA ligase were added again and incubation continued for 3 h. Transfection was into $CaCl_2$ treated cells[38] rather than spheroplasts. We found that single-stranded viral DNA had an infectivity of $\sim 10^3$ plaque-forming units (PFU) per μg compared with $\sim 10^6$ PFU per μg for double-stranded DNA in $CaCl_2$-treated JM101. The dodecanucleotide primer was synthesized as described in ref. 16 with the following modifications. The support was prepared by coupling 5′-*O*-(dimethoxytrityl)-3′-(-4-*p*-nitrophenyl succinyl)-*N*-benzoyldeoxycytosine to silica treated with 3′-(triethoxysilyl)propylamine. The activated nucleoside was prepared at room temperature and used immediately. Synthesis was carried out in a modified Merrifield apparatus using 150 mg of derivatized support (46 μmol g^{-1}). At each condensation 90 μmol of activated nucleoside was used. Fifty mg of the resulting silica covalently attached to the deoxyoligonucleotide was treated for 90 min with thiophenol/triethylamine/dioxane (1:1:2). The silica was isolated by centrifugation and washed four times with dioxane, three times with methanol and once with diethylether. 400 μl of concentrated ammonium hydroxide were added to the silica. The sealed tube was shaken for 3 h at room temperature followed by centrifugation. The supernatant was transferred to another tube, sealed and heated to 50 °C for 22 h. The sample was dried *in vacuo* and 250 μl of 80% acetic acid were added. After 60 min, the sample was dried *in vacuo* and applied to a 1.5 cm × 50 cm G50/40 column in 0.01 M triethylammonium bicarbonate. Fractions (1.2 ml) were taken and the first three fractions containing UV-absorbing material ($\sim 10A_{260}$) were pooled, lyophylized to dryness, dissolved in 150 μl of 80% formamide and applied to a 20 cm × 20 cm 20% polyacrylamide/7 M urea gel. After electrophoresis the band containing the desired oligodeoxynucleotide was excised, eluted and desalted on a Bio-Gel P 2 column (3 cm × 60 cm). The 2.5-ml fractions were monitored by UV absorption. The fractions containing the compound were pooled (4.4 A_{260}). The sequence of the oligonucleotides was verified by two-dimensional TLC as described previously[40] using Homomix V. *b*, Insertion of pm975 into the complete adenovirus genome. Bold lines represent adenovirus sequences, light lines M13G*ori*1 DNA and broken lines pBR322 sequences. Small numbers refer to Ad2 map units; one map unit is equal to 1% of the Ad2 genome—~350 nucleotides. A derivative of pBE5, pEIX[19], which contains Ad2 sequence from 0 to 3.6 map units inserted between the *Pst*I and *Eco*RI sites of pBR322 (ref. 41), was prepared. The mutation in M13GG1 pm975 was introduced into pEIX by digesting 0.5 μg pEIX with *Sac*II, *Eco*RI and calf intestinal phosphatase; ligating the products of these reactions to 5 μg *Sac*II, *Eco*RI-digested double-stranded M13GG1 pm975; and using the reaction products to transform *E. coli* C600 to Tc^r all as described in ref. 37. Plasmids from transformed colonies were screened by size and restriction endonuclease analysis to identify the desired construct, pEK pm975, which includes the entire left terminus of Ad2. The presence in this plasmid of the T → G transversion at 975 in the Ad2 sequence was confirmed by DNA sequencing[17,18]. 4.5 μg pEK pm975 were digested with *Xba*I and *Bam*HI (to minimize recircularization) and ligated to 1 μg of the large *Xba*I fragment of Ad5 d1309 isolated as described in ref. 19. Ad5 d1309 is a phenotypically wild-type variant of Ad5 containing a single *Xba*I site at 3.8 map units. The ligation creates complete 35 kilobase infectious adenovirus genomes, which include the T → G transversion at base pair 975. The ligation products were transfected into 293 cells by the calcium phosphate technique[42]. Ad2/5 pm975 was collected from a well isolated plaque and the plaque was purified a second time on 293 cells.

problem we used oligonucleotide mutagenesis to create a T → G transversion at position 975 in the Ad2 sequence (Fig. 1). This nucleotide, which is the second base in the 12S mRNA intron, is also the third base of the GGU codon specifying glycine in the overlapping 13S mRNA. Because there is degeneracy in the genetic code, the new codon, GGG, created by this mutation also specifies glycine, thereby leaving the 289 amino acid protein completely unaltered.

We find that the single base change prevents efficient RNA splicing and specifically eliminates the 12S mRNA. Studies with this mutant, Ad2/5 pm975 (pm = point mutation), demonstrate that the 13S mRNA encodes all the early EIA functions required for normal early gene regulation and virus replication in human cells.

Construction of the specific adenovirus point mutant

The T → G transversion was introduced into a bacteriophage M13 clone of EIA by oligonucleotide-directed mutagenesis[13,14]. Conditions for this site-specific mutagenesis have been optimized by Gillam *et al.*[15] for isolating a mutant with a single point mutation at high efficiency without biological selection. The method (Fig. 2*a*) entails hybridization of a synthetic oligonucleotide to a single-stranded circular bacteriophage genome. The oligonucleotide is complementary to the phage DNA except at a single predetermined nucleotide. The hybridized oligonucleotide is used as a primer for DNA polymerase, and the resulting duplex molecules are ligated to form infectious covalently closed circles. In this work, the mutating oligonucleotide was a dodecanucleotide (12 mer) synthesized on a solid support by a modification of the phosphite coupling method of Mattucci and Caruthers[16]. The 12 mer is complementary to the L strand of EIA encompassing the 12S mRNA 5′ splice site except for a mismatch at nucleotide 975 in the Ad2 sequence. The heteroduplexes were transfected into *Escherichia coli* giving rise to a mixed population of mutant and wild-type

Table 1 Host range analysis of pm975

Virus	293	PFU per ml HeLa	HeLa/293
Wild-type Ad2	6.63×10^9	8.71×10^9	1.3
Ad2/5 pm975	1.38×10^9	1.76×10^9	1.3
Virus	HEK	HeLa	HEK/HeLa
Wild-type Ad2	1.17×10^{10}	1.46×10^{10}	0.80
Ad2/5 pm975	1.96×10^9	3.03×10^9	0.65

Stocks of Ad2 and plaque-purified pm975 prepared on 293 cells were serially diluted and assayed in duplicate by plaque formation on 293 and HeLa cells, and HEK and HeLa cells. Titres are based on the average of duplicate plates yielding 30–300 plaques.

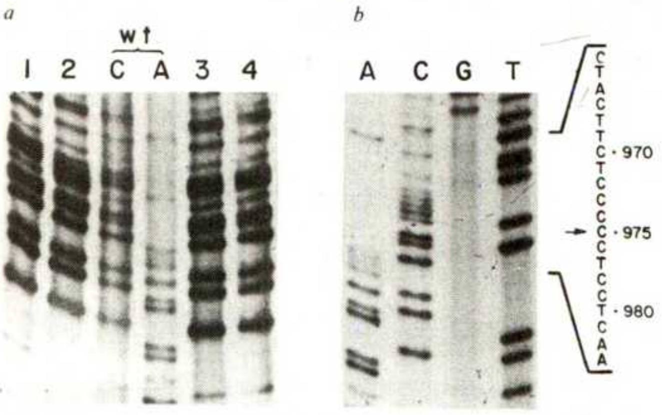

Fig. 3 Identification of M13GG1 pm975 and Ad2/5 pm975 by dideoxy sequencing. *a*, Following the second cycle of enrichment[15], bacteriophage were collected from eight plaques and amplified overnight in 25-ml cultures of JM101; phage were precipitated with polyethylene glycol[38], and viral DNA was isolated as described previously[43]. Purified DNAs were screened for the mutation by reverse transcriptase dideoxy sequencing using dideoxy CTP. The primer was a 31-base *Hpa*II fragment extending from nucleotides 1,009 to 1,040 in the Ad2 sequence. The sequences of four of the eight phage DNAs screened are shown in tracks 1, 2, 3 and 4 adjacent to the wild-type C and A lanes. Sequences shown are of the R strand of Ad2 in the vicinity of the 12S mRNA 5′ splice site. The DNA in track 2 contained the desired mutation at nucleotide 975. *b*, Identification of Ad2/5 pm975. Adenovirus DNA was prepared as described elsewhere[37] from 293 cells infected with virus from well isolated plaques picked from a transfected 293 plate (see Fig. 2 legend). The DNA was digested with exonuclease III creating single-stranded termini ~1,500 nucleotides long[44]. Sequence analysis was by the dideoxy method using the same primer as for *a*. The 20 nucleotide sequence in the vicinity of the 12S mRNA 5′ splice site is listed and the positions of nucleotides 970, 975 and 980 are indicated.

clones. The heterogeneous population of DNA molecules was subjected to two cycles of enrichment by performing the oligonucleotide hybridization in conditions favouring hybridization to the mutant sequence[15]. Potential mutant clones were screened by DNA sequencing by the dideoxy chain termination method using dideoxy CTP[17,18]. Of eight phage plaques thus screened, seven were wild type and one (Fig. 3*a*, lane 2) had the desired point mutation at base pair 975 (M13GG1 pm975). The mutation was introduced into a phenotypically wild-type adenovirus genome, Ad5 d1309, by the method of Stow (ref. 19; Fig. 2*b*).

Unable to predict whether the mutation at base pair 975 would eliminate an essential function, we transfected the reconstructed mutant genome into 293 cells which are capable of complementing all essential EIA functions[8,20]. 293 cells are a line of Ad5-transformed human embryonic kidney cells containing an integrated copy of the left 12% of the Ad5 genome[21] which constitutively express EIA and EIB mRNAs[5] and proteins[22]. DNA sequence analysis showed that three out of four plaques screened contained the point mutation (Fig. 3*b*). The mutant, Ad2/5 pm975, was plaque-purified a second time on 293 cells and sequenced again to confirm the desired base pair change.

12S mRNA is eliminated

EIA mRNAs were assayed by the hybridization/S_1 nuclease technique[23]. Early cytoplasmic RNAs were isolated 6 h post infection from HeLa cells infected with Ad2 or Ad2/5 pm975 and hybridized in DNA excess to a ^{32}P-labelled single-stranded M13 clone of the coding strand of EIA and the 5′ 350 nucleotides of EIB. The hybridization products were digested with S_1 nuclease and the protected fragments were resolved by electrophoresis on a denaturing polyacrylamide gel and detected by autoradiography.

Figure 4*a* displays the DNA fragments protected by hybridization to the wild-type EIA and EIB mRNAs. The 614 nucleotide fragment corresponds to the 5′ exon of the 13S mRNA, the 476 base band to the 5′ exon of the 12S mRNA, the 405 nucleotide fragment to the 3′ exon common to both the 12S and 13S mRNAs and the 350 nucleotide protected fragment to the terminal portion of the 5′ exons of EIB mRNAs. An additional but minor band of 750 nucleotides is protected by RNA species identical to the 13S mRNA except for a ~140 nucleotide extension at the 5′ end[24].

S_1 analysis with RNA prepared from pm975-infected cells reveals bands co-migrating with each of the wild-type Ad2 bands except for the 476 nucleotide protected fragment corresponding to the 5′ exon of the 12S mRNA (Fig. 4*a*). To enhance the sensitivity for detecting the 12S mRNA, poly(A)$^+$ RNA isolated from cells during the late stage of infection was analysed (Fig. 4*b*). The level of 12S and 13S mRNA is increased approximately twofold during the late phase in cells infected with wild-type virus. In addition, a new 9S spliced mRNA having the same 3′ exon as the 12S and 13S mRNAs and a still shorter 5′ exon becomes the predominant form of EIA message[25,26]. This gives rise to the increase in the proportion of protected DNA in the 405 nucleotide fragment and may account for the S_1 protected fragment of ~250 nucleotides. The level of EIB mRNAs is also increased several fold during the late phase[25]. Despite these changes in the pattern of S_1-resistant

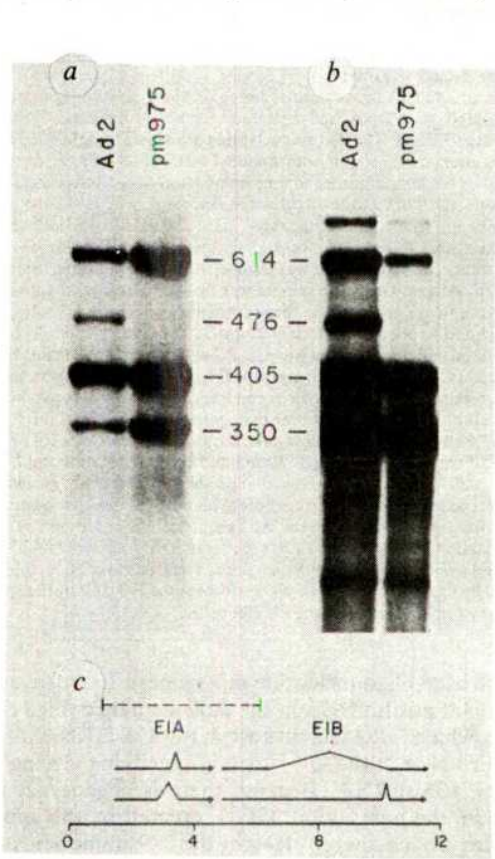

Fig. 4 Hybridization/S_1 nuclease analyses of EIA and EIB mRNAs from pm975 and Ad2. *a*, EIA and EIB early mRNAs. Cytoplasmic RNA was collected as described previously[5] from 500-ml suspension cultures of log phase HeLa cells 6 h after infection with pm975 or Ad2 at 20 PFU per cell. 350 μg cytoplasmic RNA was hybridized to 0.028 μg M13-EIA single-stranded DNA labelled with ^{32}P to a specific activity of 3×10^6 d.p.m. μg^{-1} (ref. 45) for 30 min at 68 °C in 50 μl 1.0 M NaCl, 10 mM Tris *p*H 7.4, 1 mM EDTA. S_1 nuclease digestions in 500 μl were as described previously[23] except that digestions were with 15 Vogt units[46] per reaction at 37 °C for 30 min. Protected fragments were denatured, fractionated by electrophoresis on 14-cm 8 M urea–5% polyacrylamide gels for 15 h at 60 V, dried and visualized by autoradiography with an intensifying screen. The sizes of the predominant bands are indicated in nucleotides. *b*, Analysis of late poly(A)$^+$ EIA and EIB cytoplasmic RNAs. Poly(A)$^+$cytoplasmic RNA (20 μg) isolated from late infected cells[47] was analysed as described in *a*. The autoradiogram was exposed for 17 days with an intensifying screen. *c*, M13 EIA single-stranded DNA probe (R. B. Gaynor and A.J.B., in preparation). The M13 EIA probe is similar to M13GG1 except that the R strand of Ad2 is cloned into the viral strand of M13G*ori*1. The long solid line represents a portion of the adenovirus genome marked off in map units. The horizontal lines joined by carot symbols refer to the exons of the major mRNAs transcribed from EIA and EIB at early times. Arrowheads indicate the 3′ ends of mRNAs. The broken line delineates the adenovirus sequence included in the M13 EIA single-stranded probe.

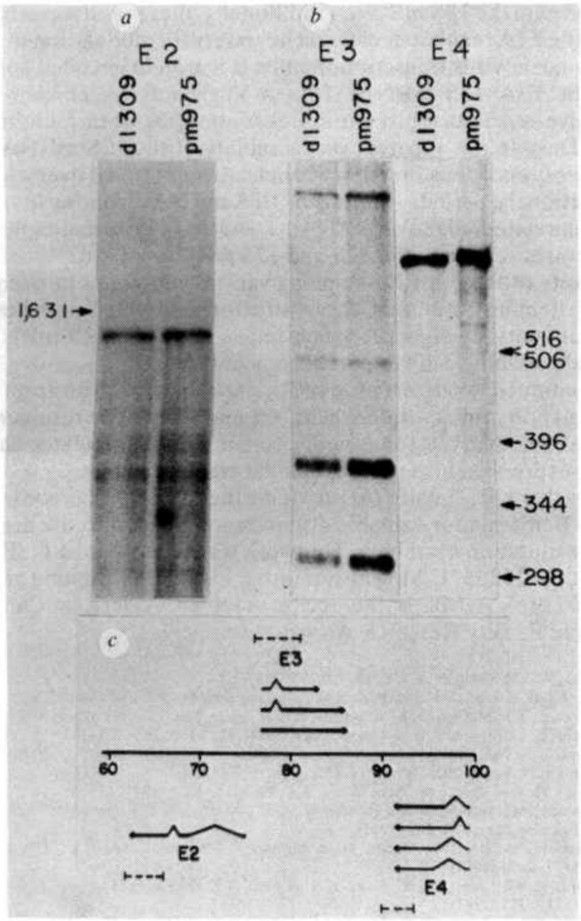

Fig. 5 Hybridization/S_1 nuclease analysis of mRNAs from early regions 2, 3 and 4. Five μg of early poly(A)$^+$ cytoplasmic RNA, prepared from HeLa cells 6 h post-infection with pm975 or d1309, were hybridized to M13 E2, E3 or E4 probes equivalent to 0.2 μg of the complete adenovirus genome. S_1 digestion and gel electrophoresis were as described for Fig. 4*a*. *a*, Early region 2 mRNA. S_1-protected fragments were electrophoresed for 18 h at 120 V. The position of the 1,631 nucleotide *Hin*fI pBR322 marker is indicated. *b*, Early region 3 and 4 mRNAs. The protected fragments were fractionated by electrophoresis for 18 h at 50 V. Although the patterns of protected fragments are identical for d1309 and pm975, the structures of the E3 mRNAs differ from wild-type Ad5 due to a substitution and deletion in the E3 DNA sequence of d1309 (ref. 8). The positions of *Hin*fI pBR322 fragments are included to the right. *c*, M13 E2, E3 and E4 single-stranded probes (R. B. Gaynor and A.J.B., in preparation). The M13 E2 probe was constructed by inserting a *Kpn*I–*Xho*I fragment of Ad2 DNA (61.3–66.0 map units) between the *Kpn*I and *Xho*I sites of M13G*ori*1. The E3 probe was prepared by cloning an *Eco*RI–*Kpn*I fragment of Ad5 DNA (75.9–81.0 map units) between the *Eco*RI and *Kpn*I sites of M13G*ori*1. To construct the E4 probe an *Eco*RI–*Bal*I fragment of Ad2 DNA (89.7–93.2 map units) was cloned between the *Eco*RI and *Pvu*II sites of M13G*ori*1. The Ad5 genome and major E2, E3, and E4 early mRNAs are diagrammed as in Fig. 4*c*. Abundant mRNAs are represented by the bold lines with minor mRNA species indicated by light lines. Broken lines identify the adenovirus sequence included in each of the probes.

fragments at late times, no evidence of the 476 nucleotide S_1 protected fragment is observed in the experiment with pm975 (Fig. 4*b*). Thus, within the sensitivity of the S_1 analysis, the 12S mRNA is eliminated. Based on quantitative densitometry of these autoradiograms, we estimate that it would be possible to detect the 12S mRNA in pm975-infected cells if it were above 2% the level observed in infected wild-type cells.

These results (Fig. 4) prove that substitution of a G for U in the second base of the EIA 12S mRNA intron inhibits RNA splicing at least 50-fold. As the 13S EIA mRNA is produced in pm975-infected cells, the apparent elimination of the 12S mRNA must have been due to interference with RNA splicing. Interference with any other step in RNA processing would have eliminated the 13S mRNA as well, because it is processed from the same mRNA precursor.

13S mRNA encodes all pre-early functions required for normal growth on HeLa cells

Characterization of the functions encoded in EIA and EIB has been facilitated by adenovirus host range mutants selected for their diminished capacity to grow on HeLa cells relative to 293 cells[11]. These mutants fall into two complementation groups (I and II) which map to EIA and EIB respectively[27]. Host range mutants were used to show that EIA encodes a regulatory element[5,6] and that functions encoded in EIA and EIB are required for viral transformation on primary rodent cells[7,8]. One of the motivations for creating pm975 was to define whether one or both of the overlapping EIA mRNAs encode the functions required for virus replication in HeLa cells.

Plaque assays of pm975 and a wild-type control on HeLa and 293 cells (Table 1) establish that pm975 is not host range, and therefore the 12S mRNA is not required for plaque formation on HeLa cells. These data, together with studies of Ad5 hr1 discussed previously, show that only the 289 amino acid, and not the 243 amino acid, polypeptide is required for efficient replication of adenovirus 2 or 5 in HeLa cells.

Because HeLa cells are a continuous cell line, it was considered possible that a requirement for the 243 amino acid protein was masked by the transformed phenotype of these cells. Therefore, plaque assays were repeated with pm975 on HEK cells, a secondary cell culture of human origin, and compared with titres on HeLa cells. The results (Table 1) show that the 12S mRNA is not required for virus replication on HEK cells either.

13S mRNA encodes all pre-early viral regulatory proteins

The pattern and levels of mRNA induced by pm975 and a phenotypically wild-type control (either d1309 or Ad2) were compared using the hybridization/S_1 nuclease technique. The hybridizations were performed between M13G*ori*1 single-stranded DNAs containing portions of the coding strand of each of the early transcription units and early cytoplasmic RNAs extracted from infected HeLa cells. Analysis of the fragment bands protected from S_1 digestion reveals no quantitative or qualitative differences between the early mRNAs induced by pm975 and Ad2 or Ad5 d1309 (see Fig. 4*a* for EIB, Fig. 5 for E2, E3 and E4). These results prove that the EIA regulatory elements that modulate early transcription are not encoded by the 12S mRNA and therefore must be specified by the 13S mRNA only.

Conclusions

A single U → G transversion introduced into the ubiquitous G-U at the 5′ splice site succeeded in eliminating the 12S mRNA in EIA, leaving the overlapping 13S mRNA intact. This demonstrates that a single nucleotide alteration in the 5′ consensus sequence is sufficient to interfere with the RNA splicing apparatus.

The fastidious nature of the splicing apparatus for an unaltered 5′ consensus sequence has also been demonstrated in studies with a nitrous acid-derived Ad5 mutant, Ad5 hr440, which similarly fails to express the 12S EIA mRNA[28]. This mutant has two alterations in the 5′ consensus sequence, at positions five and six of the 12S intron (nucleotides 978 and 979 in the Ad2 sequence). One of these base pair changes creates a termination codon in the 13S mRNA, disrupting translation of the EIA 289 amino acid protein. Therefore, Ad5 hr440 is not useful in discriminating between the functions encoded in the two overlapping early EIA mRNAs.

Analysis of naturally occurring mutations in the β-globin gene from patients with β-thalassaemia has provided evidence that the integrity of the consensus sequence is also required for efficient splicing of cellular mRNAs. Restriction endonuclease[29] and sequence[30] analyses of these mutant β-globin genes have revealed nucleotide alterations only within the 5′ consensus sequence of some of these genes. It is probable that these

β-thalassaemias are associated with disruption of RNA splicing, although this has not been confirmed experimentally.

Models have been advanced suggesting mechanisms for splicing based on hybridizations between small nuclear RNAs and the consensus sequences at the 5′ and 3′ splice sites of mRNA precursors[1-3,31]. These proposals are supported by recent evidence that a small nuclear ribonucleoprotein particle is required for splicing of adenovirus early RNAs[32]. They suggest that failure to splice the pm975 12S mRNA may result from instability of a precursor–small nuclear RNA hybrid. Alternatively, the enzyme(s) involved in the cutting and ligating steps of RNA splicing[33] may have a high degree of specificity for a U in the second position of the intron.

We selected the specific point mutation on the basis of its likelihood to disrupt the 12S mRNA splicing event while leaving the 289 amino acid protein encoded by the 13S mRNA unaltered because of degeneracy in the genetic code. This represents an effective approach with general applicability for ascribing specific functions to individual messages in a series of overlapping spliced RNAs.

Despite the absence of the 12S mRNA, the phenotype of Ad2/5 pm975 on HeLa and HEK cells is indistinguishable from wild-type Ad2 or Ad5, indicating that the only early region 1A function necessary for virus replication in human cells is encoded in the 13S mRNA. Additionally, these results establish that the EIA regulatory element necessary for modulation of the early adenovirus transcription units is a protein encoded solely by the EIA 13S mRNA. Thus a single mRNA encoding a positive regulatory protein in eukaryotes has been identified.

Despite the apparent dispensability of the 12S mRNA, it probably encodes a function which has been selected over a long evolutionary period. Analysis of EIA mRNAs from serotypically unrelated adenoviruses (Ad 7 and Ad 12) reveals spliced structures similar to the 12S and 13S mRNAs of Ad2[34,35]. The ubiquity of these mRNAs among various subgroups of adenovirus demonstrates that these structures survived significant evolutionary divergence, which implies that *the 12S mRNAs* encode a biologically important function *in situ.*

Continued analyses of pm975, including its transforming capacity on primary rodent cells, are underway. The results will reveal whether the same viral protein which modulates early gene expression also induces cellular transformation.

We thank R. Gaynor for providing the M13 DNA probes and Tom Benjamin for valuable discussions which led to the design of the mutational strategy. This work was supported by USPHS grant CA25235. C.M. was supported by USPHS training grant A1 07116. A.J.B. is the recipient of an American Cancer Society Faculty Research Award.

Unusual physical organization of the *Halobacterium* genome

Carmen Sapienza & W. Ford Doolittle

Department of Biochemistry, Faculty of Medicine, Dalhousie University, Halifax, Nova Scotia, Canada B3H 4H7

The genomes of the extremely halophilic bacteria, Halobacterium halobium *and* Halobacterium volcanii, *contain many repeated sequences. These sequences comprise many families, seem to be highly mobile and are arranged in both clustered and dispersed fashions within these genomes. At least some repeated sequences are more strongly conserved between the two species than are unique sequence DNAs.*

THE archaebacteria (halobacteria, methanogens and certain thermophiles) are thought to have diverged from eubacteria, and from the lineage which gave rise to the nucleus and cytoplasm of eukaryotic cells, at a very early stage in cellular evolution[1-3]. The metabolism, physiology and molecular biology of archaebacteria exhibit some traits which are unique and others which may be considered either 'eubacterial' or 'eukaryotic' in nature[1-4]. Virtually nothing is known about archaebacterial genomes except their genetic complexities. That of *Methanobacterium thermoautotrophicum* has a molecular weight of $\sim 1.1 \times 10^9$ (ref. 5), that of *Thermoplasma acidophilum*[6] $\sim 0.8 \times 10^9$ and those of several halobacteria[7,8] have molecular weights of 2.5×10^9.

The DNA of *Halobacterium halobium* and related species can be separated into components of 66–68 and 57–60 mol % $G+C$ (refs 7, 8). Much, but not all, of the latter fraction comprises a

0028-0836/82/050384—06$01.00

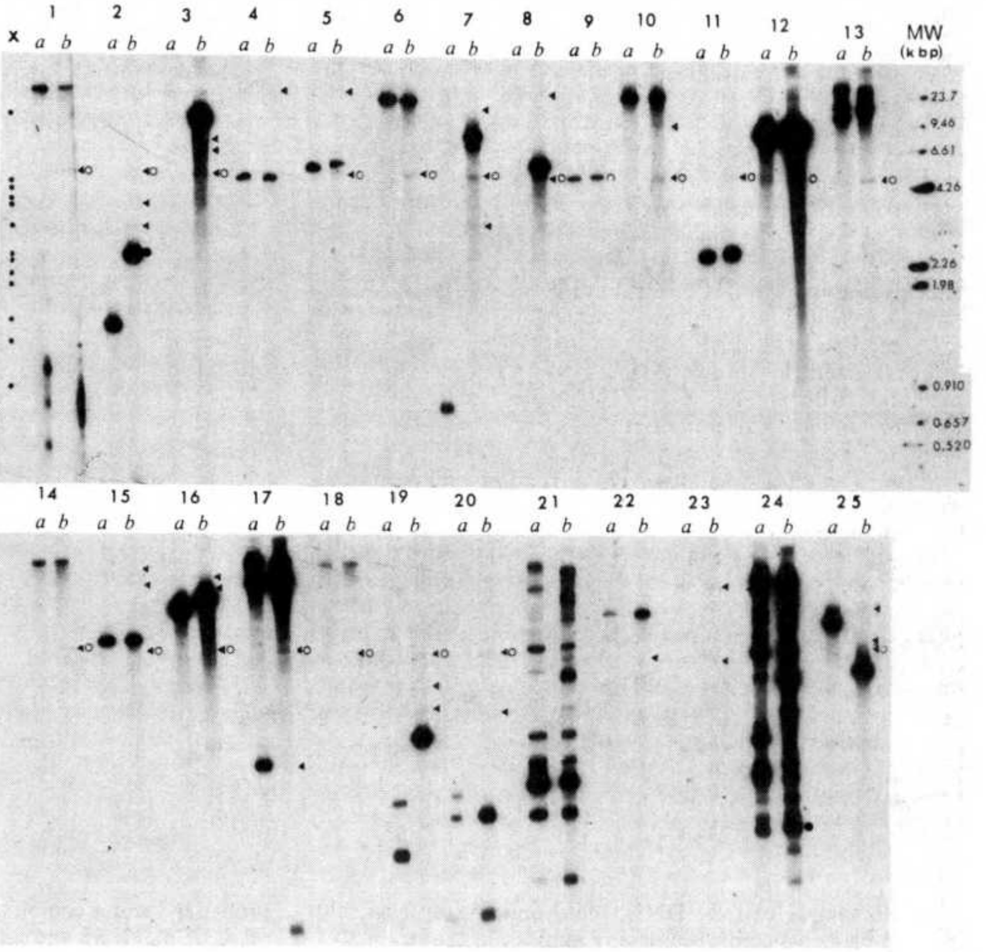

Fig. 1 Autoradiogram showing hybridization of individual ^{32}P-labelled recombinant plasmid DNAs from a genomic library of *H. halobium* R-1 to total DNA from *H. halobium* NRC-1 (tracks *a*) and *H. halobium* R-1 (tracks *b*). ◄, Position of faint bands of hybridization; ○, position of an ~5 kbp band probed by many of the cloned DNAs. Large closed circles in tracks 2*b* and 24*b* indicate hybridization to plasmid DNA fragments. Small closed circles in track X indicate the positions of *Eco*RI fragments of strain R-1 plasmid DNA. The genomic library was constructed by ligating *Bam*HI–*Eco*RI restriction endonuclease (Boehringer) double-digested *H. halobium* R-1 DNA to similarly cleaved pBR322 using T4 DNA ligase[15] (Boehringer). *E. coli* JF1754 (obtained from J. Friesen) was transformed[16] with the ligation mixture and plasmid DNA isolated[17] from 35 Amp^r Tet^s colonies. The recombinant plasmid DNAs were labelled with [α-^{32}P]dCTP (NEN) by nick-translation[11]. *H. halobium* R-1 and NRC-1 DNA was prepared as described elsewhere[18], cleaved with *Eco*RI and subjected to electrophoresis in a 1.2% agarose gel (Sigma). DNA was transferred to a sheet of nitrocellulose filter paper[12] (Millipore) and 0.5 cm strips cut from the sheet. Each probe was hybridized to one 'blot' of each of NRC-1 and R-1 DNA and washed in stringent conditions[19]. Molecular weight markers were λc1857 Sam7 DNA digested with *Hin*dIII and plasmid pBR322 DNA digested with *Alu*I.

150 kilobase pair (kbp) plasmid, four to five copies of which are present in *H. halobium* (ref. 9 and F. Pfeifer, personal communication). Changes in plasmid DNA restriction endonuclease digestion patterns, which can be interpreted as resulting from complex and multiple insertion and deletion events, are associated with easily detectable phenotypic alterations in gas vacuole and pigment production[10]. Such alterations occur with astonishing frequency, suggesting that the *Halobacterium* genome may contain many transposable elements or regions of sequence homology promoting recombination in and between chromosomal and plasmid DNAs.

Renaturation kinetic analyses show no substantial rapidly reannealing fraction which might represent the DNAs of a few, high copy number, repeat sequence families[7,8]. Data presented here, however, do show that (1) the genomes of halobacteria harbour many different, and perhaps rather small, families of repeated sequences whose members are probably both dispersed and clustered in both plasmid and chromosomal DNAs, (2) some repetitive DNAs are more highly conserved in sequence between two distantly related halobacterial species than are unique sequence DNAs, and (3) genomic rearrangements affecting the location of repetitive sequences are frequent and not necessarily associated with detectable phenotypic alterations.

Repeated sequences in a *Bam*HI–*Eco*RI library of *H. halobium* R-1 genomic clones

H. halobium strain R-1 was isolated as a spontaneously occurring, gas vacuole-deficient variant of the 'wild-type' strain NRC-1 in 1969 (W. Stoeckenius, personal communication). It harbours a plasmid of ~50 kbp. Total R-1 DNA doubly digested with *Bam*HI and *Eco*RI was ligated into similarly digested pBR322 and used to transform *Escherichia coli* JF1754. Thirty-five Amp^r Tet^s transformants were randomly selected, and their recombinant DNAs were labelled by nick-translation[11] with ^{32}P-dCTP and used to probe *Eco*RI-digested strain NRC-1 or strain R-1 DNAs bound to nitrocellulose paper strips[12]. Thirty-one of the labelled DNAs probed more than one *Eco*RI fragment of NRC-1 or R-1 DNA; thus each probe contained at least one sequence present more than once in these genomes. Figure 1 shows results for 25 of these cloned probes (faint bands detectable on the original autoradiograph are indicated by ◄). All but clone 9 probe *Eco*RI fragments in addition to those corresponding to the fragment cloned. Sixty to seventy such 'extra fragments' are probed in strain R-1 DNA (tracks *b*); slightly fewer strain NRC-1 DNA fragments (tracks *a*) are probed, and many of these have mobilities different from the probed R-1 fragments. Clones 2 and 24 each probe single and different fragments (indicated by large closed circles) with similar mobilities to *Eco*RI fragments of strain R-1 plasmid DNA (data not shown, but positions of plasmid bands indicated by ● in track X); most of the remaining probed fragments are of chromosomal origin. Although no clones seem to show identical probing patterns (considering patterns obtained with both NRC-1 and R-1), all but clones 4, 21, 22, 23 and possibly 24 probe, with varying intensities, a common ~5 kbp chromosomal fragment in R-1 DNA (○) which is not probed in NRC-1 DNA. For four of these clones probing this fragment (clones 6, 11, 14 and 18), it is the only fragment probed in addition to that cloned; the remaining 15 probing this common 5 kbp fragment probe fragments in addition to this and the fragment cloned (except clone 9, which may contain only the 5 kbp fragment). Thus the 5 kbp common fragment must contain copies of many (>10) different elements which are present in one or two locations elsewhere in the genome. This cluster must either have been created in strain R-1, or disrupted in strain NRC-1, since their divergence 12 yr ago.

The 25 clones used for Fig. 1 and the remaining 10 (not shown) contain in total 250 kbp of *H. halobium* DNA, or 6% of the genome, and contain a minimum of 31 different elements present at least once elsewhere in the genome. If they represent

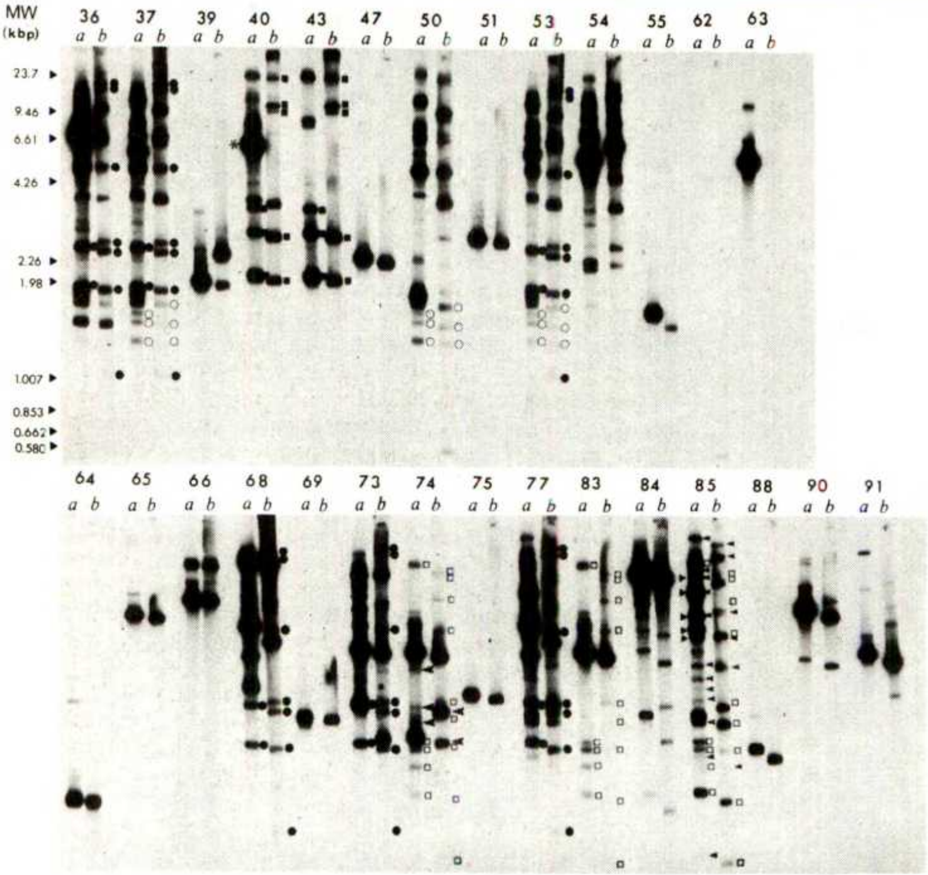

Fig. 2 Autoradiogram showing hybridization of individual ^{32}P-labelled recombinant plasmid DNAs from a genomic library of *H. halobium* NRC-1 to *Eco*RI-digested total DNA from *H. halobium* NRC-1 (tracks *a*) and *H. halobium* R-1 (tracks *b*). The library was constructed by ligating *Eco*RI-digested NRC-1 DNA into *Eco*RI-digested pBR322. All experimental procedures were as described in Fig. 1 legend except that both [α-^{32}P]dCTP and [α-^{32}P]dATP were included in the nick-translation reaction. Open and closed circles and squares indicate shared subpatterns probed by some of the cloned fragments. Small and large arrowheads indicate fragments which distinguish clones 74 and 85 from each other and from clone 83. Closed triangles adjacent to clone 85 (track *a*) indicate *Eco*RI fragments of *H. halobium* NRC-1 DNA which are also probed by several *H. volcanii* cloned DNAs (see Fig. 3*b*).

a random sample of total DNA, there must be at least 500 repeated elements comprising many families in the strain R-1 genome. Some elements must be clustered on cloned DNA, or present in copy numbers >10 in the genome, because clones 21 and 24 alone probe more than one-third of the 'extra' fragments. Variations in intensity of hybridization signals (most obvious with clones 17, 21 and 24) could mean that the fragment probed contains divergent copies of the elements present on the probe, or varying numbers of copies of such elements, or that the probes themselves contain several different repeated elements. The latter interpretation is favoured by data discussed below.

Repeated sequences in an *Eco*RI library of *H. halobium* NRC-1 genomic clones

Strain R-1 is a mutant, and the unknown event which created it may have resulted in the dispersal of repeated sequences within the genome. We constructed a library of wild-type (NRC-1) *Eco*RI fragments cloned into *Eco*RI-digested pBR322 and used 28 of the resulting labelled recombinant DNAs to probe NRC-1 and R-1 DNAs digested with *Eco*-RI (Fig. 2). One of these (clone 62) probed only a single fragment of NRC-1 and R-1 DNAs; the rest probed multiple fragments of either NRC-1 or R-1 DNA. As the NRC-1 plasmid is large (150 kbp), not easily isolated and gives a complex *Eco*RI digestion pattern, it is difficult to say how many probed fragments are of plasmid origin. Most of the fragments probed by at least one of these clones (clone 37) are, however, not of plasmid origin, as judged by comparisons of mobilities of probed *Eco*RI-, *Hin*dIII-, *Sal*I-, *Sst*I- and *Sst*II-generated fragments to plasmid fragments produced by these enzymes (data not shown). All cloned fragments produced different Southern hybridization patterns with DNAs of strains NRC-1 (Fig. 2 tracks *a*) and R-1 (Fig. 2 tracks *b*), and all (except for clones 37 and 53, which may be identical) produced different, probe-specific patterns with each of these DNAs. However several fragments are jointly probed, in different combinations, by different cloned fragments, and can be used to identify at least four shared 'subpatterns' (indicated by open and closed circles and squares in Fig. 2) which are probed in various combinations by clones 36, 37, 40, 43, 50, 53, 68, 73, 74, 77, 83 and 85 (◄ identifies some fragments which distinguish clones 74 and 85 from each other and from clone 83, which otherwise probe common fragments). These 'subpatterns' are also apparent when the same clones are used to probe *Pst*I-digested NRC-1 DNA; those probing various sets of *Eco*RI fragments in different characteristic combinations also probe different sets of *Pst*I fragments in different characteristic combinations (data not shown). The remaining clones produce hybridization patterns with *Eco*RI-digested NRC-1 DNA which appear unique (and also produce unique patterns with *Pst*I-digested DNA). It is not clear whether these patterns too are composed of 'subpatterns', but intensity variations suggest they are. In any case, at least 21 different repetitive sequences are present among these 28 clones (some several times), and most or all of these are different (because they produce different probing patterns) from the repetitive sequences present in clones of the *Bam*HI–*Eco*RI strain RI library. Note that clones 40 and 43 probe common fragments and thus must contain a common element(s), and yet the NRC-1 DNA insert in clone 40 (indicated by an * in Fig. 2) is not itself detectably probed by clone 43. Also, some identical fragments probed by clones 50 and 53 (or 83 and 85) produce hybridization signals of different intensities.

Many of the cloned fragments in the *Eco*RI strain NRC-1 library bear copies of different repetitive elements, some of which must lie close to each other in the genome. Cloned fragments which unquestionably bear two different elements (clones 36, 37, 40, 50, 53, 74, 77 and 85) have an average length of only 3.3 kbp (range 1.75–4.6 kbp). We suspect that the differing intensities with which individual fragments are probed by different cloned DNAs reflect the presence of different numbers of copies, on both probed and cloned fragments, of shared sequences.

There should be (on the basis of its G+C content) ~300 *Eco*RI fragments in the *H. halobium* genome. Elements indicated by symbols in Fig. 2 appear to be present on 10 or fewer *Eco*RI fragments, and yet one of these elements appears five or six times and two of them two or three times in our 28 clones. There are two possible explanations for this apparent statistical improbability. (1) Such elements are present in many copies on the few *Eco*RI fragments which are detected as probed, and also present on a much larger number of other *Eco*RI fragments, but in too few copies to give detectable hybridization signals. Clones bearing *Eco*RI fragments of the latter type would then only probe strongly fragments of the former type. The results with clones 40 and 43 noted above might be consistent with this interpretation. (2) The repetitive sequences represented in Fig. 2 are preferentially located in A+T-rich regions of the genome which are more frequently attacked by *Eco*RI. Indeed, most of the cloned fragments are smaller (average length 3 kbp) than the expected distance between *Eco*RI sites (12 kbp). We may be repeatedly sampling only a small portion of the genome.

To test the latter possibility, we constructed a small library of *Pst*I fragments of NRC-1 DNA inserted into *Pst*I-digested pBR322. The *Pst*I recognition site is similar in G+C content to the *H. halobium* genome. Thirteen such cloned DNAs were used to probe *Pst*I digests of total DNA of strain NRC-1. None probed fragments other than that corresponding in mobility to the fragment cloned, and yet the 13 clones contained in total 48.7 kbp of *H. halobium* NRC-1 DNA, or 51% of the 94.7 kbp represented by *Eco*RI clones shown in Fig. 2, in which there are at least 30 repetitive elements of at least 21 different families.

Repeated sequences in *H. volcanii* genome

16S ribosomal RNA (rRNA) catalogue analyses show *H. volcanii* to be as remote phylogenetically from *H. halobium* as *Pasteurella* or *Aeromonas* species are from *E. coli*[2]. To determine whether *H. volcanii* also contains families of repeated elements and shares any of these with *H. halobium*, we constructed an *Eco*RI library of *H. volcanii* total DNA and used cloned fragments to probe *Eco*RI-digested *H. volcanii* and *H. halobium* NRC-1 DNAs (Figs 3*a*, *b*). Of 30 randomly selected clones, 10 (v71, v82, v86, v107, v110, v113, v118, v123, v144 and v146) contained unique sequence DNA and only probed fragments identical in mobility to the fragment cloned; none of these probed any fragment of NRC-1 DNA. The remaining 20 cloned DNAs probed multiple fragments of *H. volcanii* DNA (the faintest of which are marked by ▲ in Fig. 3*a*). Five different cloned DNAs (v7, v33, v50, v60 and v97) probed an identical large set of *H. volcanii* fragments (some are indicated by ● in Fig. 3*a*). Clone v147 probed the same set, plus several additional fragments. The remaining multiply probing cloned fragments produced hybridization patterns which appear unique, although only two of these (v88 and v122) probed more than three or four fragments in addition to that representing the cloned insert. Only those *H. volcanii* clones probing more than three or four *H. volcanii* DNA fragments probed *H. halobium* NRC-1 DNA but each of these probed multiple fragments (Fig. 3*b*). Thus some repeated sequences are more highly conserved than are unique sequence DNAs.

The clones probing *H. volcanii* fragments indicated by closed circles in Fig. 3*a* probed multiple and similar fragments of *Eco*RI-digested *H. halobium* NRC-1 DNA. Clone v147, which

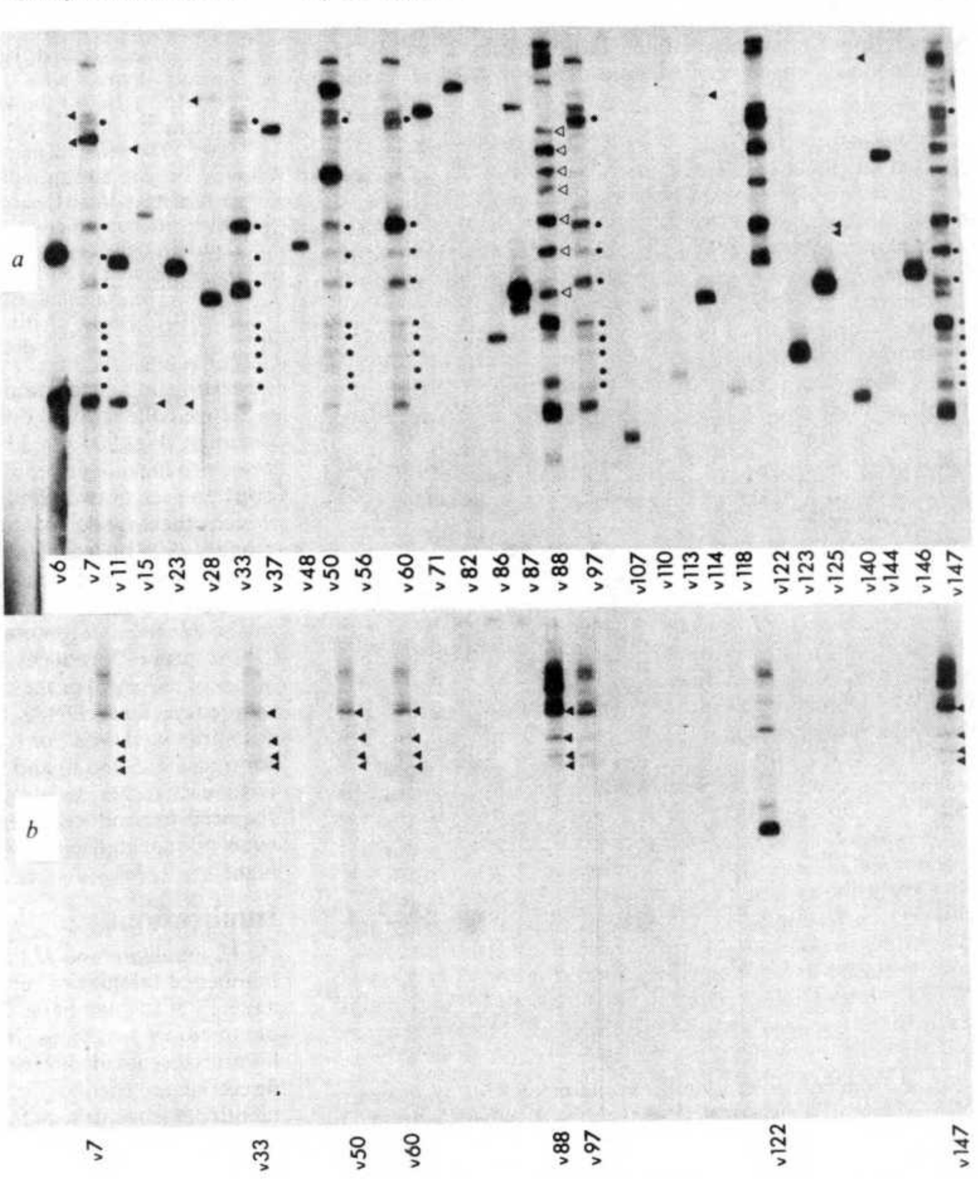

Fig. 3 Autoradiogram showing hybridization of individual ^{32}P-labelled recombinant plasmid DNAs of a genomic library of *H. volcanii* to *Eco*RI-digested total DNA from *H. volcanii* (*a*) or *H. halobium* NRC-1 (*b*). The library was constructed by ligating *Eco*RI-digested total *H. volcanii* DNA to similarly digested pBR322. Both [α-^{32}P]dCTP and [α-^{32}P]dATP were included in the nick-translation reaction. All other experimental procedures were as for Fig. 1. In *a*, ◄ indicates faint bands detected on the original autoradiogram; ●, *Eco*RI fragments of *H. volcanii* DNA hybridized by several *H. volcanii* cloned DNAs and by two *H. halobium* cloned DNAs (see Fig. 4); ◁ adjacent to clone v88 indicates *Eco*RI fragments of *H. volcanii* DNA also hybridized by three *H. halobium* cloned DNAs (see Fig. 4). In *b*, ◄ indicates *Eco*RI fragments of *H. halobium* DNA probed by several *H. volcanii* cloned DNAs and probed by *H. halobium* clone 85 (see Fig. 2).

must contain two different repetitive elements, probed the same fragments and one or two others. Clone v122 probed a unique set of *H. halobium* NRC-1 fragments. More unexpectedly, clone v88 probed the same set of *H. halobium* NRC-1 fragments as did clones v7, v33, v50, v60, v97 and v147, although it does not probe the same set of *H. volcanii* fragments. Thus, repeated elements which are usually separated in *H. volcanii* DNA are usually associated in *H. halobium*.

In a reciprocal experiment (Fig. 4), selected *Eco*RI clones of *H. halobium* NRC-1 DNA which probed multiple *Eco*RI fragments of that DNA were used to probe *Eco*RI-digested *H. volcanii* DNA. Clones 54 and 85 (Fig. 2) probed identical sets of *H. volcanii* DNA fragments, which seem to include all the fragments probed by *H. volcanii* clones v88 and v97 (or others like it), plus some additional high-molecular-weight fragments. This provides reciprocal confirmation of the conclusion reached above. These clones contain inserts of only 3.3 and 1.75 kbp, respectively. However, *H. halobium* NRC-1 clone 84 probes only those fragments probed by *H. volcanii* clone v88, so this clustering is not obligatory in *H. halobium*. Of the remaining seven *H. halobium* NRC-1 clones tested, four (37, 40, 51 and 91) probed unique sets of *H. volcanii Eco*RI fragments and three probed no *H. volcanii* fragments.

Rearrangements affecting *H. halobium* repetitive sequences

Figure 5 shows results obtained by probing *Eco*RI (*a*) or *Sal*I (*b*) digested DNAs from strain NRC-1 (track 1), two NRC-1 single-colony isolates out of 20 picked from a single plate as phenotypically indistinguishable from NRC-1 (tracks 2 and 3), two spontaneously arising gas vacuole-deficient NRC-1 variants (tracks 4 and 5) and strain R-1 (track 6) with two DNAs bearing what we believe to be different and single repetitive elements. The first (Fig. 5*a*) is a 330 bp *Alu*I fragment which appears to comprise most of an ~500 bp repetitive element present in one copy on each of two *Hin*dIII–*Eco*RI fragments of NRC-1 DNA which otherwise do not cross-hybridize. The second (Fig. 5*b*) is a cloned ~900 bp fragment containing an element present on one of two otherwise identical *Hin*dIII fragments of the *H. halobium* R-1 plasmid. (This element is also present at least a dozen times in the *H. volcanii* genome; data not shown.) None of the six DNAs probed produces identical hybridization patterns with either of these two probes, even though the cell populations used to prepare these DNAs derive from phenotypically identical colonies ('wild type' for tracks 1, 2 and 3; gas vacuole-deficient for tracks 4, 5 and 6) and were (except for strain R1) separated from each other by only the number of generations (~30) required to produce enough cells to prepare DNA. Mobility, even of repeated elements selected randomly, is remarkably high.

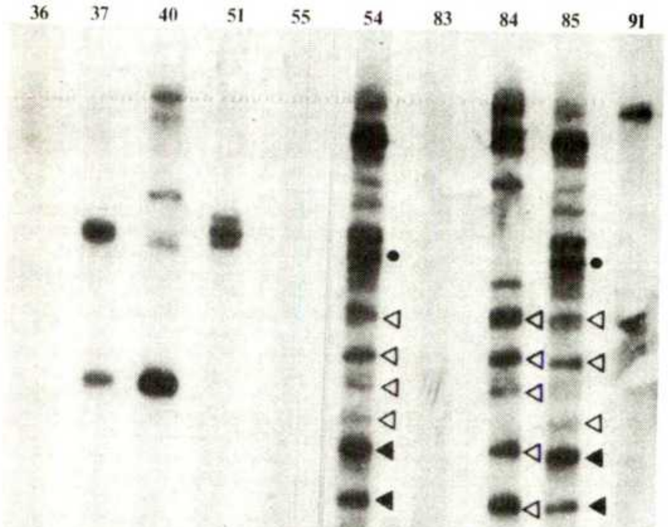

Fig. 4 Autoradiogram showing hybridization of *H. halobium* NRC-1 recombinant plasmid DNAs (see Fig. 2) to *Eco*RI-digested *H. volcanii* DNA. ●, ◁, Fragments also hybridized by *H. volcanii* cloned DNAs (see Fig. 3). ◀, Superimposed symbols ● and △.

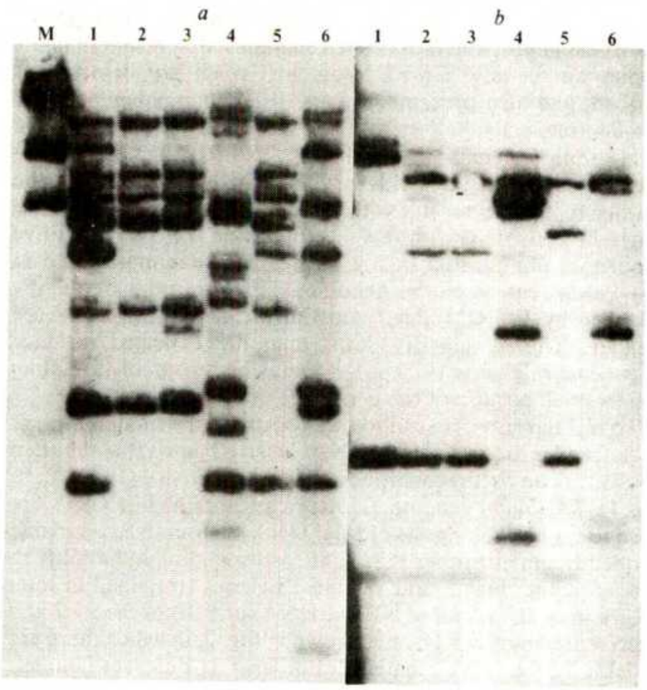

Fig. 5 *a*, Autoradiogram showing hybridization of a ^{32}P-labelled 330 bp *Alu*I fragment of *H. halobium* NRC-1 DNA to *Eco*RI-cleaved total DNA from *H. halobium* NRC-1 (lane 1), two apparently wild-type colonies of strain NRC-1 selected from 20 such isolates (see text; lanes 2 and 3), two gas vacuole-deficient mutants of strain NRC-1 (such mutants arise at a frequency of $1\text{–}3\times10^{-2}$) (lanes 4 and 5), and *H. halobium* R-1 (lane 6). Lane *M* contains ^{32}P-labelled λc1857 Sam7 DNA cleaved with *Hin*dIII. The 330 bp *Alu*I fragment used as a probe appears to comprise most of an ~500 bp repetitive element present in one copy on each of two *Hin*dIII–*Eco*RI cloned fragments of NRC-1 DNA which do not otherwise cross-hybridize (data not shown). *b*, Hybridization of a ^{32}P-labelled 900 bp *Pst*I–*Sal*I strain R-1 cloned DNA fragment to *Sal*I-cleaved DNAs from different *H. halobium* strains. This fragment was discovered as a 900 bp insertion in a *Hin*dIII fragment of strain R-1 plasmid DNA (see text). Lane designations as in *a*.

Implications

(1) *H. halobium* and *H. volcanii* genomes each contain a large number of families of repeated sequences, each of which may have 2–>20 members. The different hybridization patterns obtained when clones from each of the two *H. halobium* libraries discussed above, and a third *Hin*dIII–*Eco*RI library not discussed, are used to probe *Eco*RI-digested *H. halobium* DNA identify at least 50 such families, and there may be many more. The possession of multiple repetitive sequence families is not typical of all archaebacteria; comparable cloning and hybri-

dization experiments with the DNA of the much smaller genome of *T. acidophilum* (not shown) revealed no repetitive sequences. (2) Repetitive elements are often clustered together with other repetitive elements of other families within small genomic regions. Elements of a given family may be clustered with elements of different families in different regions. Some clusters may themselves comprise repeat sequence families, but we cannot be certain of this. (3) Some clusters, such as the 5 kbp fragment identified in Fig. 1, may contain quite large numbers of different elements. (4) Rearrangements which affect the disposition of repeated sequences occur very frequently, and are not obligatorily coupled with any detectable phenotypic alteration, although such alterations are themselves very frequent. The high frequencies of both types of event make it difficult to relate them causally[10]. (5) Sequences which are repeated in the genome of *H. halobium* are frequently present and repeated in the genome of *H. volcanii* and vice versa. They may often be clustered with elements of different repeat sequences in different ways in the two genomes. Most unique sequence DNAs are not conserved between the two genomes. (6) The genome may contain regions of non-random variation in G+C content, in which elements of different families are mostly clustered, because libraries prepared with restriction endonucleases recognizing targets of different per cent G+C contain different numbers and kinds of repeated elements. Although the *H. halobium* chromosome and plasmid are of different G+C contents, they do not contain mutually exclusive sets of repetitive elements (Figs 1, 2 and data not shown). Such compartmentalization, if it exists, is a property of the whole genome.

We know of no other data on prokaryotic genomes which reveal the complexity of repeat sequence composition, arrangement and rearrangement demonstrated here. The only detailed body of data of comparable complexity is that bearing on repeated sequences in the genomes of plants[13] and sea urchins[14], but we hesitate to suggest, on this basis alone, that the halobacterial genome resembles the genomes of eukaryotes more than those of eubacteria. This issue deserves more intensive scrutiny.

Detection of $HC_{11}N$ in IRC+10°216

M. B. Bell, P. A. Feldman, Sun Kwok & H. E. Matthews

Herzberg Institute of Astrophysics,
National Research Council of Canada,
Ottawa, Canada K1A 0R6

The observations of three rotational transitions ($J = 70 \rightarrow 69$, $71 \rightarrow 70$, and $72 \rightarrow 71$) of $HC_{11}N$ (cyano-deca-penta-yne) in the microwave emission spectrum of the circumstellar envelope of the cool carbon star IRC+10°216 are reported here. The abundances relative to molecular hydrogen and HC_7N are estimated to be $\sim 7 \times 10^{-8}$ and ~ 0.7, respectively. With these observations, taken during March and May 1981 at the Haystack Observatory, $HC_{11}N$ becomes the largest and heaviest molecule yet detected outside the Earth's atmosphere.

The cool carbon star IRC+10°216 (=CW Leo) is believed to be undergoing extensive mass loss and its dense circumstellar envelope is known to be rich in neutral molecules and free radicals. Its comparative proximity to the Earth (~200 pc) and correspondingly large angular diameter (~2.5 arc min as measured in the emission of the CO molecule[1]) have made it especially rewarding in this respect.

Observations of the microwave inversion lines of ammonia in the envelope of IRC+10°216 have shown the presence of a weak feature (U23.698) close to the $NH_3(1,1)$ line. The feature appears in observations made at both the 46-m telescope of the Algonquin Radio Observatory[2] and the 37-m telescope of the Haystack Observatory[3]. After these observations we tentatively identified U23.698 as the $J = 70 \rightarrow 69$ transition of the linear carbon-chain (cyanopolyyne) molecule $HC_{11}N$ (cyano-deca-penta-yne) on the following grounds:

(1) Of the 17 known molecules in the envelope of IRC+10°216, seven have carbon–carbon bonds and 10 have appended CN radicals.

(2) The derived rotational constant ($B_0 \simeq 169.27$ MHz) would be only ~210 kHz greater than the value predicted by Oka[4] on the basis of a simple numerical extrapolation from lower cyanopolyyne chains. The magnitude (~0.1%) and direction of this discrepancy could be readily explained in terms of a slight molecular non-rigidity which is expected on the basis of the extended vibrational satellite patterns found for carbon-chain molecules[5].

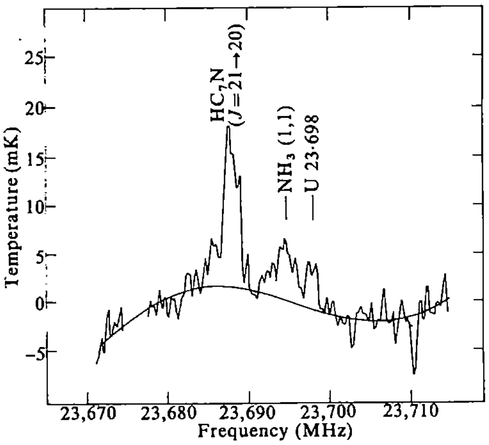

Fig. 1 The spectrum of IRC+10°216 in the region of the $NH_3(1,1)$ line, before baseline removal. Features due to HC_7N ($J = 21 \rightarrow 20$) and the proposed $J = 70 \rightarrow 69$ transition of $HC_{11}N$ (U23.698) also appear in the window. The ordinate is antenna temperature corrected for zenith-angle variations of gain and atmospheric absorption. The gap in the spectrum omits a feature of instrumental origin.

0028-0836/82/050389—03$01.00

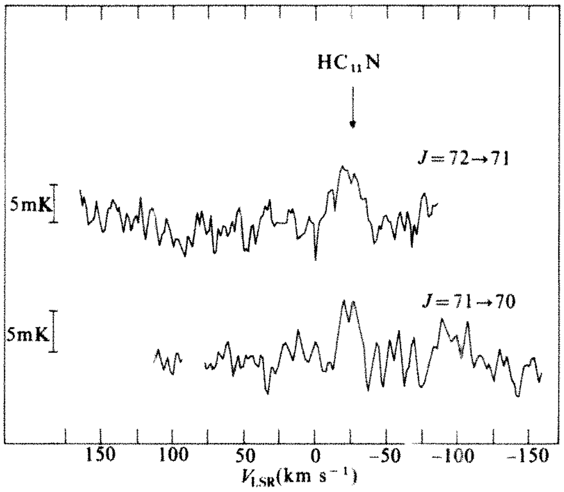

Fig. 2 Two adjacent transitions of HC$_{11}$N in the spectrum of IRC+10°216. The features have been aligned on a common velocity scale using the rest frequencies given in Table 1. The antenna-temperature scales are indicated on the left of the figure. Other details are as for Fig. 1.

(3) Long-chain cyanopolyynes, such as HC$_7$N, are relatively abundant in IRC+10°216. An extrapolation from the lower members of the molecular series[6] suggested that $[HC_{11}N]/[HC_7N] \geq 0.1$. The direct comparison afforded by the presence of both U23.698 and the $J = 21 \rightarrow 20$ transition of HC$_7$N in the NH$_3$(1,1) spectrum[3] is consistent with this expectation.

We have detected two further microwave transitions of HC$_{11}$N (H—C≡C—C≡C—C≡C—C≡C—C≡C—C≡N) using frequencies derived from the above result. This suggests that the identification of HC$_{11}$N is fairly secure and now represents the heaviest (147 AMU) and largest (~15 Å) extraterrestrial molecule known.

At the frequencies employed (close to 24 GHz) the 37-m telescope of the Haystack Observatory has a peak aperture efficiency of 22% at 45° elevation and a beam efficiency of 25%, including radome losses. The half-power beamwidth is 1.4 arc min. The observations were carried out with a maser receiver and an autocorrelation spectrometer of total bandwidth 40 MHz and an effective resolution of 4.9 km s^{-1}.

The observations in March were used to search for the $J = 72 \rightarrow 71$ transition of HC$_{11}$N, expected at ~24,374 MHz. The total-power observing method was used; ~25 h of on-source integration time were accumulated, of which about 30% were affected by adverse weather and were discarded. A further 33 h of on-source time was obtained in May when observations were made of the $J = 71 \rightarrow 70$ transition, predicted to be close to 24,037 MHz. On this occasion, measurements were made using a modified 'double-Dicke' mode[7] when the weather deteriorated, and no data editing was necessary.

Figure 1 shows the spectrum of IRC+10°216 in the region of the NH$_3$(1,1) line as obtained at Haystack[3]. Our new observations of spectral windows containing the proposed $J = 71 \rightarrow 70$ and $J = 72 \rightarrow 71$ transitions of HC$_{11}$N are shown in Fig. 2. The arrow indicates the expected position of the line as predicted from the $J = 70 \rightarrow 69$ transition first detected at ARO ($B_0 = 169.275$ MHz).

Table 1 Transitions of HC$_{11}$N in IRC+10°216

Date	Telescope	Transition $J_u \rightarrow J_l$	Measured rest frequency (MHz)*	Derived B_0 (MHz)†
April 1979 May 1979 February 1980	ARO ARO ARO	70 → 69	23,698.2±0.3‡	169.275±0.002
November 1980	Haystack	70 → 69	23,697.9±0.4‡	169.273±0.003
March 1981	Haystack	72 → 71	24,375.2±0.2§	169.274±0.001
May 1981	Haystack	71 → 70	24,037.1±0.1§	169.277±0.001

* Peculiar velocity −26.0 km s^{-1} assumed.

‡ Line may be confused with NH$_3$(1,1); error quoted includes estimate of possible systematic effects.

§ 1σ formal errors.

Including the earliest measurement[2] of the $J = 70 \rightarrow 69$ transition with the 46-m telescope, four independent observations of microwave rotational transitions of HC$_{11}$N have been made: the results are summarized in Table 1. The rest frequency has been determined for each case from the data assuming a peculiar velocity for IRC+10°216 with respect to the local standard of rest of −26.0 km s^{-1} (see ref. 1). The $J = 70 \rightarrow 69$ transition is confused with the NH$_3$(1,1) line and we take the error in determining the rest frequency in this case to be about three times greater than the formal value. The rotational constant B_0 was calculated for each transition using a centrifugal distortion constant $D_0 = 0.22$ Hz. The latter was estimated from the semi-empirical relation $D_0(HC_nN) \propto [B_0(HC_nN)]^{2.37}$, which provides a good fit to the measured values of the rotational constants of HCN, HC$_3$N, HC$_5$N, and HC$_7$N, and which is consistent with the published transitions of HC$_9$N in TMC 1 (refs 8, 9).

The weighted average of B_0 for all four observations is 169.275±0.001 MHz. This result is unchanged if we omit the poorer-quality 46-m observations of the $J = 70 \rightarrow 69$ line, or if we neglect all the $J = 70 \rightarrow 69$ data on the grounds of its possible confusion with the NH$_3$(1,1) line.

For better estimates of the line parameters we have averaged together the $J = 71 \rightarrow 70$ and $J = 72 \rightarrow 71$ observations on a common velocity scale (see Fig. 3). The line profile thus obtained may show an indication of the non-gaussian (relatively flat-topped) shape found for other molecules in this source[1,10]. We derive a full width at half maximum for the line of 25±2 km s^{-1} and a peak antenna temperature of 6±1 mK.

We have detected three lines in the circumstellar envelope of IRC+10°216, which we believe to be adjacent rotational transitions of the long carbon-chain molecule HC$_{11}$N. While we are confident of the correctness of this assignment, we must still consider whether there are viable alternatives.

The exact agreement in the frequency intervals between the two pairs of lines, and the fact that all three lines have the same intensity leaves little doubt that a single linear species is responsible. If the transitions we detect are not in fact adjacent, but still belong to a single species, that species must have a molecular weight in excess of ~200 AMU. We can argue on abundance grounds that this is much less likely than HC$_{11}$N.

Certain other linear carbon-chain molecules whose exact line frequencies are not known are expected to have a B_0 of the same order; for example, C$_{12}$H and C$_{11}$N. Since C$_4$H and C$_3$N are the longest C$_n$H and C$_n$N carbon chains of their respective types that have yet been found, and because the derived abundance of HC$_{11}$N (see below) is in rough agreement with that extrapolated from lower-order cyanopolyynes, we are led to identify HC$_{11}$N as the source of the detected lines.

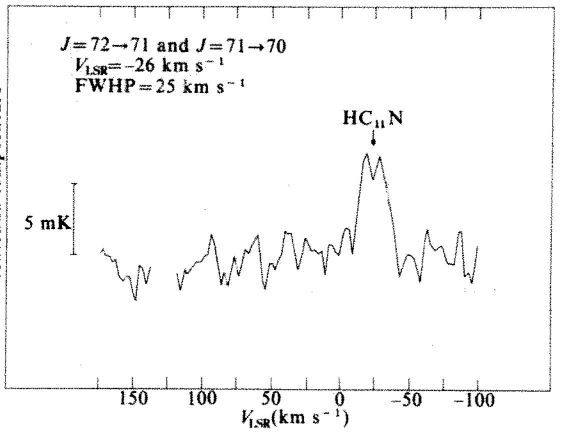

Fig. 3 The average of the $J = 72 \rightarrow 71$ and $J = 71 \rightarrow 70$ transitions of HC$_{11}$N in the spectrum of IRC+10°216. Other details are as for Fig. 1.

Table 2 Cyanopolyyne abundances in IRC + 10°216

Molecule	Observed transition $J_u \rightarrow J_l$	Observed T_A^* (mK)†	Abundance relative to H_2 $\beta = 0.6$	$\beta = 0.8$
HC_5N‡	9 → 8	400 ± 80	7.3×10^{-7}	5.2×10^{-7}
HC_7N	21 → 20	56 ± 8	1.0×10^{-7}	1.0×10^{-7}
$HC_{11}N$	71 → 70 72 → 71	24 ± 4	7.0×10^{-8}	8.0×10^{-8}

See text for details of model used.

† Main-beam brightness temperature corrected for atmospheric absorption and telescope gain-zenith angle efficiency variation.

‡ Measured during May 1981 session.

Molecular line excitation in a circumstellar environment has to be treated differently from that in interstellar dust clouds. Not only does the gas density (and thus also collisional excitation) decrease radially outward from the star, but so also does the IR radiation field responsible for the vibrational excitation. Previous radiative transfer models for the CO and NH_3 molecules[2,11] in the circumstellar envelope of IRC + 10°216 show that the excitation temperature gradient can be approximated by a power law of the form $T_{ex}(r) = T_0(r_0/r)^{\beta}$ where $T_0 = 350$ K at $r_0 = 2 \times 10^{15}$ cm, and $0.6 \leq \beta \leq 0.8$. A gradient of this type, while unimportant for the low rotational states normally observed in the lower-order cyanopolyynes, becomes a significant factor for higher-order members of the series. In the present case, the observed transitions occur between states of rotational energy equivalent to 40 K. The lower excitation temperature in the outer parts of the circumstellar envelope thus leads to a non-uniform distribution of level populations across the molecular gas within the telescope beam.

Model calculations for the circumstellar envelope of IRC + 10°216 have been performed assuming the lines are optically thin and the population distribution at each radius to be in LTE at a temperature $T_{ex}(r)$. We further assume that there is neither significant formation nor destruction of the molecules beyond several stellar atmospheric scale heights[12].

The line brightness temperature over the envelope surface is then computed and the results convolved with the telescope beam. Scaling the results to the observed values leads to the molecular abundances (n_{mol}/n_{H_2}) given in Table 2. Note that the derived abundances scale as (distance/200 pc)^2 × (mass-loss rate/$2 \times 10^{-5}\, M_{\odot}\, yr^{-1})^{-1}$ and are uncertain due to the lack of precise values for these parameters. Table 2 also includes results for the $J = 9 \rightarrow 8$ transition of HC_5N, a short observation of which was made in the May 1981 session at Haystack Observatory for comparison purposes. In addition, although we did not observe a transition of HC_9N, we can predict that in IRC + 10°216 the HC_9N $J = 41 \rightarrow 40$ line should be approximately twice as strong as the lines of $HC_{11}N$ reported here if $n_{HC_9N}/n_{H_2} = 10^{-7}$.

Thus the abundance of $HC_{11}N$ is ~0.7 of that of HC_7N (independent of distance and mass-loss rate). This is interesting in that it is rather higher than would have been expected from an extrapolation from lower-order members of the series. The decrease in abundance as a function of cyanopolyyne molecular weight in the envelope of IRC + 10°216 also seems to be less steep than in TMC 1 (ref. 8) and other interstellar molecular clouds[13]. Moreover, the cyanopolyyne relative abundances compared with molecular hydrogen in IRC + 10°216 are much higher than those found in dark molecular clouds. For example, MacLeod *et al.*[14] reported an abundance ratio $[HC_5N]/[H_2] \approx 10^{-8}$ in TMC 1. We find that this ratio is ≈60 times higher in the case of IRC + 10°216. In fact, relative to H_2, $HC_{11}N$ is ≈7 times more abundant in the envelope of IRC + 10°216 than HC_5N is in TMC 1.

Although the exact mechanism for the formation of long-chain carbon molecules in interstellar space is still in controversy[15–18], we now have evidence that large numbers of such molecules can be produced in the atmospheres of carbon stars like IRC + 10°216 where activation energies can be overcome[19]. Formation of dust grains will quickly lead to momentum grain-gas coupling which will eject the molecules[20].

The current rate of mass returned to the interstellar medium by late-type stars is $6 \times 10^{-10}\, M_{\odot}\, pc^{-2}\, yr^{-1}$ (ref. 21). Assuming 10% of all late-type stars are capable of manufacturing long-chain carbon molecules, our derived abundances for $HC_{11}N$ implies an ejection rate of 10^{39} $HC_{11}N$ molecules $pc^{-2}\, yr^{-1}$ into the interstellar medium alone. While most of these molecules will probably be destroyed by interstellar EUV radiation, clearly the molecular production by stars can be an important ingredient in chemical models of the interstellar medium.

We thank the staff of Haystack Observatory, in particular A. Haschick and B. Leslie, for hospitality and assistance, also L. W. Avery, N. W. Broten, and J. M. MacLeod for encouragement and advice. The Algonquin Radio Observatory is operated by the National Research Council of Canada, Ottawa, as a national radio astronomy facility. Radio astronomy at the Haystack Observatory of the Northeast Radio Observatory Corporation is supported by the NSF.

On the reported detection of sub-GeV antiprotons in galactic cosmic rays

David Eichler

Astronomy Program, University of Maryland,
Maryland 20742, USA

Buffington *et al.*[1] claim to have detected a $\bar{p}/p$ ratio of $2.2 \pm 0.6 \times 10^{-4}$ at energies between 130 and 320 MeV. This is several orders of magnitude above theoretical predictions[2–4] at these lower energies for $\bar{p}$ fluxes resulting from collisions of primary cosmic rays with the interstellar gas. Measurements at higher energies by Golden *et al.*[5] show a $\bar{p}/p$ ratio of $5.2 \pm 1.5 \times 10^{-4}$, in excess, by a factor of about 3, of the expected values if $\bar{p}$s are of secondary origin in the standard model of galactic cosmic rays. The reported $\overline{He}/He$ ratio[1] is significantly lower than the reported $\bar{p}/p$ ratio, raising difficulties with some scenarios[6] in which the $\bar{p}$s are primary cosmic rays from anti-galaxies. Kiraly *et al.*[7] suggest black hole evaporation as a $\bar{p}$ source. I discuss here scenarios in which the reported sub-GeV $\bar{p}$ excess might be produced as secondaries in high energy collisions. Such production must take place in compact, optically thick sources.

It is assumed that the low energy $\bar{p}$s have lost a few hundred MeV due to modulation by the solar wind. However, while modulation effects may enhance the $\bar{p}$ excess at low energies, they are not nearly strong enough to account for the claimed value (ref. 7 and R. Jokipii, personal communication) (though such considerations could ease the demands on any model of low energy $\bar{p}$ production). In addition to decelerating cosmic rays,

---

Present address: Department of Nuclear Physics, Weizmann Institute of Science, Rehovot, Israel.

0028–0836/82/050391—03$01.00

solar modulation lowers their spatial density so that the low energy p̄ flux is significantly greater outside the heliosphere than in the Earth's vicinity.

Kiraly *et al.*[7] have shown, using Liouville's theorem, that the inferred p̄ flux beyond the heliosphere depends very weakly on the assumptions made about modulation. To infer the interstellar number density, N_{Buf}, implied by Buffington *et al.* I assume that the p̄/p ratio they report ($R_{\mathrm{Buf}} = 2.2 \times 10^{-4}$ at ~ 200 MeV) is reached at 600 MeV ($p = 1.2\, m_{\mathrm{p}}c$) beyond the heliosphere, and that the integral interstellar momentum spectrum of primaries goes as $p^{-1.7}$. The p̄/p ratio R_{Gol} reported by Golden *et al.* at 7 GeV ($p \approx 8m_{\mathrm{p}}c$) is 5.2×10^{-4}. Hence, N_{Buf} is given by

$$N_{\mathrm{Buf}} \simeq \left(\frac{8}{1.2}\right)^{1.7} \left(\frac{R_{\mathrm{Buf}}}{R_{\mathrm{Gol}}}\right) N_{\mathrm{Gol}} \simeq 10\, N_{\mathrm{Gol}} \tag{1}$$

N_{Gol} exceeds the p̄ number density N_{s} predicted by the standard leaky box model of galactic cosmic rays[2-4] by a factor of 3 or so, hence N_{Buf} exceeds that prediction by about one and a half orders of magnitude.

If the p̄ excess is real, and if the p̄s are secondaries, they are apparently decelerated outside the heliosphere from their production energy ($\gtrsim 3$ GeV) down to 600 MeV or so. Scenarios for decelerating secondary p̄s can be broken down into two categories: (1) the p̄s are produced at large cosmological redshift, and are decelerated by the expansion of the Universe; (2) the p̄s are produced and decelerated within the Galaxy. Such scenarios have difficulties with overproduction of secondary products which leads to a model in which the p̄s are produced in dense, optically thick environments—perhaps the galactic centre.

If the p̄s were produced at high redshift, their present cosmic energy density (which would then equal that inside our Galaxy) implied by Buffington *et al.* would be $\sim 10^{-4}$ eV cm^{-3}. As the $\bar{\mathrm{p}}/\nu$ ratio in high energy collisions is $< 10^{-2}$, the implied energy density in high energy νs would exceed 10^{-2} eV cm^{-3}. (The low γ-ray background immediately constrains the p̄s to be produced in dense compact regions where γ rays would be stopped by collisions with other photons.) The Reines experiment[8] limits the cosmic neutrino background at $E > 0.5$ GeV to $< 3 \times 10^{-3}$ eV cm^{-3}, (ref. 9), apparently ruling out the cosmological deceleration scenario.

Stochastic diffusion in momentum space is one possible mechanism[1] for generating low-energy p̄s. However, such a process would cause the cosmic ray spectrum to approach the equipartition differential momentum spectrum $N(p)dp \propto p^2 dp$, which differs vastly from the observed spectrum $N(p) \propto p^{-2.7}$.

We henceforth consider only adiabatic expansion as a deceleration mechanism. Assume that there is some 'new' cosmic ray population that traverses much matter within a compact expanding region. To produce the reported p̄ flux without adding significantly to the observed secondary to primary ratio, (1) the product of the galactic power output P_{N} of the new population and the traversed grammage g_{n} must be at most comparable with that of the 'standard' CR population $P_{\mathrm{s}}g_{\mathrm{s}}$ or (2) the new population must traverse enough grammage near the production site for the secondaries to be thoroughly broken down. 50 g cm^{-2}, roughly 5 destruction pathlengths for L, Be and B, suffices[10]. Note, however, that at grammage larger than 50 g cm^{-2}, the p̄s begin to annihilate before escaping the compact region. Hence this means of avoiding too much secondary production requires 'fine tuning' of the traversed grammage.

A more general constraint is the γ-ray emission from the galaxy above 100 MeV, 8×10^{38} erg s^{-1}. To within a factor of 2, this is what is expected from the standard CR population interacting with 5 g cm^{-2} of matter before escape[11]. It would seem, then, that the total collision rate involving galactic cosmic ray protons and the resulting p̄ production rate cannot be much greater, in optically thin regions, than expected from the standard cosmic population aside from 'factor of 2' uncertainties. If $N_{\mathrm{Buf}} \gg N_{\mathrm{S}}$, this poses difficulties for models that would produce the p̄ excess claimed by Buffington *et al.* in regions from which γ rays escape.

The γ-ray constraint could be circumvented by postulating p̄ production in very young supernova remnants ($T < 10$ yr), for then the associated γ-ray production is sporadic, and could presently be in an 'off' stage. (In any case, in order that primaries produced within the young remnant traverse many g cm^{-2}, it is easy to show that they must do so when the remnant is younger than 10 yr.) This, however, implies that the p̄s suffer enormous adiabatic losses before being deposited in the interstellar medium, and in turn raises the total cosmic ray power and time averaged γ-ray luminosity required to account for the observed p̄ flux by an enormous factor. It can be shown that young supernova remnants in nearby galaxies would then be bright γ-ray sources, contrary to observation.

Another constraint on p̄-production comes from the e$^+$ flux. This constraint is independent of extensive galactic parameters as the p̄/e$^+$ yield depends only on the physics of the high energy collisions. While the results of Buffington *et al.* and Golden *et al.*, given the experimental numbers and other uncertainties, do not necessarily imply too large a p̄/e$^+$ yield in the galaxy, it should be noted that a very large high energy collision rate in the galaxy must be arranged without affecting the observed e$^+$ flux appreciably. (Possibly, the e$^+$s can be disposed of at $E > 1$ GeV by synchrotron radiation in the enhanced magnetic field of a dense environment, if they are produced there.)

In view of the indications that the galactic $\bar{\mathrm{p}}/\gamma$ production ratio (and possibly the p̄/e$^+$ ratio) is higher in our Galaxy than expected from cosmic ray collisions, it is worth considering p̄ production scenarios that yield such high p̄/e$^+$ and $\bar{\mathrm{p}}/\gamma$ ratios. In particular, suppose the anti-protons are produced in dense, compact regions where the radiation density is sufficiently high to block γ-ray escape through photon–photon collisions and to degrade e$^+$s through inverse-Compton reactions at a faster rate than p̄ annihilation. If the p̄s are produced within ejected fluid, they can be adiabatically cooled, and ultimately deposited into the interstellar medium unaccompanied by π^0-decay γ rays or $\pi^{\pm}$-decay e$^+$s.

γ rays at $E_\gamma \simeq 100$ MeV are blocked most effectively by X rays at $10 < E_{\mathrm{x}} < 100$ keV. In any compact source the number density n_{ph} of photons of energy E_{ph} is at least $L/4\pi R^2 c E_{\mathrm{ph}}$, where L is the luminosity in these photons and R is the source radius. The source interior is then opaque to γ rays ($\sigma_{\gamma\gamma} n_{\mathrm{ph}} R > 1$) if

$$(L/L_{\mathrm{ed}})(R_{\mathrm{s}}/R)(\sigma_{\gamma\gamma}/\sigma_{\mathrm{T}})(m_{\mathrm{p}}c^2/E_{\mathrm{ph}}) > 1 \tag{2}$$

Here σ_{T} and $\sigma_{\gamma\gamma}$ are the cross-sections for Thompson scattering and pair production, R_{s} is the Schwarzschild radius, and L_{ed} is the Eddington luminosity defined by $L_{\mathrm{ed}} = 4\pi G M m_{\mathrm{p}} c/\sigma_{\mathrm{T}}$, where M is the mass of the compact object and m_{p} is the proton mass. For $E_\gamma > 100$ MeV, $10 \lesssim E_{\mathrm{ph}} \lesssim 100$ keV, this condition is satisfied by accreting compact X-ray sources by a very large margin. (The X rays need not escape; even if they are eventually blocked and converted into fluid motion, they can still block γ rays close to the compact object.) Indeed, high-energy collisions can be postulated to exist near any compact object where $L/L_{\mathrm{ed}} \gtrsim 1$, independent of its mass, without running into the difficulty of overproducing γ rays. Primary high energy ps can be produced (say, by collisionless shocks) within the accretion or ejection flow near the object, but the particular mechanism for producing them is not crucial to the model.

The column density in Eddington-limited flow onto any compact object is known, by familiar dimensional arguments, to be of the order of 1 g cm^{-2} or more, independent of mass: $L \approx L_{\mathrm{ed}}$, $L \approx \varepsilon \dot{M} c^2$, where $\dot{M}$ is the mass accretion rate, $\varepsilon \lesssim R_{\mathrm{s}}/R$, $\dot{M} \lesssim 4\pi n m_{\mathrm{p}} R^2 \beta c$ where n is the number density of the accreting material and βc is the radial infall velocity, all of which imply that the column density $n m_{\mathrm{p}} R \gtrsim m_{\mathrm{p}}/\beta\sigma_{\mathrm{T}} > 1$ g cm^{-2}. Hence any high energy particles produced in the vicinity of compact objects are likely to have a substantial amount of target matter to interact with.

Finally, if the object ejects matter in the manner of active galactic nuclei or SS433, it can adiabatically decelerate p̄s produced in its vicinity and deposit them into the interstellar medium.

The above scenario also predicts low energy e^+–e^- pairs and photons with $E_{ph} \geqslant 100$ keV from the electromagnetic cascade, and has been proposed[12] to account for the pair production at the galactic centre that is implied by the observed e^+–e^- annihilation radiation[13]. The variable 0.51-MeV line emission from the galactic centre requires $\sim 10^{38}$ erg s^{-1} in pair production if the pairs each have a few MeV in energy, and, according to this scenario, probably requires more than $\sim 10^{39}$ erg s^{-1} in relativistic primary production. Within an optically thick medium, the p̄/p ratio can approach 2×10^{-3}, so a p̄ output of 2×10^{36} erg s^{-1} or more is reasonable for such a source. This compares favourably with the product of the galactic primary output, 3×10^{40} erg s^{-1}, and the p̄/p ratio measured by Buffington *et al.* of $\sim 2 \times 10^{-4}$. A single source of the sort postulated here, or a few of them, could readily account for the galactic p̄ output on energetic grounds. (Note that a necessary condition for producing an e^+–e^- annihilation line is the presence of enough ambient matter so that any e^+s produced within annihilate. It has been suggested[14] that the clouds near the galactic centre are good candidate sites for the annihilation that separates the observed line. Thus, even if the galactic centre, where the ambient density is very high, proves to be a unique source of e^+–e^- annihilation radiation, the phenomenon that produces the e^+s may be a common one. Other hard X-ray sources, for example, remain possible e^+ and p̄ sources through the cascade mechanism even if they display no annihilation line.)

10^{36} erg s^{-1} in high energy neutrinos at a distance of 10 kpc is detectable by DUMAND, so neutrino astronomy might eventually provide independent evidence for such a p̄ scenario.

While the results of Buffington *et al.* may be explainable, they are surprising nonetheless, and independent experimental confirmation is needed. I have also emphasized that the p̄/e^+ and p̄/γ flux ratios are more important than the p̄ flux itself in setting constraints on models of p̄ origin.

I thank Drs T. Gaisser and D. Ellison for useful discussions. This research was supported by NSF grant AST800 2673 and by the Alfred P. Sloan Foundation.

Vortex solitary waves in a rotating, turbulent flow

E. J. Hopfinger

Grenoble, 38041 France

F. K. Browand

Department of Aerospace Engineering, University of Southern
California, Los Angeles, California 90007, USA

Turbulent flow in a rotating container has been widely studied[1–5], but here we consider an experiment in which the axis of rotation is vertical, the tank deep and a vigorous turbulence is produced near the bottom by a horizontal grid oscillating in the vertical direction. The flow within the rotating container can be envisioned to result from: (1) the disorganized, turbulent motion produced by the grid which, in the absence of rotation, would yield a random field with turbulent intensity decreasing upwards (away from the grid) and turbulent length scale increasing upwards[6]; (2) the organizing influence of rotation which, in the absence of turbulence, would generate a (trivial) flow having a single vertical component of vorticity, 2Ω (Ω is the tank rotation rate), uniform throughout the tank. These two competing effects combined produce a flow field which is surprisingly complex. The major feature of the flow consists of a collection of regions of highly concentrated vorticity, or vortices. These vortices extend coherently throughout the depth of the container. Waves having the form of compact, helical distortions propagate along the vortex cores. We show that the waves are well described by the vortex soliton theory of Hasimoto[7].

The Rossby number, $Ro = u/2\Omega l$, measures the local importance of inertia to rotation in the flow field. Both u, the turbulent velocity, and l, the turbulent length scale, can be assumed constant in planes perpendicular to the axis of rotation but, of course, vary with depth. The Rossby number at the grid location is fixed by the motion of the grid itself, and is given by $Ro_g = n/2\Omega$, where n is the grid oscillation frequency. In our

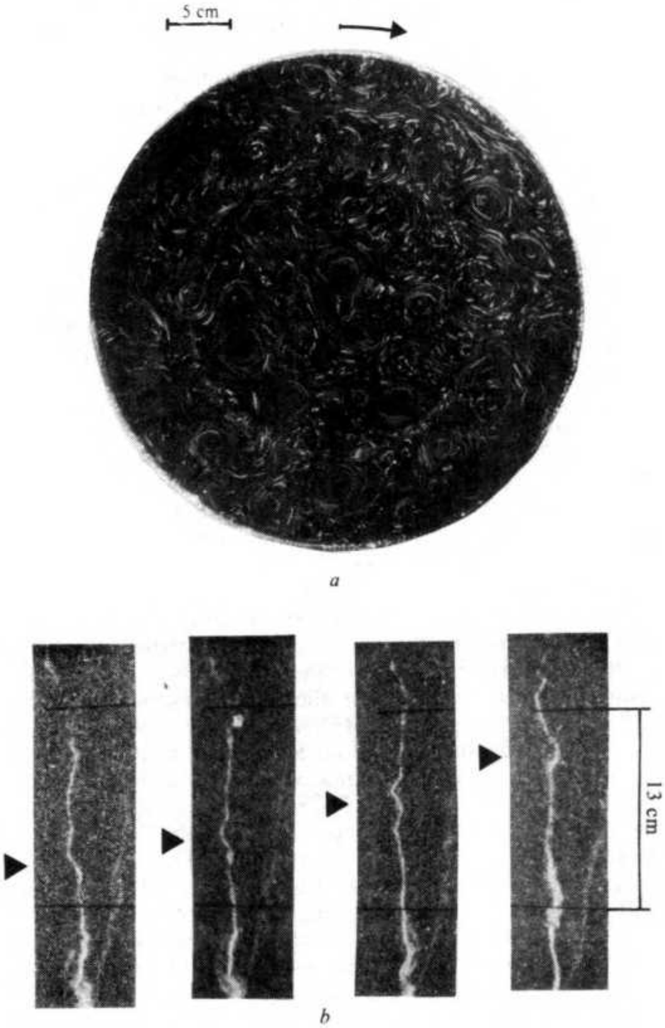

Fig. 1 *a*, Streak photograph illustrating flow in a horizontal plane, $Ro_g = 3.32$. Exposure time is 0.25 s. *b*, Vertical plane visualization of a typical vortex core, utilizing small gas bubbles for illumination. A travelling vortex core wave is marked by arrows.

experiment Ro_g is large, 0(3–30), and the turbulent flow near the grid is relatively unaffected by rotation. Away from the grid the influence of rotation becomes more important, and at some well defined height the flow changes character completely. A collection of concentrated vortices fill the remainder of the tank depth. These vortices are seen in Fig. 1*a* for a grid Rossby number of 3.32. Here the flow in horizontal planes is visualized by passing a light sheet through the tank and observing the trajectories of small wood particles. The local Rossby number associated with the transition height (and with the vortices above) has a constant value of about 0.20 for the range of grid Rossby numbers investigated. Above the transition, there is almost no additional vertical variation of average turbulence quantities.

For a better visualization of these regions of concentrated vorticity, a vertical light sheet is utilized. Small gas bubbles introduced at the bottom of the tank collect in the core regions to provide the ilumination seen in Fig. 1*b*. (The bubbles themselves do not affect the flow significantly, as the same motions are observed when bubble densities are very low.) Only a fraction of the tank depth is shown, but the vortex cores extend to the top of the tank. The lower ends of the cores terminate in the strongly three-dimensional region near the grid. Quantitative estimates show that a typical vortex has a vorticity 40 times the tank vorticity (2Ω), and a core radius $\varepsilon = 0.1$–0.15 cm—a remarkable and unexpected result. A complete description of experimental results can be found in ref. 8. Here we concentrate on one interesting consequence of the presence of these vortex regions—the existence of travelling wave disturbances.

A wave disturbance (marked by arrows) can be seen on the vortex core in Fig. 1*b*. The wave disturbance has the form of a helical distortion of the core. A straight vortex induces no motion on itself, but the wave-distorted core produces a self-induced velocity field which allows propatation of the disturbance. (The propagation of a smoke ring is a simpler example of self-induced motion. The induced velocity field is analogous to the magnetic field which would be produced were the vortex a current-carrying conductor.) The possibility of such vortex core motions was discussed in general by Batchelor[9] and by Hasimoto[7]. Simple dynamical arguments suggest four possible wave types, as outlined in Fig. 2. Waves *a* and *b* are a left-handed kink and anti-kink, respectively, and propagate in a direction opposite to the core vorticity vector. The kink pattern rotates oppositely to the rotation of the core, while the anti-kink rotates in the same sense as core rotation. Waves *c* and *d* are mirror images of *a* and *b*. All these wave types were observed in our experiment.

The waves appear to propagate as single entities and to travel many times their length without appreciable change in shape. This suggests the possibility of a solitary wave (soliton) description for the phenomenon. Hasimoto[7] has demonstrated analytically that solitons can exist on a single, isolated vortex core in an irrotational flow. Wave properties are governed by a non-linear Schroedinger equation for a model which assumes constant circulation and no vortex stretching. The induced motion is calculated as if the vortex filament were a circular ring having the same curvature as the actual filament. For a filament which is straight at infinity, there is a particular solution giving a soliton of constant torsion and varying curvature (torsion is the rate of change of bi-normal direction along the filament).

The assumptions of the theory are not precisely appropriate to the present experiment. There are many cores in the experiment, not just a single core; the outer flow is not irrotational; and there is rotation of the container as a whole. These complications seem to be relatively unimportant, however. Individual vortex cores are often far from neighbouring cores, and the concentration of core vorticity by a factor of 40 above the tank vorticity may qualify them approximately as 'isolated' vortices. Finally, Rossby numbers associated with the wave-induced motions are moderately large, that is, $Ro = \text{(group velocity)}/2\Omega\text{(wave amplitude)} > 1$. Rotation, then, is responsible for the regions of concentrated vorticity, but has little direct effect on the waves themselves.

The wave chosen for detailed comparison is shown sequentially in Fig. 1*b*, travelling upwards with anticlockwise rotation (a left kink). The wave length is ~5 cm, and the total lateral excursion of the core is ~0.6 cm. The corresponding tank rotation rate is 1 revolution per second and the grid oscillation frequency is 6.63 Hz. Two simple comparisons with theory are possible—wave shape and the ratio of propagation speed along the core to the rotation speed of the pattern. The theoretical wave shape predicted by Hasimoto (in suitably non-dimensionalized coordinates) depends on a single parameter,

$$T = \frac{2\text{(Wave torsion)}}{\text{(Maximum wave curvature)}}$$

The quantity used to non-dimensionalize the physical lengths is

$$\nu = \tfrac{1}{2}\text{ (Maximum wave curvature)}$$

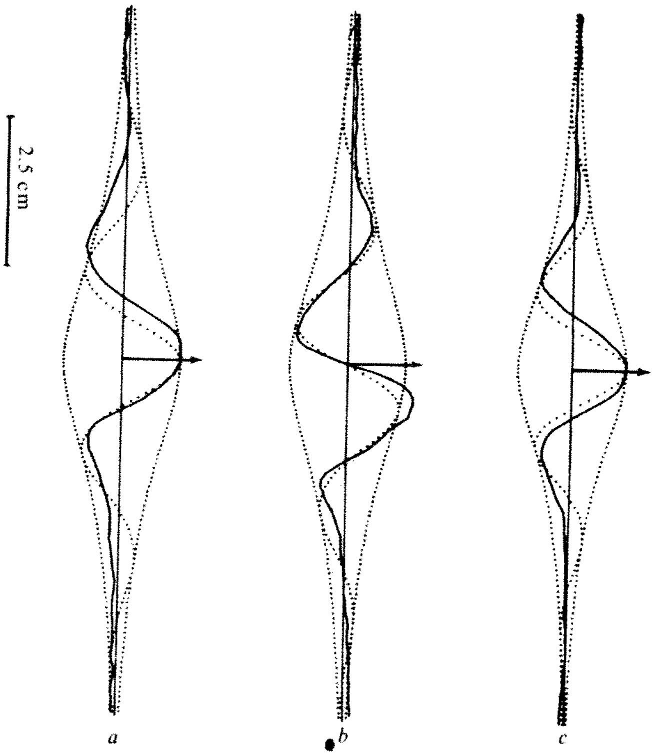

Fig. 3 Comparison of experimental (——) and theoretical (· · ·) soliton wave shapes. *a*, $t = 0$; *b*, t = one-quarter period; *c*, t = one-half period. Lateral scale has been doubled.

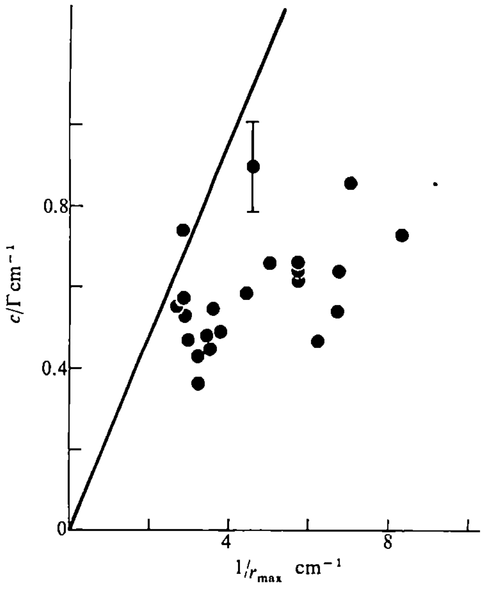

Fig. 4 Observations of group velocity as a function of the inverse of maximum wave radius (taken from film). Solid line is the theoretical upper bound. Error bar indicates relative level of confidence.

In practice, T and ν are chosen to best fit the overall wave shape at three instances of time. The three waves shapes are spaced in time at precisely one-quarter of the pattern revolution, and together represent one-half revolution of the wave. The result of the comparison is shown in Fig. 3. Best overall fit for the three shapes yields the values $T = 3.125$, $\nu = 0.64\,\mathrm{cm}^{-1}$. The wave torsion and maximum curvature are then computed to be, respectively, $2.00\,\mathrm{cm}^{-1}$ and $1.28\,\mathrm{cm}^{-1}$. The theoretical envelope is a hyperbolic secant, and the wave shape is a sinusoidal function within the envelope. Theory predicts additional oscillations at the ends of the wave which are not observed experimentally, and this is the most noticeable discrepancy. However, these oscillations are extremely small—<0.1 cm—and are probably below the resolution of our visual measurements. Overall, the match between experiment and theory is exceedingly good.

The wave envelope travels upwards with group velocity $c = 15.7\,\mathrm{cm\,s}^{-1}$ $\pm 10\%$, and has a rotation rate $\omega = 13.2\,\mathrm{rad\,s}^{-1}$ $\pm 10\%$. Using the observed maximum radius of 0.29 cm, the ratio

$$\frac{\text{Wave envelope speed}}{\text{Maximum rotation speed}} = \frac{c}{\omega r_{max}} \cong 4.05 \pm 0.7$$

The theoretical prediction is

$$\left|\frac{c}{\omega r_{max}}\right| = \left|\frac{T(T^2+1)}{(T^2-1)}\right| = 3.84$$

for $T = 3.125$. Thus, the theoretical estimate agrees with measurement within the accuracy of the measurement. The tentative conclusion is that these isolated waves are indeed solitons and are well described by the theory of Hasimoto.

The theory can be used to draw several additional conclusions in qualitative agreement with experimental observation. The theoretical prediction for the group velocity is

$$c = K\left[\frac{2T}{(T^2+1)}\frac{1}{r_{max}}\right]\Gamma$$

The quantity in parentheses is the wave torsion, here given in terms of T and the maximum wave excursion (or amplitude), r_{max}. Γ is the vortex circulation and K is a constant related to the asymptotic, local-induction approximation. The wave properties just determined, together with an estimated value for the vortex circulation, allow a rough estimate for the constant K. Thus

$$c \cong 0.48 \frac{T}{(T^2+1)}\frac{\Gamma}{r_{max}}$$

The conclusion is that waves of fixed amplitude, on cores of fixed circulation, travel at different speeds depending on wave shape. Furthermore, waves of fixed shape and fixed circulation travel at a speed inversely proportional to wave amplitude. The reason is that the group velocity is proportional to wave torsion (not to wave amplitude); and for fixed shape, a wave of smaller amplitude has the greater torsion. An approximate upper bound on group velocity is obtained by noting that the quantity $T/(1+T^2)$ has a maximum value equal to 1/2 at the value $T = 1$. This value gives

$$c \leqslant 0.24 \frac{\Gamma}{r_{max}}$$

for waves on a core of circulation Γ, and having a maximum radial excursion r_{max}. All group velocity measurements should lie below this estimate. Group velocities taken from films are shown in Fig. 4, divided by the estimated value of vortex circulation, $\Gamma = 32.7\,\mathrm{cm}^2\,\mathrm{s}^{-1}$, and plotted against the inverse of the observed maximum wave radius. There is an indication that smaller waves travel faster, but the data are far from conclusive. The upper bound estimate is reasonable for the larger waves, but much too high for waves of smaller amplitude. Possibly other effects limit the propagation velocities of the smallest waves. Note also the relatively small range of wave amplitudes observed. In terms of estimates of the core radius, the largest waves have $r_{max} = (3\text{–}4)\varepsilon$ and the smallest waves $r_{max} \cong \varepsilon$.

Our rotating turbulent flow thus consists of a three-dimensional turbulent region near the forcing grid, and a quasi two-dimensional field of strong vortices farther away. Non-linear solitary waves provide the connecting link, and carry energy upwards from the strongly turbulent region. However, waves are also produced along the entire length of the vortex core. This local wave production may provide the vertical stretching and the concomitant horizontal flow convergence necessary to maintain the regions of high vorticity.

Concentrated vortices occur in external flows over wing surfaces and internally in rotating machinery and combustors. Solitary waves are present in these flows and can be seen, for example, during the break-up of wing tip vortices in the wakes of high flying aircraft. The most highly concentrated vortex found in nature is the tornado. Pulsations in core size, rapid vertical motions within the core region and various travelling (wave-like) core deformations have been observed over many years (see refs 10,11). It is plausible that some of these effects are manifestations of vortex core solitons. Solitary waves may indeed be a ubiquitous feature of most turbulent flows which contain concentrated vorticity. The contribution these waves make to turbulent vortex dynamics in complex flows would be a fascinating topic for future study.

We thank Professeur Uriel Frisch and P.-L. Sulem for bringing the paper by Hasimoto to our attention, Yves Gagne for helpful discussions and Serge Layat for experimental assistance. A suspended sediment front in the Severn Estuary

R. Kirby & W. R. Parker

Institute of Oceanographic Sciences, Crossway, Taunton,
Somerset TA1 2DW, UK

A zone of marked local gradient in the regional suspended solids field has been located along the axis of the Severn Estuary. This front occupies virtually the same position on ebb and flood and on spring and neap tides, although the amplitude of the gradient fluctuates. Thermohaline fronts have been described in coastal waters[1,2] suspended sediment fronts associated with the discharge of major rivers into the sea are common[3–5] whilst fronts caused by convergence of secondary circulations within estuaries have also been reported[6,7]. The previous work describes features with significant differences in the salinity or temperature fields in which any suspended sediment contrasts present are incidental and do not, of themselves, produce large horizontal density variations. In contrast, in the Severn, strong thermohaline gradients in the vicinity of the suspended solids front have not been detected. The mechanisms for the formation and maintenance of the front are not yet known.

The Severn Estuary (Fig. 1) has a large and variable tidal range (12.3 m mean spring range and 6.5 m mean neap range at Avonmouth). It is well mixed with regard to salinity and temperature[8] but commonly stratified with respect to suspended solids concentration[9]. The suspended load over the greater part of the water column ranges between 0.25 and $>10\ \mathrm{g\,l^{-1}}$ and its vertical distribution is controlled by the semi-diurnal and spring–neap tidal energy cycles. At maximum flow on spring tides the suspended load is mixed throughout the water column, whereas near slack water on springs and throughout the neap tides, considerable stratification is apparent with concentration levels in the lower layers well in excess of $10.0\ \mathrm{g\,l^{-1}}$ (ref. 9).

The structure of the suspended solids field was observed using a free-fall array consisting of two narrow-gap optical turbidity meters, a pressure (depth) sensor and, occasionally, a continuously recording conductivity meter, allowing continuous and rapid ($1\ \mathrm{m\,s^{-1}}$) vertical profiles to be made from drifting or anchored vessels. Laboratory calibrations using indigenous material in the range $0–20\ \mathrm{g\,l^{-1}}$ were later corrected with field samples. Performance curves for the turbidity meters were prepared and they were only used within the ranges where errors were $<10\%$. Over the range of concentration values for which the instruments were calibrated they were known to respond to changes in mass concentration and to be insignificantly affected by changes in the state of aggregation of the solids (T. J. Smith personal communication).

Measurements from anchored vessels have been placed in a regional context during wide ranging surveys of the suspended solids field in the area, resulting in 3,500 vertical profiles from 210 stations based on 17 estuary cross-sections, (standard lines), extending from Watchet to The Shoots (Fig. 1). The regional measurements were made chiefly between 1973 and 1979 on all ranges of tide from spring to neap and during most seasons.

Most of the data have been obtained as time series of cross-sections in which the survey vessel repeatedly traversed a standard line stopping at each station to measure a vertical profile. Between stations the array was towed 2–3 m below the surface and a continuous horizontal traverse was recorded. One complete traverse can be made in approximately 1–1.5 h, in a time series continuing over a 12.5-h semi-diurnal tidal cycle.

The regional surface and bed suspended solids distributions on spring and neap tides was studied by grouping the analogue records into spring (all data >9.0 m range) and neap (all data <9.0 m range) tides. For most stations this resulted in a minimum of 10 profiles but the limited accessibility of shallow areas resulted in a poor coverage. The surface and bed concentration values for these groups were averaged. The regional spring surface and spring bed distributions (Fig. 2) show the front as a zone of marked gradient (from <0.5 to $>4.0\ \mathrm{g\,l^{-1}}$ at the bed in 2 km or less) approximately along the axis of the estuary between The Shoots and the Holm Islands, and extending across the inner Bristol Channel to the English coast in the region of Watchet, in Bridgwater Bay. The more turbid water mass lies on the English side of the estuary. On neap tides the regional distribution is similar, although the contrast between surface and bed concentration values is greater.

For more detailed analyses, data from each cross-section have been grouped into spring ebb and flood and neap ebb and flood conditions and the average concentration calculated for each

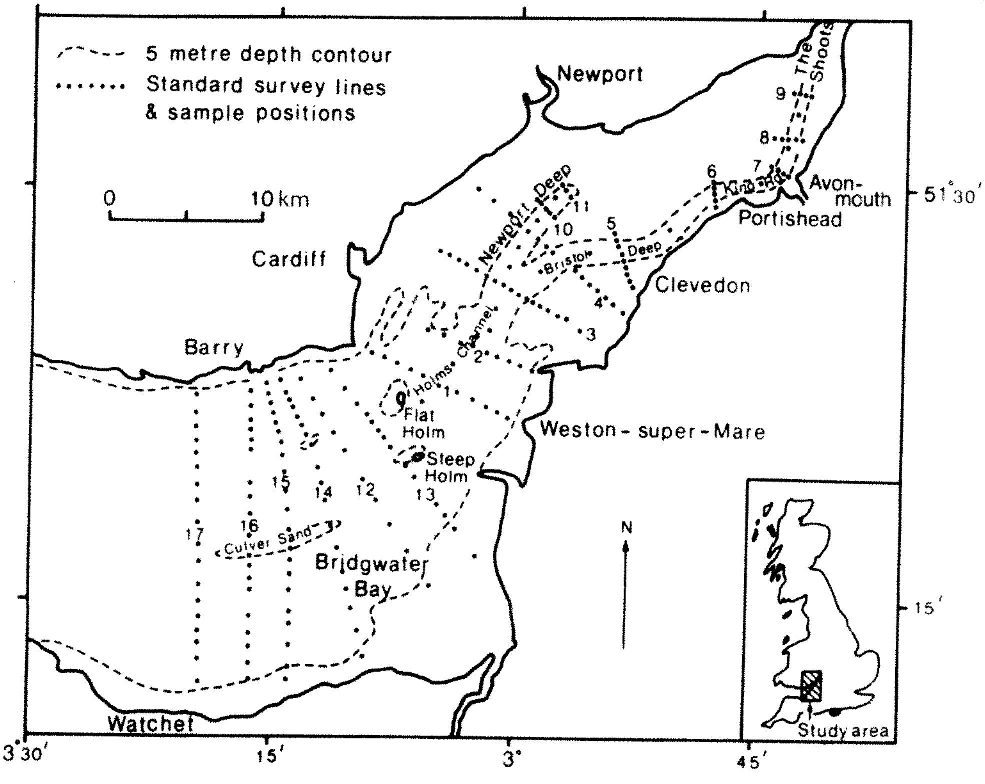

Fig. 1 Location of standard stations used in surveys of suspended solids distribution.

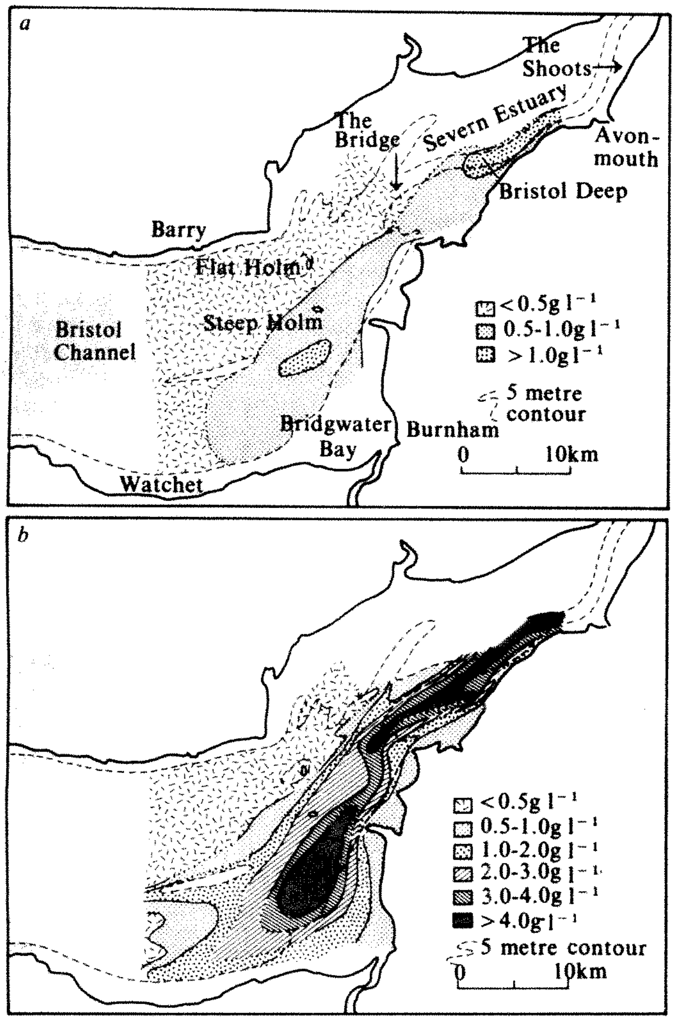

Fig. 2 Plan distributions of spring surface average (*a*) and spring bed average (*b*) suspended solids concentration based on vertical profile data.

tenth percentile of the depth at every station on the cross-section. Plots of average concentration for each sub-group of data in every cross-section were arranged in sequence along the estuary to show the mean position and structure of the front in three dimensions. These plots show that the front is more prominent on spring than on neap tides and on ebb rather than flood tides. An average of all spring ebb data, Fig. 3, shows steeply inclined concentration contours across the gradient zone in the region between The Bridge and a line joining Barry and Burnham. Upstream from The Bridge, in the Bristol Deep, the front is duplicated by a similar, but smaller front on the Welsh side, whilst downstream from the Barry to Burnham line the concentration contours assume a more horizontal attitude.

Figure 3 illustrates the location and nature of the front in the study area but obscures the sequence of development and stability on a semi-diurnal time scale. In Fig. 4, the time series of cross-section plots represents individual traverses along standard line 1 during a spring tidal cycle of ~12.0 m range. The apparent slopes of the water surface are due to the rise and fall of the tide during the period taken by the vessel to steam along the line and have no dynamic significance. Figure 4 shows the effects of mixing of the sediment into the water column during accelerating phases of the tide and settling towards the sea bed on decelerating phases. Although well displayed at times when the tide is running in either direction, settling causes the front to be less evident at the surface and enhanced near the bed at slack water. However, the approximate position of the front remains constant on this time scale, although the concentration differences across it vary. Virtually the same sequence of changes was observed during time series at other ranges of tide at line 1 and also at the other standard lines.

Despite the averaging processes the position of the front remains well defined throughout spring tides (Figs 2, 3), most markedly at the bed during neap tides and during most of the semi-diurnal cycle (Fig. 4). These plan distributions and cross-sections suggest that, although the front is a marked feature on a regional scale, the gradient extends over 2 or more kilometres. In fact, from upstream of The Shoots to the Holm Islands the front can occasionally be seen at the sea surface in calm weather as a sharp interface separating 'blue' and 'brown' water. Continuous horizontal traverses made near the surface show that the front may be as little as 2-m wide at the upper end of the estuary (Fig. 5).

Unpublished data from IOS horizontal suspended solids traverses suggests that the front is not a passive feature associated with some controlling salinity and temperature structure

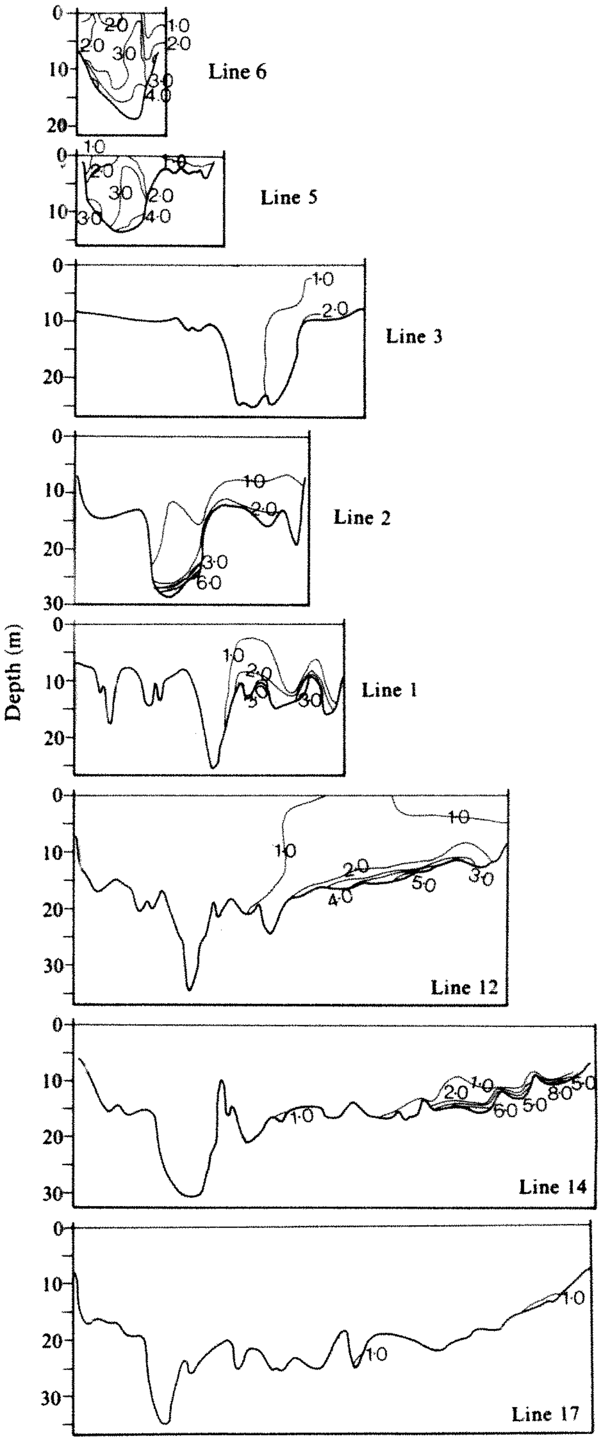

Fig. 3 Spring ebb average suspended solids distributions for cross-sections of the Severn Estuary and Inner Bristol Channel between Avonmouth and Watchet, concentration in g l^{-1}.

in the estuary. Published data show only low longitudinal and vertical salinity gradients. Strong lateral salinity gradients are confined to the coastal margins, even on neap tides, and no marked lateral gradients have been detected along the channel axis[8]. Neither is the phenomenon a plume-type front associated with the sediment discharge of a large river, since the estuarine suspended sediment concentrations are higher than in the inflowing rivers. Recent work (T. J. Smith, personal communication) has shown that the front is not associated with horizontal variations in vertical mixing rates and hence not analogous to the thermal or saline fronts frequently observed in British coastal waters[10].

The front may be due to an interaction between the regional and local topography, Coriolis effects and lateral phase differences in tidal elevation across the estuary, which set up secondary water circulation cells in the plane of the cross-section, leading to convergence along the main channel axis. Velocity measurements over several tidal cycles made from an anchored vessel in the Holms Channel may be interpreted in support of this secondary circulation hypothesis. The vertical distribution of the lateral component of tidal mean velocity obtained from these measurements indicates a north-west going residual at the bed and a south-east going residual at the surface, in agreement with earlier data[11], placing the survey vessel on the Welsh side of a convergence. Such a circulation, combined with the non-conservative nature of the suspended sediment, the highly rectilinear tidal current regime and the fact that the dominant fine sediment source area, Bridgwater Bay, lies on the south side of the estuary may be the main factors which maintain the high concentrations along the English side of the estuary.

We conclude that, whilst the Severn estuary is generally well mixed with regard to salt, it shows marked lateral partitioning of suspended sediment with a stably positioned front forming the junction between the two water masses. This lateral disposition of suspended sediment compliments the vertical stratification already reported in this estuary[9]. Evidently, whilst salt does get well mixed across the estuary the fine sediment does not, indicating that it is unwise to treat the dispersion of fine sediment in the same way as that of salt.

The residual water circulation in the estuary cannot be driven entirely by the saline density field because comparison of the

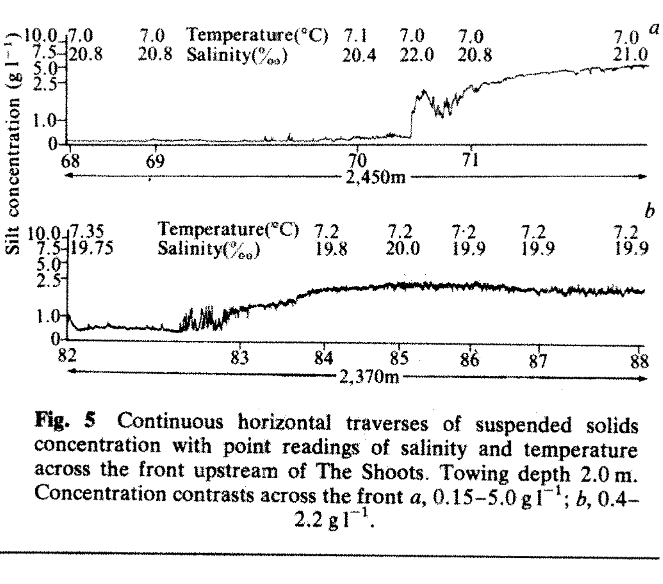

Fig. 5 Continuous horizontal traverses of suspended solids concentration with point readings of salinity and temperature across the front upstream of The Shoots. Towing depth 2.0 m. Concentration contrasts across the front *a*, 0.15–5.0 g l^{-1}; *b*, 0.4–2.2 g l^{-1}.

lateral and longitudinal density fields due to depth average salinity and depth average salinity plus suspended solids, shows that density differences due to suspended solids are at least equal to those due to salt[12]. This comparison was achieved by calculating and comparing the depth mean density of the water column at individual stations across the estuary and along the estuary from Avonmouth to 3°30′ W. Density differences computed using the actual suspended solids vertical profiles, as opposed to depth average values, show the suspended sediment density field to dominate.

As the suspended sediment load is strongly laterally partitioned and vertically stratified, sediment erosion and transport models should take account of the fact that any sediment entrained cannot be assumed to mix completely in lateral and vertical directions since the discontinuities represent a barrier to dispersion. Similarly, the presence of persistent lateral and vertical discontinuities within the suspended sediment concentration field also has an influence on the dispersion of those pollutants which travel with the sediment.

We thank Dr T. J. Smith for advice and encouragement.

Successive palaeomagnetic reversal records from Kauai

Scott W. Bogue & Robert S. Coe

Earth Sciences Board, University of California, Santa Cruz,
California 95064, USA

Geomagnetic field reversal is a rapid phenomenon[1,2], perhaps taking only a few thousand years. Knowledge of how the field behaves during these brief and active periods may eventually help to constrain theories of the geodynamo and thus inform us about conditions in the Earth's core. Unfortunately, reliable and detailed palaeomagnetic records of transitional field behaviour are few, almost entirely from Northern Hemisphere sites, and heavily biased toward reversals of the reverse–normal (R–N) sense. We report here new data from basalts on the island of Kauai, Hawaii, which have recorded successive R–N and N–R field reversals. The sequences of changing field directions for the two reversals are very similar, as would be expected if a standing nondipole component controlled the transitional field. The data are also consistent with zonal flooding models in which the reversal process depends on the sign of the field. Other reversal records, however, cannot be explained by these same models unless the standing field or flooding process changes between some reversals.

Two simple models of the reversing field have been proposed in the past 5 years[3,4]. The two involve conceptually different source mechanisms and, in their purest forms, make distinct predictions of transitional field behaviour. Although it is possible that no single process controls transitional fields, we will treat these two models as alternative explanations of palaeomagnetic records of field reversals.

Hoffman's model[3,5] of the reversing field is based on the notion that the reversal process 'floods' through the fluid core from a localized zone or point of initiation. The entire dipole source remains active, but normal and reverse flux is produced simultaneously in different regions. The resulting transitional field depends on how the reversal process propagates through the dipole source. If the reversal initiates at either of the poles or the equatorial zone of the core, essentially axial quadrupolar or octupolar fields, respectively, will predominate during the middle stages of the reversal process. In these purely axisymmetric cases, reversal of the field vector at the Earth's surface occurs by rotation in the north–south vertical plane; the equivalent virtual geomagnetic pole (VGP) moves along the great cricle defined by the geographical poles and the observer's site. Depending on the sense of the reversal, where in the core source region the reversal process initiates, and the hemisphere of the observer, the VGP path for the reversal will be 'near sided' (same longitude as the site) or 'far sided' (180° away)[6].

In contrast to the model of Hoffman, which we will refer to as the flooding model to emphasize its active character, is the standing field model[4]. The latter is a special case of the long held idea[7] that, during reversals, the main dipole field diminishes greatly while at least parts of the nondipole field do not. In particular, the standing field model requires a stationary component of the nondipole field to persist unchanged through dipole reversals. Palaeomagnetic evidence suggests that the dominant part of the nondipole field changes sign with the dipole field[8,9]. Thus, the postulated standing field would have to be in some sense independent of both the dipole and the rest of the nondipole fields.

In the standing field model, the transitional field at any site is the sum of a steady nondipole component plus an axial dipole component that changes only in magnitude and sign. As with simple cases of the flooding model, the equivalent VGP paths are longitudinal great circles. There is, however, no site dependence of path longitude unless the standing nondipole field direction everywhere lies in the north–south vertical plane.

Hoffman[10] has recently proposed a test to distinguish between the flooding and standing field models. The former model predicts that, as long as a reversal is initiated at the same zone in the core each time, successive reversals will be characterized by transitional VGP paths that differ in longitude by 180°. The latter predicts identical VGP paths for successive reversals. Records of back-to-back reversals thus directly test the two models.

On the island of Kauai, Hawaii (22° N), we have collected samples through R–N and N–R transition zones. The thin, shield-building basalt flows of the Napali Formation (Fig. 1), which record the R–N reversal, have yielded K–Ar ages ranging from 4.5 to 5.6 Myr (ref. 11). The thicker, caldera-filling flows of the Olokele Formation (Fig. 1) have not been dated, but can be shown on geological grounds[12] to be synchronous with the upper portion of the Napali sequence. The transition zones in the Napali and Olokele Formations, however, are at nearly the same elevation. In addition, extensive reconnaissance with a portable fluxgate magnetometer has shown that all Napali flows exposed above the R–N horizon and all Olokele flows below the N–R horizon are normally magnetized. It is thus very likely that the two transition zones record a back-to-back, R–N–R reversal pair from the early Pliocene.

Equal-area plots of the flow-averaged palaeomagnetic directions from the two transition zones are shown in Fig. 2. Seven samples per flow were collected, and alternating fields of 100–200 Oe reduced substantially any secondary components of magnetization that were present. We sampled the R–N transition at three widely separated localities (Fig. 1), and the sequence shown in Fig. 2*a* is based on the simplest correlation of directions from the three sections. We sampled only a single section of the N–R transition because of the thick, horizontal character of the caldera basalts.

Neither transition zone displays an abundance of intermediate field directions. This lack of detail may be interpreted as the result of ill-timed lulls in volcanic activity both times the field was reversing. An alternative hypothesis is that the duration of

0028–0836/82/050399—03$01.00

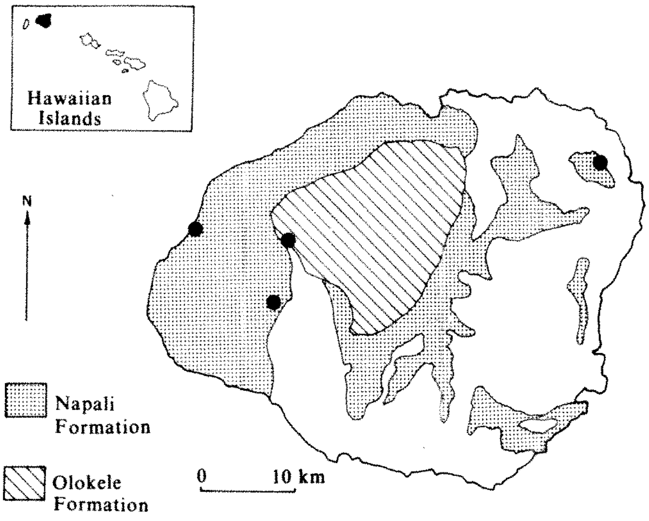

Fig. 1 Map showing outcrop extent of Napali and Olokele Formations on Kauai. Dots indicate locations of palaeomagnetic sampling sites.

intermediate field directions was very short. Our observation that contacts between flows were almost never marked by weathered zones or soil horizons supports the latter idea. In addition, the palaeomagnetic results show clearly that the three sections across the Napali reversal horizon are not identical, and thus that lavas on the flanks of the ancient Kauai volcano were of rather local extent. This pattern is entirely consistent with the modern eruptive style on the big island of Hawaii. Including the Olokele site, therefore, there are a total of four widely separated and essentially independent transitional sections that show this paucity of distinct intermediate directions. These two lines of evidence are mutually consistent, and we tentatively infer that the major change in direction occurred extremely rapidly during both reversals.

In spite of the lack of detail, and regardless of its cause, the pattern of change in field directions is clear for both transitions and is sufficient to apply Hoffman's[10] test. In the R–N transition, the field direction remains southerly while shallowing to nearly horizontal. A single layer with normal polarity occurs among these lower flows. We have examined the anomalous unit and are convinced that it is a flow and not a sill; examples of the latter are easily recognized on Kauai by their distinctive jointing and much greater resistance to weathering. Thus the ancient field apparently underwent a rapid 'flip' in direction during the transition much like those observed in several other detailed records[13–15]. The shallow southerly directions are followed by a steeply downward directed field vector which subsequently shallows to the expected normal field direction. In the N–R reversal, the same sequence is seen except in reverse; a steep northerly field direction precedes shallow southerly directions. Thus, both reversals are characterized by transitional directions that lie near the north–south vertical plane or, equivalently, by VGP paths that pass near the site.

At first glance, this site dependence is most naturally explained by the zonal flooding model. An awkward complication arises, however, because the R–N and N–R paths are so nearly identical. Their similarity requires the presumed flooding processes for the two reversals to have initiated in opposite regions of the core[6]. More specifically, if the transitional field was predominantly octupolar, as is consistent with the very low field intensities that have been inferred from other transition zones[16–18], then flooding for the R–N reversal would have begun at the equator. For the N–R reversal, one is forced to conclude that the reversal somehow initiated simultaneously at both poles. Similarly, quadrupolar transitional fields require initiation at the south pole for R–N reversals and at the north pole for N–R reversals.

If generally true, systematic behaviour such as just described would mean that the postulated flooding mechanism, and hence the reversal process, depends on the sign of the field. Global palaeomagnetic data suggest that statistically significant and long-term differences do exist between the morphology and stability of normal and reversed geomagnetic fields[19], and thus that asymmetry in the reversal process might be allowed. Such asymmetry, however, is intuitively unappealing and cannot arise directly from the basic dynamo equations[6,19].

Theoretical considerations aside, it is important to ask whether the regularities predicted by the flooding models are discernible in the rest of the palaeomagnetic record. Near-sided VGP paths seem to predominate in the R–N reversal records presently available from Northern Hemisphere sites[3,20]. This characteristic is evident in the R–N reversal from Kauai, supporting the general observation. A pattern in the N–R records, on the other hand, is not yet apparent. Several N–R transition zones from Iceland have been reported[21–23]; shallow directions with easterly or westerly declinations are common, so that VGP paths are not strongly near or far sided. Shallow westerly directions are also found in a detailed N–R transition in volcanic rocks of the Shigarami Formation, Japan[24]. Overall, however, this record shows the field tending towards far-sided behaviour. Two N–R records from California[25,26], which we will discuss in more detail with respect to the standing field model, are characterized by intermediate directions which are shallow and easterly. The equivalent VGP paths are slightly near sided. A pair of VGP paths from Russian sites[27,28], the only N–R data considered in detail in a recent review, are not longitudinally confined, but are generally far sided.

More convincing evidence of far-sided N–R behaviour has been found in back-to-back transition zones of Miocene age from Crete[29]. The VGP path for the N–R reversal follows a longitudinal path almost exactly 180° from the site. This record and that from the Olokele Formation on Kauai represent our best examples of site-dependent N–R paths, yet the former is far sided and the latter near sided. Thus, the N–R data as a whole display no coherent trend and, moreover, the two most clearcut records conflict directly. This evidence suggests that, at least for the N–R transitions, the flooding mechanism varies considerably from one reversal to the next.

The similarity of the N–R and R–N reversal records from Kauai is easily explained by the standing field model. Reversals in the early Pliocene were quite frequent[30], and the Kauai data require a standing field that persisted for only a few hundred thousand years. Results from two California localities suggest that a standing field may persist for a much longer period.

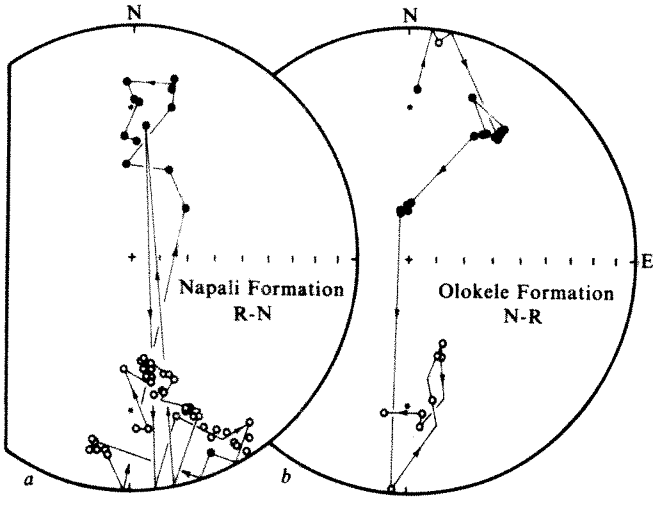

Fig. 2 *a*, Equal-area plot of flow-averaged directions from the R–N transition zone. Results from three sites in the Napali Formation are combined. ● (○) indicate downward (upward) directed magnetization vectors. Connecting lines and arrows show the stratigraphic order from oldest to youngest flows. Centre of plot marked by a plus sign, and ticks indicate 10° intervals. The axial dipole direction (asterisk) is shown for comparison. *b*, Directions from the N–R transition zone in the Olokele Formation.

Volcanic rocks from Clear Lake, California[25], record intermediate directions from two N–R reversals that occurred several hundred thousand years before the Matuyama–Brunhes transition. The VGP's equivalent to these directions fall right on the Matuyama–Brunhes R–N transition path that Hillhouse and Cox[4] found at Lake Tecopa, also in California. Even more remarkable is a detailed record of the Gauss–Matuyama transition in dry lake sediments from Searles Valley, California[26]. This reversal, 1.6 Myr earlier still and N–R, also repeats the Lake Tecopa path. Note that these three VGP paths are not strongly near or far sided, the VGPs passing almost 90° to the east of the site. Such grossly nonaxisymmetric field behaviour, nearly identical for reversals of both senses, can arise only in very special cases of the generalized flooding model[5]. Thus, the California results more strongly support the standing field model than do the Kauai data. More significantly, the ages of the three sites in California imply that the standing field, if that is what controlled the transitional fields, remained unchanged for several millions of years.

The back-to-back reversal records from Crete[29] again provide conflicting evidence. The VGP paths from these two reversals differ from one another by 135°. Marine sediments such as those now exposed on Crete may not record changing field directions as faithfully as rapidly deposited lake sediments or volcanic rocks. Nevertheless, it is difficult to dismiss the general features of these reversal records, especially the significant longitudinal separation of the VGP paths. Unless the standing field can occasionally change between reversals or be masked by other effects (flooding processes?), the results from Crete cannot be reconciled with the standing field model.

An additional problem is that the concept of standing fields has no clear independent basis. Yukutake and Tachinaka[31] mathematically divided the historic nondipole field into standing and drifting parts. The analysis provided a better description of secular variation, but the separation of the field into two parts is arbitrary; it allows but is not strong evidence for an actual standing field. Moreover, analysis of historical field behaviour is not sufficient to demonstrate that a field component can last for millions of years as required by the model; such evidence must come from palaeomagnetism. The 'standing fields' that emerge from analyses of global palaeomagnetic data[19] are by definition statistical; that is, they represent long-term properties of the time-averaged geomagnetic field. Standing fields of the sort needed for the reversal model are again allowed, but in no way proven, by analysis of the time-averaged field. In short, no standing nondipole field capable of controlling transitional fields has been observed, palaeomagnetically or otherwise, except by inference in some of the transition zone data.

In conclusion, the similarity of VGP paths in back-to-back reversal records from Kauai and in several records from California favours the standing field model, according to the test proposed by Hoffman[10]. Conversely, the large latitudinal separation of VGP paths in back-to-back reversal records from Crete and the predominance of near-sided VGP paths in the available R–N records from the Northern Hemisphere favour the zonal flooding model. However, unless the standing field or flooding process can change, at least occasionally, from reversal to reversal, neither model can explain all of the available transition data. It may thus be too simple to assume that a single type of transitional field is always present during reversals. Furthermore, palaeointensity data we are currently analysing for the Kauai R–N reversal suggests that more complex versions of these mechanisms may be required to model even a single reversal. These results will be discussed elsewhere.

We thank C. S. Grommé, J. C. Liddicoat and R. T. Merrill for helpful comments. This work was supported by NSF grant EAR78-12951.

Rapid growth of a deep-sea manganese nodule

J. L. Reyss*, V. Marchig† & T. L. Ku‡

‡ University of Southern California, Los Angeles, California 90007, USA

Recent studies on marine ferromanganese nodules have suggested a relationship between their growth rate and their chemical composition[1–3]. The suggestion is based on the hypothesis that the metals in nodules have two sources of supply: bottom seawater (hydrogenous) and sediment pore water (diagenetic)[4–7]. The diagenetic source calls for upward diffusion of Mn mobilized in a deeper, low *Eh* zone of the sediment column and its subsequent precipitation in an oxidized surface zone[8]. Addition of the remobilized Mn to surface nodules would augment their accretion rate. It would also render the oxide layers to contain higher Mn/Fe ratios than layers resulting from hydrogenous precipitation. We report here a radiometrically determined accretion rate of 168 ± 24 mm Myr^{-1} for a deep-sea manganese nodule from the Peru Basin in the Pacific. This rate is about two orders of magnitude higher than that frequently found in nodules of deep-sea origin, and emphasizes the importance of sediment diagenetic processes on the growth of manganese concretions.

When compared with their open-ocean counterparts, manganese deposits from shallow-water, continental margin environments commonly show growth rates that are three or more orders of magnitude faster ($1\text{–}10^3$ mm kyr^{-1} compared with 1–10 mm Myr^{-1}), and Mn/Fe ratios that are generally higher, although with large variations (0.5–50 compared with $\simeq 1$) (refs 5–9). Aside from the distance involved in the continental runoff supply of metals, such contrasts have generally been held to reflect the preponderance of the aforementioned one source of Mn over the other. That is, nearshore nodules are principally of diagenetic origin whereas pelagic nodules are hydrogenous[5,10–12]. However, we intend to assert here that the above is not meant to be a dichotomy between nodule growth in shallow marine and in deep abyssal sedimentation regimes. Although the *Eh*-controlled diagenetic reactions should depend geographically on surface productivity and sedimentation rate, nodules of deep-ocean occurrence may

0028–0836/82/050401—03$01.00

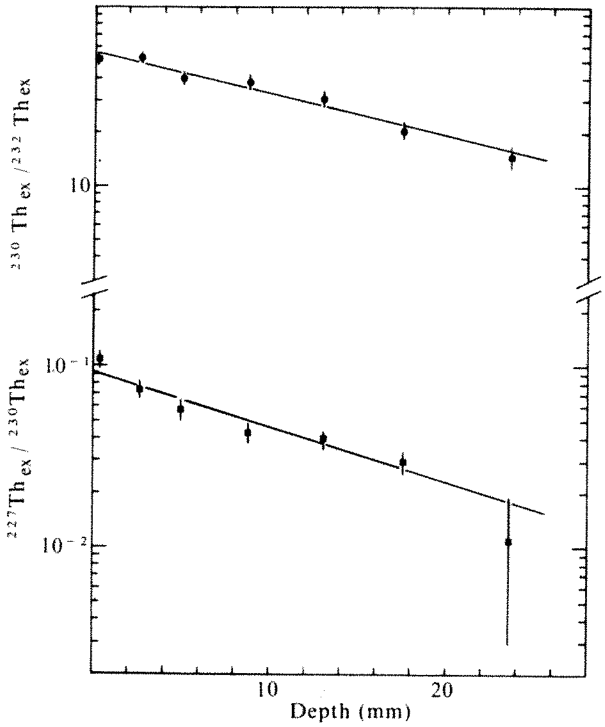

Fig. 1 Plots of ^{230}Th/^{232}Th and ^{227}Th (as ^{231}Pa)/^{230}Th activity ratios as a function of depth in nodule 278 DK. The mean accretion rates (●, $V = 173 \pm 25$ mm Myr^{-1}, ■, $V = 162 \pm 40$ mm Myr^{-1}) shown are determined from the weighted least-square fits (solid lines). Half lives used are 75,200 yr and 34,300 yr for ^{230}Th and ^{231}Pa, respectively.

themselves exhibit, as manifestations of regional variations in diagenetic influence, a range of Mn/Fe and accretion rate values.

As Halbach and his co-workers pointed out [7,13], there is a south-to-north increasing trend in the Mn/Fe ratio of nodules in the Peru Basin, south-east Pacific (the 'Sonne Basin') suggestive of a rising influence of diagenetic supply of Mn towards the north, which lies near the equatorial region of high surface biological productivity. Halbach *et al.*[7] estimated that nodules in this northern region grow at a rate of >60 mm Myr^{-1}, as opposed to rates of a few mm Myr^{-1} in the south. However, these estimates are very uncertain as they are based on extrapolation of the crude relationship between Mn/Fe and growth rate obtained by Heye and Marchig[2].

We have determined the accretion rate of a nodule from the northern part of the basin using U and Th series isotopes. The specimen (sample 278 DK) is a large, spheroidal nodule ~15 cm in diameter. It was retrieved from 4,240 m water depth at 7°40.0′ S and 91°59.5′ W during cruise SO 11/1 of the german RV Sonne. Its high Mn/Fe ratio ≈60 (Table 1) and its botryoidal, highly-mammillated constitution conform with the Halbach[13,14] Ac type nodule, the formation of which they describe as being largely influenced by sediment diagenesis near the sea floor. Each mammillae consists of alternate compact and porous laminations ranging in thickness from 1 to 7 mm.

We have measured U and Th series isotopes in nine oxide layers from surface to 25.5 mm inward, and in sediments attached to the nodule surface. After total acid dissolution of the samples, we measured ^{238}U, ^{234}U, ^{232}Th and ^{230}Th using procedures similar to those of Ku and Broecker[15]. The isotope ^{231}Pa was measured through its granddaughter ^{227}Th, assuming the two are in secular equilibrium. Results are presented in Table 1.

The isotopes found in nodule layers have three possible sources: seawater, pore water and detrital sediment included in the oxides. (No active volcanic activity exists in this part of the ocean floor; thus direct precipitation from hydrothermal solution as a source can be discounted.) From their Al-Si contents (Al <0.8%, Si <3%), the oxide layers seem to include <10% by weight of detrital sediment.

The nodule material contains two to three times more U than the associated sediment, indicating that most of their U isotopes come from seawater and/or pore water. Data on the ^{234}U/^{238}U ratio (Table 1) are consistent with this assessment. This ratio in seawater, pore water and deep-sea sediment has been reported as, respectively, 1.14, 1.17–1.23, and <1.00 (refs 16–19). For the other isotopes: ^{232}Th, ^{230}Th, and ^{231}Pa (^{227}Th), all three sources may have contributed to their presence in the oxide layers. Unlike U, evidence for the possible contribution of the Th isotopes from detrital sediment source includes that ^{232}Th in the sediment is about an order of magnitude higher than in the oxides, and that ^{230}Th/^{232}Th ratios in the surface layers and in the sediment are similar (Table 2). Although little is known about the Th and Pa isotopes in pore fluid, Moore *et al.*[20] have shown the supply of ^{231}Pa and ^{230}Th from this source to the bottom face of a nodule. According to them, a preferential loss of ^{231}Pa relative to ^{230}Th from the sediment to its pore fluid may occur. The ^{227}Th/^{230}Th ratio of 0.11 measured for the outermost layer of nodule 278 DK as compared with the ratio of 0.07 for the associated sediment (Table 2) accords with this possibility.

The accretion rate of 278 DK can be estimated from the rate of decrease of excess ^{230}Th (^{230}Th$_{ex}$) $T_{1/2} = 75.2$ kyr and/or ^{231}Pa (^{231}Pa$_{ex}$) $t_{1/2} = 34.3$ kyr in the nodule. The use of ^{230}Th$_{ex}$/^{232}Th and ^{231}Pa$_{ex}$/^{230}Th$_{ex}$ activity ratios is preferred to the use of specific activities (for example, d.p.m. ^{230}Th$_{ex}$ per gramme of nodule material), in view of the nodule's textural variations. Indeed, the considerable variation of the ^{230}Th specific activities with depth (Table 1) is largely removed when normalized against those of ^{232}Th and ^{227}Th (^{231}Pa) (Table 2).

The sedimentary source for U is unimportant and the uranium precipitated from seawater or pore water is assumed to carry little or no ^{230}Th and ^{231}Pa. Thus the U-supported ^{230}Th and ^{231}Pa should be nil when deposited and increase towards secular equilibrium with uranium at depth. The rate of increase of these U-supported ^{230}Th and ^{231}Pa, as well as the rate of decrease of ^{230}Th$_{ex}$ and ^{231}Pa$_{ex}$ mentioned above, depends on the accretion rate and the decay constants involved. Using an iterative procedure analogous to that of Koide *et al.*[21] for the sediment ^{226}Ra geochronology, we calculate the ^{230}Th$_{ex}$/^{232}Th and

Ratios were calculated using an iterative procedure analogous to that of Koide *et al.*[21] for nodule 278 DK and associated sediment.

$^{227}Th_{ex}/^{230}Th_{ex}$ values corresponding to their respective least-squares fits for an exponentially decreasing function with depth. These values are listed in Table 2 and plotted in Fig. 1. The slopes of the fits give accretion rates estimated for the nodule: 173 ± 25 mm Myr^{-1} from the $^{230}Th_{ex}/^{232}Th$ plots and 162 ± 40 mm Myr^{-1} from the $^{227}Th_{ex}/^{230}Th_{ex}$ plots.

Such rapid accumulation rates have been radiometrically determined for the ridge-hydrothermal and shallow-water manganese deposits[9,22–24]. This is the first determination for a manganese nodule of deep-water origin. Our results support the concept that diagnetic remobilization of Mn in sediment column could significantly affect the growth of manganese nodules at the sediment–water interface[3,7].

Preliminary results on a nodule from the southern part of the basin show a slow growth rate of 4.5 mm Myr^{-1} and a ratio Mn/Fe of about 3. The trend is that nodules largely have a diagenetic origin (278 DK type) in the north and are hydrogenous in the south as deduced from their Mn/Fe ratio[7], the two processes may occur concurrently in intermediate areas. From these data we could expect slow precipitation from bottom sea water, plus, depending on the ambient oxidation potential, or thickness of the surface oxic layer of the sediment, a more or less important diagenetic contribution, resulting in variable growth rates ranging from millimetres to hundred of millimetres per million years. Work in progress should elucidate the relationships between the growth rate and composition of nodules and the oxidative characteristics of their sediment substrates in the Peru Basin.

We thank Dr R. Fellerer, Chief scientist of the cruise SOII in the Peru Basin, J. Labeyrie for his encouragement, C. Lalou for helpful discussions, C. A. Huh for assistance in the computer calculation, and J. Devineau for technical assistance. Laboratory studies were funded by the French CEA, CNRS and the NSF grant OCE81.00662.

Biogenic calcite structures forming in Lake Fryxell, Antarctica

Robert A. Wharton Jr*, Bruce C. Parker*, George M. Simmons Jr*, Kenneth G. Seaburg* & F. Gordon Love†

* Department of Biology and † Department of Geological Sciences, Virginia Polytechnic Institute and State University, Blacksburg, Virginia 24061, USA

Stromatolites are organosedimentary structures produced by microorganisms which have been used extensively in the interpretation of Precambrian and, to a lesser extent, Phanerozoic history[1–5]. Modern stromatolites are generally restricted to hot springs or warm, hypersaline and/or alkaline aquatic environments[3]. Recently, however, we documented[6] the presence of modern stromatolites in several cold, perennially ice-covered Antarctic dry valley lakes. Here, we report a finding in Lake Fryxell, Antarctica, of biogenic calcite structures not observed in our previous study of other Antarctic lakes. These structures were laminated, indurate, unbranched, and had either a vertical or horizontal orientation. We infer that these calcite structures are biogenic in origin, and hence stromatolitic based on the following evidence: (1) the presence of an actively metabolizing algal mat on their surface; and (2) an internal composition of filamentous blue-green algal cell wall fragments, diatom frustules and calcite crystals.

Lake Fryxell (77°37′ S, 163°07′ E) is located at the eastern end of Taylor Valley in southern Victoria Land, Antarctica (see Table 1 for physicochemical features). It is 16 m above sea level, 20 m deep, 5.2 km long, 1.7 km wide and has a surface area of 5.4 km^2. This latitude receives approximately 4 months each of sunlight, twilight and darkness. The perennial 4–5-m thick ice-cover of Lake Fryxell overlies ~15 m of water <4°C and allows penetration of <2% of the incident photosynthetically

* Per cent transmission of surface photosynthetically active radiation (400–700 nm wavelength light) through ice and water at depth indicated.

active radiation (400–700 nm wavelength) during the austral summer. The ice cover also prevents free exchange of gases with the atmosphere, wind-generated turbulence and internal mixing of the lake water. This is exemplified by oxygen supersaturation in the upper few metres of the water column, descending to anaerobic conditions below 10 m. The lake lacks outflowing streams, and receives sediment, salts and nutrients from glacial meltstreams during the austral summer.

During the 1980–81 austral summer we melted two dive holes through the ice-cover of Lake Fryxell and SCUBA divers observed and photographed the sub-ice environment. Benthic cores collected at a water depth of 7–9 m revealed that the upper mat layer (0.2–1.0 cm thick) contained actively metabolizing organisms. Metabolic activity was inferred from microscopic examination of motile blue-green algal filaments and diatoms in the mat, isolation of viable microorganisms, and from measurements of photosynthetic pigments, ATP and ^{14}C primary productivity. This top layer of mat consisted primarily of the blue-green alga *Phormidium frigidum* Fritsch, pennate diatoms (for example, *Navicula* sp., *Caloneis* sp.) and heterotrophic bacteria. Below this layer were alternating bands of organic-rich and sediment-rich layers to a depth of ~50 cm. Five organic layers, isolated from 7–32 cm in the sediment, had an average organic matter content of 8.7%. These organic and sediment laminations are similar to the Antarctic stromatolites previously reported by Parker *et al.*[6]. Embedded within these sediments were discrete structures composed of calcite (Fig. 1). These calcite structures were laminated, indurate and unbranched and had developed either a vertical or horizontal orientation. The vertical structures (1–5 cm in diameter, 1–10 cm long) were usually hollow, terete and covered by a 0.2–1.0-cm thick layer of algal mat (Fig. 2). At a depth of ≥ 50 cm in the sediment was a stratiform layer of calcite ~5 mm thick. Microscopic examination of these structures revealed diatom frustules and filamentous blue-green algal cell wall fragments ~1–2 μm diameter, the latter resembling filaments of *Phormidium*.

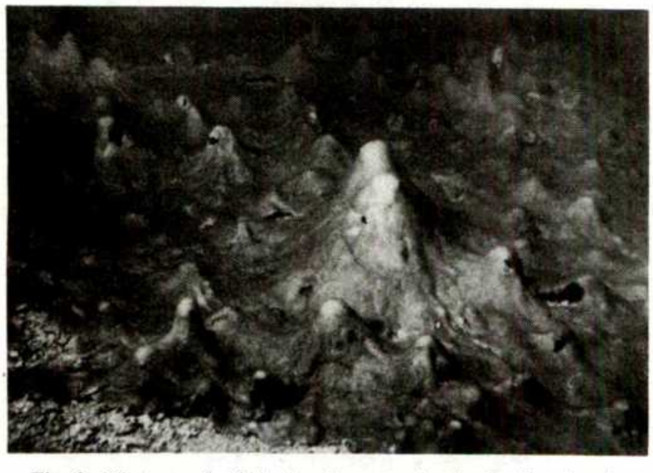

Fig. 2 Photograph of the benthos at a depth of ~7 m showing surface morphology of living algal mat in which trapped photosynthetically produced oxygen has induced lift-off from the substrate (maximum vertical relief, ~10 cm).

The vertical calcite structures in Lake Fryxell apparently result from the growth of the algal mat in dimly-lit, shallow, non-turbulent water. Austral summer photosynthetic production of O_2 causes gas bubbles to be trapped within the sticky mucilaginous algal mat matrix and initiates a vertical growth habit[6–10]. In other Antarctic lakes observed, buoyant forces sometimes tear the mat matrix, and the algal mat detaches completely from the substrate[6–13]. However, in Lake Fryxell, much of the gas-charged mat is stabilized by the precipitated calcite and does not tear loose from the substrate. The hollow nature of the structures suggests that calcite precipitation follows the orientation of the growing mat.

The vertical structures in Lake Fryxell closely resemble some of the calcite-impregnated defluidization structures recently reported from Mono Lake, California[14]. However, in contrast to the Mono Lake structures, which were considered to be formed by physicochemical carbonate deposition, the Antarctic structures seem to be primarily the result of algal activity. The horizontal structures are formed either at greater depth in the sediment where no light is available for photosynthesis or at depths where photosynthetic activity is insufficient to accumulate trapped oxygen, which results in a flat mat growth habit.

Several unique biological, physical and chemical features of Lake Fryxell produce and preserve these stromatolitic structures[6]. (1) While a few tardigrades, rotifers and nematodes inhabit the algal mats in the shallow peripheral margins of the lake, major burrowing and browsing organisms (such as cladocerans, copepods, annelids, gastropods, insect larvae and fish) are entirely absent[15], leaving these mats essentially undisturbed by metazoans. (2) Sediment influx to the lake consists of periodic influxes of glacial meltstreams which flow at most 10–12 weeks of the austral summer, contributing insufficient sediment to obliterate the mats. (3) Except for localized mixing of lake water near glacial meltstream deltas, no internal mixing of lake water occurs which prevents disturbance of existing sediments. (4) Low temperatures and a paucity of metabolically active bacteria possibly slow the decomposition of organic matter. (5) Sufficient calcium and dissolved carbonate[16,17] are available for the biogenic calcite precipitation[18].

These Antarctic stromatolites may resemble ancient permanently submerged stromatolites of the Precambrian era[6,7,9]. Because of low light intensities, lack of water turbulence and absence of burrowing and/or grazing metazoans, the benthos of Lake Fryxell may simulate some of the conditions that occurred in Precambrian deep subtidal marine or lacustrine environments which were dominated by stromatolite-forming microorganisms[5]. Thus, Lake Fryxell is an unusual habitat where modern stromatolites are forming, and further investigation may provide insight into the palaeoecology of Precambrian stromatolites.

Neural reorganization during metamorphosis of the corpora pedunculata in *Drosophila melanogaster*

Gerhard Technau & Martin Heisenberg

Institut für Genetik und Mikrobiologie, 87 Würzburg, FRG

Adult fruit flies and *Drosophila* larvae have very different bodies and behaviour patterns. The question therefore arises: how much reorganization does the brain undergo during pupation? Some apparent shape changes have been documented, for example, the growth of the optic lobes and the separation of the prothoracic and suboesophageal ganglia[1,2]. In the central brain, the issue is less clear. Most neurone cell bodies persist through metamorphosis[3], and the general shape of certain neuropil regions is conserved. However an identified motoneurone in another holometabolous insect (*Manduca*) has been shown to change its dendritic arborization patterns during pupation[4]. Here we report that the mushroom body, a major neuropil area in the insect brain, is extensively reorganized during pupation (that is, many of the intrinsic fibres are broken down and made anew). This reorganization is cryptic—the overall morphology of the mushroom body is apparently constant throughout pupation. We have now studied this reorganization by examining two mutations (*mbd, mud*) which cause derangement of this structure during metamorphosis, and we report that this reorganization is one of the most extensive yet found in insect metamorphosis.

As in most arthropods, the mushroom bodies of *Drosophila* are two conspicuous substructures of the median protocerebrum arranged in mirror symmetry to the saggital midplane. The numerous, relatively small cell bodies of their intrinsic neurones (Kenyon cells) are situated in the posterior dorsal cortex. The calyx is formed by postsynaptic glomerulus-like arborizations of the Kenyon cell fibres and by collaterals of the antennal glomerular tract (AGT) as presynaptic elements. From there, the Kenyon cell axons grow as a large bundle—the peduncle—from back to front through the whole brain on either side of the central complex. Near the anterior margin of the neuropil, most of the axons divide, sending one branch towards the midplane (β-, γ-lobes), the other one upwards (α-lobe). Thus the whole stalk system consists of three arms (peduncle, α-lobe, β-, γ-lobes) oriented roughly parallel to the three main axes of the fly[5–7]. It is this bizarre shape which makes the mushroom bodies already well discernible in the brain of the early first instar larva, where they are found in the same position and orientation as in the imago. Thus, at first sight, mushroom body development seems to imply no more than the addition of Kenyon cells and the elongation of their axons with the growth of the surrounding central brain neuropil.

Recently several mutants altering the morphology of the mushroom bodies have been described[6]. In two of them (*mushroom bodies deranged*^{KS65}, *mbd* and *mushroom body defect*^{KS63}, *mud*) the lobe and stalk system of the mushroom bodies is missing (not always completely in the case of *mbd*) and the calyces are enlarged. We noticed, to our surprise, that these mutant phenotypes occur only in the imago (Fig. 2). In the late third instar mutant larvae, the mushroom bodies have the same shape as in wild-type flies (Fig. 3). Twenty hours after puparium formation their neuropil is more or less completely degraded. Apparently, the newly growing 'imaginal' Kenyon cell axons fail to find their normal way through the central brain neuropil and remain at the site of the calyces, causing abnormal enlargement of these structures. Cell proliferation in the mushroom body cortex still seems to be normal in *mbd* (increased in *mud*). In these mutants, as in wild-type flies, neuroblasts are no longer detectable 3 days after puparium formation.

Replacement of larval Kenyon cell fibres is not a peculiarity of the mutants. A similar process occurs in wild-type individuals as well; apparently, only the course of newly growing 'imaginal' fibres is altered in the mutants. This reorganization of the wild-type mushroom body neuropil is documented by the following data.

Figure 1 shows for wild-type *Berlin* flies the number of Kenyon cell axons in the caudal peduncle, as a function of time measured from egg hatching. Counts were taken from electron micrographs of cross-sections through the peduncle, a few micrometres anterior to the calyx. The number of axons increases from about 300 in the first instar larva to about 2,100 in the late third instar larva. At the time of puparium formation, the number of axons drops abruptly. Already 12 h later, it is reduced by about 40%. From then on, it increases again until it reaches the imaginal level (2,200 fibres). From Golgi preparations of adult *Drosophila*, we know that Kenyon cell axons in the caudal peduncle have no ramifications, which could have contributed to the total cross-sectional count (K. F. Fischbach, personal communication). In electron micrographs of a series of longitudinal sections through the late larval peduncle, we found few ramifications (possibly belonging to extrinsic elements), implying that among the larval Kenyon cells as well, collaterals must be rare or even missing in this part of the mushroom bodies. Therefore we believe that the decrease of fibres in the peduncle of the early wild-type pupa reflects degeneration of whole larval axons rather than collaterals. The fact that Kenyon cell axons degenerate in the mutants supports this conclusion. Note that this is contrary to the situation of the motoneurone in *Manduca*[4] where the axon is maintained.

We have no data on whether extrinsic elements are included in this process. However, we assume that, in the peduncle, these constitute only a small minority of the profiles. In the late larval

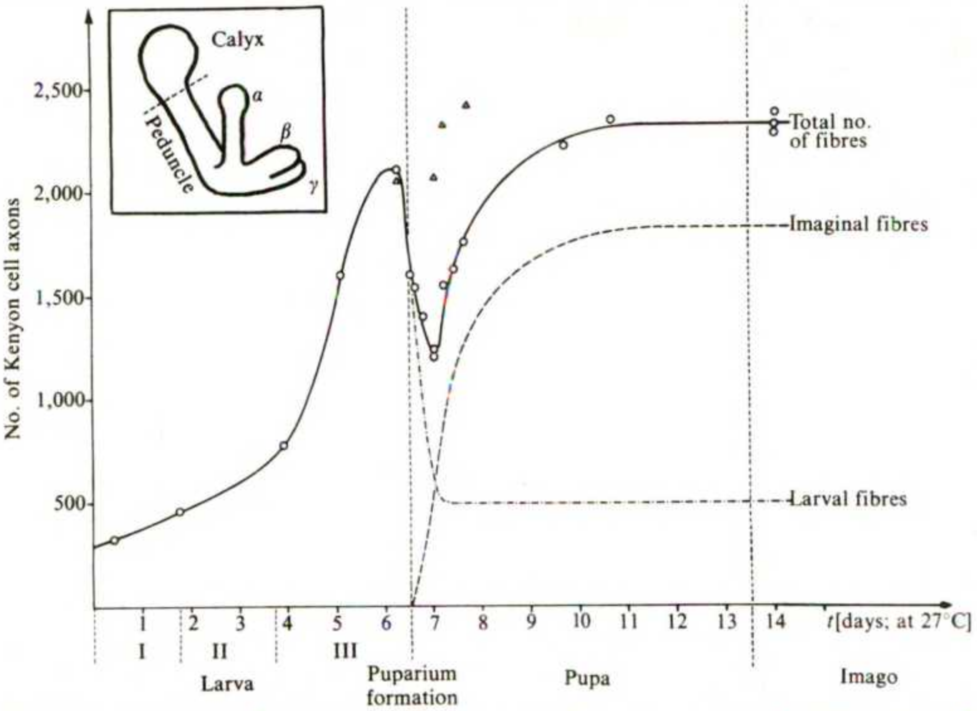

Fig. 1 Total number of Kenyon cell axons (including extrinsic elements) in the caudal peduncle of wild-type *Drosophila* (for plane of section see inset) as a function of developmental time starting at eclosion (zero time). Cell fibres are shown as open circles and cell bodies (relative counts) as triangles. Whereas the fibres of larval Kenyon cells degenerate within the first hours of pupal life, their cell bodies remain alive. The dash and dash-dot lines represent the hypothetical larval and imaginal fibre portions. The curves are based on the assumption that the bundle of (~500) thin fibres positioned centrally in the stalk system contains the only larval fibres which remain throughout metamorphosis.

stage the total number of profiles in the caudal peduncle is very close to that of Kenyon cell bodies. Hardly any tangential elements are observed which could be interpreted as penetrating extrinsic fibres or ramifications of them. Golgi preparations from adult flies rarely show extrinsic elements or specializations of intrinsic fibres in this part of the mushroom bodies. Finally, in the larva as well as the adult, cross-sections from different levels of the peduncle (except for the part close to the lobes) do not vary by more than 5–10% in their total number of profiles. Thus extrinsic elements appear to contribute little to the effect observed.

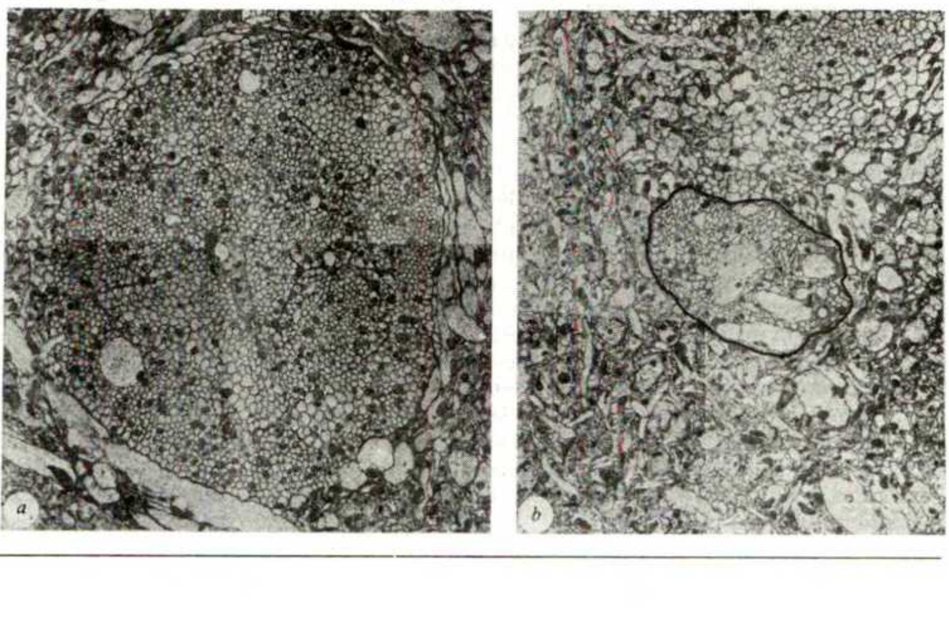
The cell bodies of the larval Kenyon cells remain alive: a staining procedure which clearly marks degenerated material (Mallory's solution of azur II and methylene blue applied to 1 μm plastic sections) shows no sign of degeneration in the mushroom body cortex at any developmental stage in either wild type or the mutant *mbd*. This is confirmed by the fact that the number of Kenyon cell bodies does not decrease during the time of fibre reduction (Fig. 1). In the pupal stage, addition of new cells to the mushroom body cortex is much less than the number of new 'imaginal' fibres, implying that at least part of these fibres belong to regenerating Kenyon cells. Presumably, sprouting of new fibres continues while larval fibres are degenerating. In fact, scattered profiles of groups of extremely thin fibres, which may represent filipodia of growing axons are found throughout the degeneration period. Thus, loss of larval Kenyon cell axons probably by far exceeds 40% (Fig. 1).

The degenerating neuropil shows typical histological alterations[8] (Fig. 4) in all parts of the mushroom bodies. Axons have short, swollen segments containing electron-dense granules (presumably glycogen), lamellar bodies and an increased number of vesicular components (Fig. 4*c*). Ramifications of glial cells in this area are drastically enlarged. They are filled with osmiophilic material and axon fragments, which suggests their active role in the degeneration process (Fig. 4*b*). Twenty hours after puparium formation, the histological signs of degeneration have already disappeared.

The misrouting of the mutant Kenyon cell axons during metamorphosis is not yet understood. In larvae and early pupae of wild-type flies we find a bundle of very thin fibres located centrally in the peduncle and β-lobe which never shows any histological signs of degeneration (Figs 3*a*, 4*a*). In the mutant *mbd* this bundle is frequently missing. If the frequency of this larval defect correlates with the expressivity of the *mbd* phenotype in the adult, the role of this bundle may be seen as a guide for the ingrowing 'imaginal' fibres. (In the mutant *mud*, cross-sectional profiles in the larval peduncle are doubled in number and are small and uniform in diameter. No special bundle can be detected.)

Since experiments with the mutant *mbd* strongly suggest that the mushroom bodies participate in the evaluation of odors (M. Heisenberg, unpublished), it is tempting to speculate about the

Fig. 2 Cross-section through the peduncle of *a*, 7-day-old wild-type imago; *b*, an imago of the mutant *mushroom bodies deranged*^{KS65}. In flies of this mutant, the number of Kenyon cell fibres (here ~250) forming the peduncle is variable, while in most flies of the mutant *mushroom body defect*^{KS63} peduncles are not detectable. ×3,599.



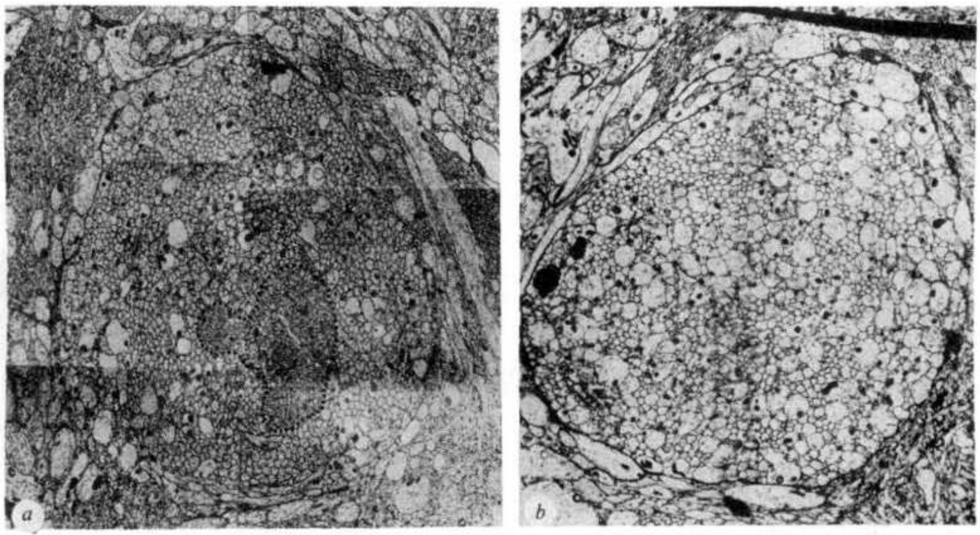


Fig. 3 Cross-section through the caudal peduncle of *a*, late third instar larva of wild type. Note centrally positioned bundle of very thin fibres (encircled by dotted line); *b*, late third instar larva of mutant *mushroom bodies deranged*^{KS65}. During larval life the mushroom bodies have the normal shape. However, in many peduncles, the bundle of thin fibres is missing. ×3,245.

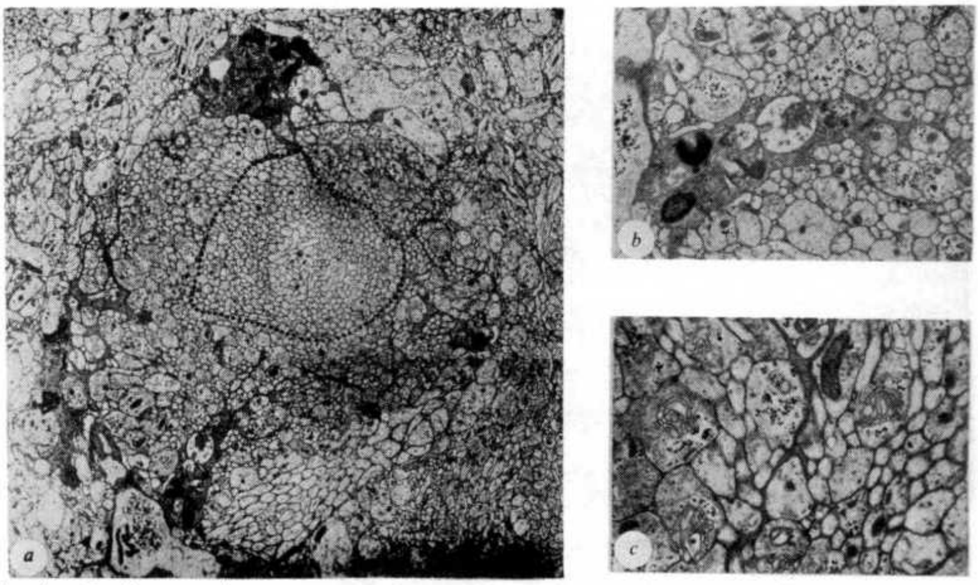

Fig. 4 *a*, Cross-section through the caudal peduncle of wild-type fly 12 h after puparium formation. ×3,658. With the exception of the centrally positioned bundle of small fibres (encircled by dotted line), mushroom body neuropil shows typical signs of degeneration. *b*, Enlarged active glial element enclosing osmiophilic material and axon fragments. ×8,184. *c*, Swollen axons with lamellar bodies, dark granules (possibly glycogen) and an increased amount of membrane-bound vesicles. ×8,184.

functional implications of the reorganization. During pupation, olfactory sense organs are completely demolished and replaced. The AGT fibres must form new connections with the antennal olfactory fibres and this possibly requires new connections between AGT fibres and Kenyon cells as well. Thus, the reorganization of the mushroom bodies may be directly related to the reorganization in the periphery. On the other hand, the presumed different synaptic contacts of the Kenyon cells may also be related to the different 'meaning' some odours have for larva and imago[9].

The reorganization of the mushroom bodies is the most extensive neuronal rewiring during metamorphosis found to date. We do not yet know whether it is characteristic of mushroom bodies in other insects, or whether other insect brain areas are also reorganized in such a wholesale manner.

We thank N. J. Strausfeld, J. R. Wolff and F.-W. Schürmann for valuable suggestions, W. G. Quinn and K. F. Fischbach for critical comments on the manuscript, and Mrs S. Newkirk for correcting the English. This work was supported by a grant from Deutsche Forschungsgemeinschaft to M.H.

Co-occurrence of substance P-like and Leu-enkephalin-like immunoreactivities in neurones and fibres of avian nervous system

Jonathan T. Erichsen, Anton Reiner & Harvey J. Karten

Department of Neurobiology and Behavior, State University of New York at Stony Brook, Stony Brook, New York 11794, USA

Neuropeptides are frequently found in neurones that also contain another putative transmitter substance such as a biogenic amine or acetylcholine[1–5]. Such co-existence has led to the suggestion that the roles of neuropeptides in the nervous system may be diverse and may in some systems include a part in conventional neurotransmission as well as an ancillary, or modulatory, role. Recently, several studies have noted the co-occurrence of two peptides within individual neurones of localized regions of the mammalian nervous system[6–9]. Here, we present the first evidence, based on an indirect immunofluorescence technique allowing the simultaneous visualization of separate tissue antigens, that substance P (SP) and Leu-enkephalin (L-Enk) co-occur within individual neurones of widespread regions of the avian central nervous system.

0028-0836/82/050407—04$01.00

The most widely used[3,4,10] immunohistochemical technique for double-label experiments has been the elution technique of Tramu *et al.*[10]. However, this technique requires comparisons of the photographic record of individual neurones following staining for each antigen (according to the indirect immunofluorescence method of Coons[11]) to determine whether any neurone has stained for the presence of both antigens. (An alternative technique involves the comparison of individual neurones in adjacent thin sections (10 μm) which have been processed separately for the presence of the two given substances[1,2,6,7].) In the present approach, immunoreactivity of two separate tissue antigens was visualized simultaneously by using non-cross-reactive primary antisera for SP and L-Enk and two distinct secondary antisera, each of which was specific for only one of the two primary antisera (see Fig. 1 legend). Furthermore, because the terminal fluorescent markers for each tissue antigen were distinct fluorophores, fluorescein isothiocyanate (FITC) and tetramethylrhodamine isothiocyanate (TRITC), the location of each antigen could be readily determined. The tissue was examined for the two fluorophores using a Leitz epi-illumina-

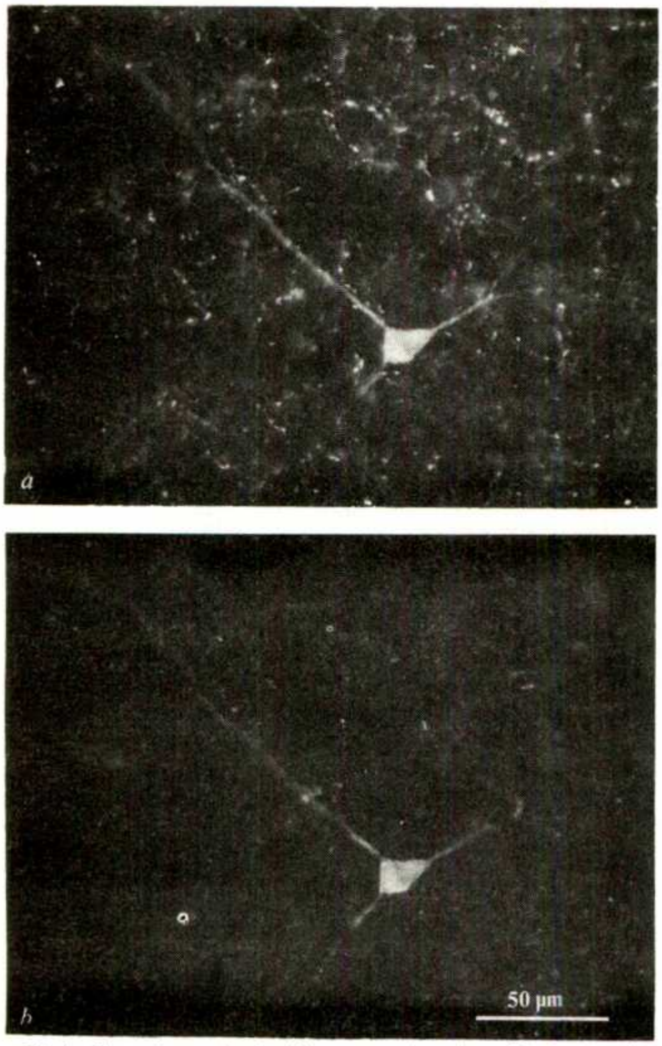

Fig. 1 Photomicrographs of an ICo neurone taken using an N cube (*a*) and an I cube (*b*) (note that different labelled fibres are seen through the two different cubes). This neurone showed TRITC (*a*) and FITC (*b*) fluorescence, indicating that the neurone stained for the presence of both a L-Enk-like substance (*a*) and a SP-like substance (*b*). The L-Enk antiserum (supplied by Dr K.-J. Chang, Wellcome) used was raised in rabbit while the monoclonal SP antiserum (Sera-Lab) used was raised in tissue culture from rat spleen hybridoma. To stain for the presence of the L-Enk and SP antisera, respectively, a goat anti-rabbit IgG conjugated to TRITC (Cappel) and a goat anti-rat IgG conjugated to FITC (Cappel) were used. As neither primary antiserum cross-reacts with either the other primary antiserum or the antigen against which the other primary antiserum is directed and as neither secondary antiserum cross-reacts with either the other secondary antiserum or the primary antigen against which the other secondary antiserum is directed, it proved possible to stain neural tissue simultaneously for the presence of both antigens.

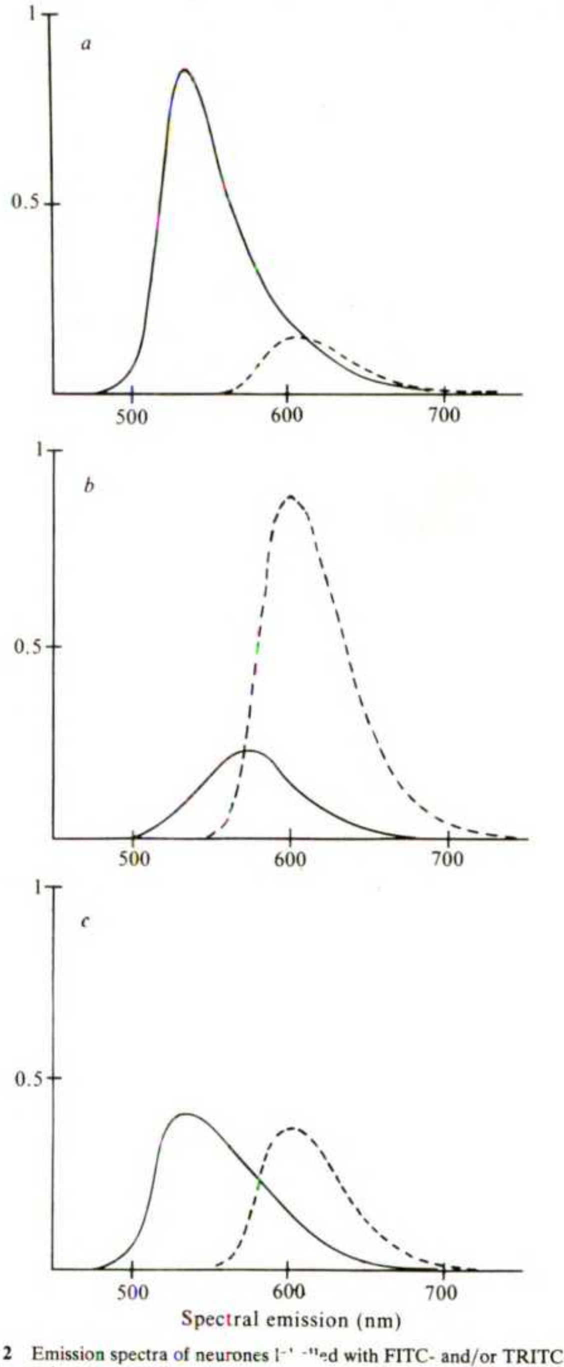

Fig. 2 Emission spectra of neurones labelled with FITC- and/or TRITC-conjugated antisera. Although the wavelength bandpass characteristics of the N cube ensured that FITC fluorescence was not detectable while the tissue was being examined using this cube, TRITC fluorescence was observable through the I cube. Nonetheless, because the TRITC fluorescence seen through the I cube is discernibly reddish while FITC fluorescence is greenish-yellow, true FITC fluorescence can be distinguished from TRITC 'breakthrough'. However, microspectrophotometry (using a Leitz MPV-2 with a B-60 Veril motor-driven filter with output recorded on an HP 2000-A *x*-*y* recorder) was used to confirm that individual neurones appearing to show both FITC and TRITC fluorescence did indeed show peak emissions through the N and I cubes at the wavelengths characteristic of TRITC and FITC, respectively. *a* Shows the spectral emission of a neurone from control series 2 (see text) that showed only FITC labelling (solid line represents emission spectrum through I cube; dashed line represents emission spectrum through N cube). The small emission recorded through the N cube represents nonspecific background binding of the anti-rabbit IgG-conjugated TRITC. *b* Shows the spectral emission of a neurone from control series 3 that showed only TRITC labelling. Note that the peak recorded through the I cube is somewhat displaced to the right of the FITC wavelength peak seen in *a*. This peak represents TRITC breakthrough on the I cube and, as can be seen, has its maximum amplitude in the red range. *c* Shows the emission spectra of the double-labelled ICo neurone shown in Fig. 1. Note that this neurone shows an emission maximum through the N cube at the TRITC peak (see *b*) and an emission maximum through the I cube at the FITC peak (see *a*). The gradations along the *y*-axis represent an arbitrary scale designed to aid comparisons of the intensity of emission at different wavelengths (*x*-axis) for different cells.

tion fluorescence microscopy system in conjunction with an 'I' cube for FITC and an 'N' cube for TRITC (Fig. 2). Control tissue incubations were carried out to confirm the specificity of the individual primary and secondary antisera.

Details of the immunohistochemical procedures used have been described elsewhere[12–14]. Tissue incubations were carried out in a primary antisera 'cocktail' consisting of both SP and L-Enk antisera at 1:1,000 dilutions; subsequently, the tissue was incubated in a secondary antisera cocktail consisting of anti-rabbit IgG-conjugated TRITC at a 1:30 dilution and anti-rat IgG-conjugated FITC at a 1:50 dilution. In some cases, three further series of sections from a given animal were run through separate control procedures: (1) incubation in a SP/L-Enk primary antisera cocktail that also contained synthetic SP and L-Enk, (2) incubation only in SP primary antiserum, and (3) incubation only in L-Enk primary antiserum. All three series of sections were subsequently incubated in the above described secondary antisera cocktail. The results of these control procedures were consistent from case to case. In the first (or blocked control) series, no labelled neurones or fibres were observed in the sections, in the second series only FITC-labelled cells and fibres were observed, and in the third control series only TRITC-labelled cells and fibres were observed (Fig. 2). The results of the first control procedure indicated that the individual primary antisera are specific for SP and L-Enk or structurally similar compounds. The specificity of the SP and L-Enk antisera in avian nervous tissue in our experimental conditions has been routinely and consistently observed in many previous single-label studies in our laboratory[12,13,15–18]. In such studies, as in the present double-label study, no immunoreactivity with either SP antiserum blocked with synthetic SP or L-Enk antiserum blocked with synthetic L-Enk was ever observed in neural regions of interest to the present study. The results of the second and third control procedures show that neither secondary antiserum observably cross-reacts with either opposing primary or secondary antisera. Together, the three control procedures indicate that the immunoreactive substances observed in our double-label experiments are SP and L-Enk or structurally similar compounds. In light of the consistent control results obtained, control procedures were not routinely run with each experimental series.

Separate observations of L-Enk-like and SP-like immunoreactive preganglionic terminal endings in the avian ciliary ganglion[15] suggested that some of the preganglionic terminals within the ciliary ganglion might contain both SP-like and L-Enk-like immunoreactivities, and we have now confirmed this in individual terminal boutons using the double-label techniques described above. Careful examination of double-labelled sections through several levels of the ciliary ganglion indicated that most preganglionic terminal endings in the ciliary ganglion contain both SP-like and L-Enk-like immunoreactivities (Fig. 3), although some terminals contain only a L-Enk-like or SP-like substance. Erichsen *et al.*[16] have shown that lesions of the nucleus of Edinger-Westphal (EW, also known in birds as the accessory oculomotor nucleus) eliminate both the SP-like and L-Enk-like immunoreactivities from the preganglionic terminal endings of the ipsilateral ciliary ganglion, thus indicating that EW contains the cell bodies of origin of the L-Enk-like and SP-like immunoreactive terminal endings in the ciliary ganglion. In birds given a 3 μl injection of colchicine (6 mg μl^{-1}) into the lateral ventricle 48 h before death, examination of the fluorescent labelling of EW neurones indicated the presence of numerous cell bodies containing both SP-like and L-Enk-like immunoreactivities, as well as neurones that showed immunoreactivity for only SP or L-Enk.

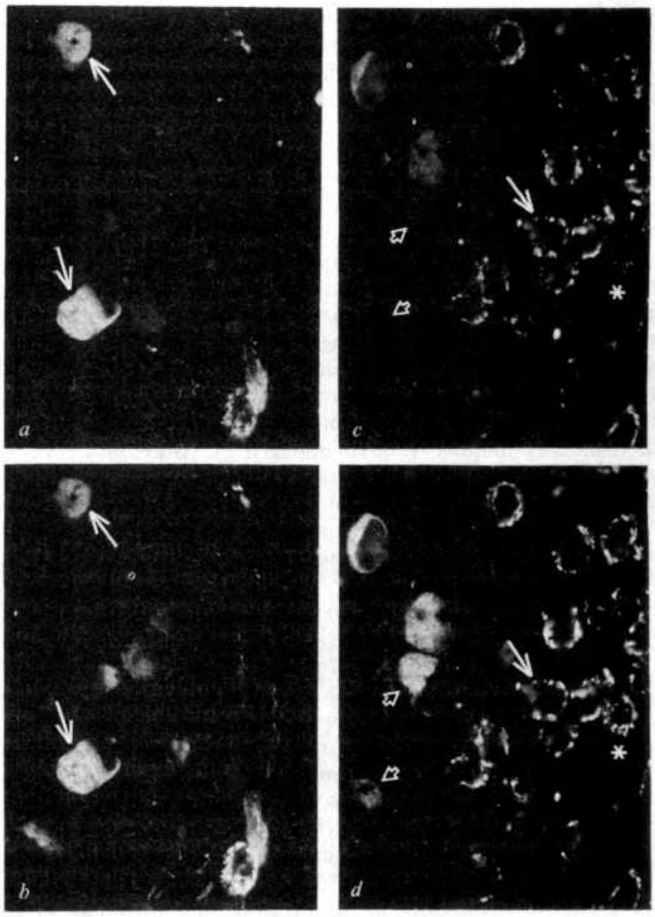

Fig. 3 Photomicrographs of labelled preganglionic terminals in the avian ciliary ganglion. The two types of preganglionic terminals previously described in the avian ciliary ganglion[23] are large cap-like structures that envelop the hilar pole of postganglionic neurones reported to project exclusively to the iris sphincter muscle and the ciliary body and endings characteristically consisting of numerous beaded terminal boutons encircling postganglionic neurones that uniquely project to the smooth musculature of the chorio-capillaris. Both types of terminal endings generally contained both a SP-like substance and a L-Enk-like substance, although the amount of immunofluorescence observed for SP relative to L-Enk varied from terminal to terminal in a given section. *a* And *b* are of the same field of view as seen through an N cube (*a*) and an I cube (*b*). Through the level of the ciliary ganglion shown in *a* and *b*, mostly cap-like endings are present and two of these (indicated by large solid arrows) show both strong TRITC immunofluorescence (indicating the presence of a L-Enk-like substance) and strong FITC immunofluorescence (indicating the presence of a SP-like substance). Several other cap-like endings showing varying amounts of both SP-like and L-Enk-like immunofluorescence are also present in *a* and *b*. One cap-like ending to the lower left in *b* and some fibres to the lower right apparently show only SP-like immunofluorescence. *c* And *d* show the same field of view through the ciliary ganglion as seen through an N cube (*c*) and an I cube (*d*). The level of the ciliary ganglion shown in *c* and *d* contains both cap-like and boutonal terminal endings. Nearly all boutonal endings show both TRITC and FITC immunofluorescence (one such double-labelled terminal ending is indicated by the large solid arrows in *c* and *d*), although variations occur in the relative amounts of TRITC and FITC immunofluorescence (for example, boutonal endings immediately above the asterisk in *c* and *d* show large amounts of SP immunofluorescence but little L-Enk immunofluorescence). The open arrows in *c* and *d* indicate a pair of cap-like endings that both show a large amount of SP-like immunoreactivity (*c*) but little to no observable L-Enk-like immunoreactivity (*d*).

Extensive searches were performed in several other regions of the avian brain known from preliminary observations and published work[17,18] to contain large numbers of neurones showing specific SP-like and specific L-Enk-like immunoreactivities. These were: (1) the small-celled zone of the basal ganglia (comprising the lobus parolfactorius and palaeostriatum augmentatum), (2) the mesencephalic subventricular nucleus intercollicularis (ICo), (3) the hypothalamus and (4) the periaqueductal grey. Immediately rostral to the confluence of the tectal ventricle with the cerebral aqueduct, we observed many ICo neurones that contained both SP-like and L-Enk-like immunoreactivities (Fig. 1). However, no neurones showing the co-existence of a SP-like and L-Enk-like substance were seen at any other level of ICo, although all levels of ICo contained neurones showing only SP-like or only L-Enk-like immunoreactivity. A population comprising neurones whose cell bodies contained both SP-like and L-Enk-like immunoreactivities and also many neurones whose cell bodies showed only SP-like or L-Enk-like immunoreactivity was found in a distinct, round cell group situated dorsally in a portion of the avian hypothalamus (or ventral thalamus) termed the stratum cellulare internum (SCI)[19]. A few neurones in the periaqueductal grey also contained both a SP-like and a L-Enk-like substance, but no such cells were found on examination of ~1,000 FITC-labelled and ~1,000 TRITC-labelled neurones in the basal ganglia.

The present demonstration of the co-existence of a SP-like substance and a L-Enk-like substance in individual neurones and/or fibre terminals in at least five separate regions of the avian nervous system raises the possibility that the co-existence of substance P and an opioid peptide in individual neurones and fibres may be a widespread phenomenon in the nervous system of a variety of vertebrates, including mammals. Consistent with this, a subpopulation of glomus cells of the carotid body of the cat has also recently been found to contain both SP-like and L-Enk-like immunoreactive material (L. Stensaas, personal communication). The functions of SP and L-Enk in neurones and fibres where they co-exist are unclear. In systems studied where they occur singly, SP and L-Enk have opposite actions, the former having excitatory postsynaptic effects and the latter inhibitory postsynaptic effects[20]. Clearly, however, the two need not have the same roles in systems where they co-occur as in those where they occur singly.

As the neurones of EW that project to the ciliary ganglion (a parasympathetic ganglion) are reported to be cholinergic[21,22], the present data suggest the co-existence of SP and L-Enk in a population of cholinergic neurones. Further, our results provide evidence that numerous individual preganglionic terminal boutons of the ciliary ganglion also contain both SP and L-Enk, and presumably acetylcholine. Erichsen *et al.*[15], using electron microscopic immunohistochemical techniques to study separately the ultrastructural localization of SP-like and L-Enk-like immunoreactivities in the preganglionic terminals of the ciliary ganglion, found that both SP-like and L-Enk-like immunoreactivities occurred in the same size class of large dense-core vesicles (85 nm, mean diameter). However, the resolution of the present light microscopic double-label technique was insufficient to determine whether SP-like and L-Enk-like immunoreactivities occurred in the same individual vesicles. Nonetheless, their presence in presumptively cholinergic preganglionic terminal boutons in the ciliary ganglion suggests that all three may have a role in neurotransmission in the ciliary ganglion.

We thank Patricia Lindaman for technical assistance, Dr. Larry Stensaas for discussion and advice during this research, and Drs Ira Cohen, James E. Krause, Thomas G. Sherman and Jeffrey F. McKelvy for their help in the preparation of this manuscript. The research was supported by EY 07039 to J.T.E., NS 15687 to A.R. and NS 12078 to H.J.K.

Rapid kinetics of single glutamate-receptor channels

S. G. Cull-Candy & I. Parker

Department of Biophysics, University College London,
Gower Street, London WC1E 6BT, UK

Drug-induced ionic channels are known to operate by opening briefly when agonist molecules bind to receptor sites[1-7] to produce rectangular current pulses, the amplitude and lifetime of which can be derived from noise analysis[1-3], or directly recorded using the patch-clamp technique[4-7]. If desensitization is neglected, the distributions of channel open and closed times can generally be fitted by single exponential functions[5-7], suggesting that a simple two-stage reaction scheme is sufficient to account for the observed kinetics[1]. Using patch-clamp recording with an improved time resolution, we have now found that glutamate-activated channels in locust muscle membrane show a large excess of both brief openings and closings over those expected from single exponential distributions. Many events which, with poorer frequency resolution, would have appeared as single openings were found to consist of two or more openings, interspersed with brief (<300 μs) closings. These observations have interesting implications for receptor/channel functioning.

Patch-clamp recordings of single glutamate-activated channels were obtained from the extensor tibiae muscle of the locust (*Schistocerca gregaria*), using techniques similar to those described previously[4,6]. Patch-clamp pipettes contained 200 μM glutamate, which gave a high frequency of channel openings, and muscle fibres were usually voltage-clamped at a potential of −110 mV to increase the size of the single channel currents. Muscles were pretreated with 1 μM concanavalin A to reduce receptor desensitization[5], and recording patches were

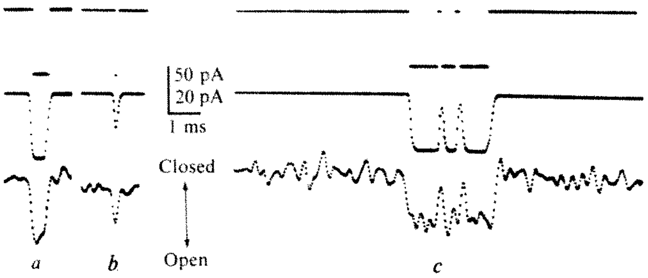

Fig. 1 Patch-clamp recordings of test pulses (*a*, *b*) and single channel currents (*c*) illustrating the time resolution of the recording system and the method of measurement. In each record the lower trace is a computer-digitized signal from the path-clamp amplifier, sampled at 25-μs intervals after sharp cut filtering ($1/f^4$) at 3.2 kHz. The upper traces show computer-generated traces used to help measure the data. A rectangular pulse (upper trace) with a height equivalent to the single channel current was generated and the position and width of this could be altered manually. A smoothing function applied to this pulse approximated the step response function of the recording system and the resultant smoothed pulse (middle trace) was displayed on a screen superimposed on the data. The position and width of the generated rectangular pulse was adjusted so that the smoothed pulse gave the best match to a channel opening and these parameters were then stored. Channel openings in each 512-point data block were fitted sequentially and a display of previously fitted openings was maintained to assist in matching brief channel closings (*c*). After analysis of several hundred data blocks, histograms of open and closed times of the generated rectangular pulses were automatically constructed. *a*, *b*, Lower traces show recordings of rectangular test pulses with durations of 500 and 50 μs respectively. Upper traces are computer-generated pulses fitted to the recordings. Calibrations, 50 pA and 1 ms. *c*, Lower trace shows single channel currents recorded from a membrane patch. Channel openings are shown as downward deflections. Upper trace shows the rectangular current pulses considered to underlie the records, whilst the middle trace shows the expected distortion of these pulses due to the frequency response characteristics of the recording system. Calibrations, 20 pA and 1 ms.

0028-0836/82/050410—03$01.00

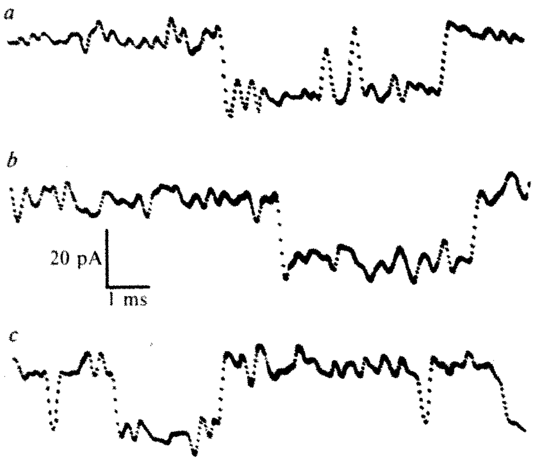

Fig. 2 Examples of single channel currents recorded with high time resolution (d.c. to 3.2 kHz). Channel openings correspond to downward deflections. Same membrane patch and recording parameters as in Fig. 1*c*. Temperature, 23 °C. Calibrations, 20 pA and 1 ms.

selected where only one active channel was present (that is, where no simultaneous openings were observed[6]). The time resolution of the recordings was improved significantly by using a circuit, after the headstage amplifier, which partially compensated for high-frequency roll-off caused by capacitance across the feedback resistor. This gave an overall frequency response of d.c. to ~5 kHz, but records were usually filtered at 3 kHz to reduce noise, before being digitized for computer analysis. Data were sampled in blocks of 512 points, at a digitization rate of 40 or 20 kHz.

The frequency response of the patch clamp was such that test pulses lasting 500 μs could be recorded with little distortion (Fig. 1*a*), whilst 50 μs pulses were detectable but became broadened and attenuated (Fig. 1*b*). The rise and fall times of single channel currents were similar to those of the test pulses (Figs 1*c*, 2), suggesting that the true transition times of the channel were faster than the resolution of the recording system. To permit more accurate measurements of brief channel openings and closings, a computer program was developed which partially compensated for the restricted frequency response of the recordings (see Fig. 1 legend). The ultimate limiting factor in time resolution was then set by the signal-to-noise ratio. We were unable to obtain seal resistances against the muscle membrane of better than 20 MΩ, so noise from this source was high[4], but as large single channel currents (20 pA) can be recorded from locust muscle the problem was not too serious.

A striking feature in our records was that many channel openings were interrupted by one or more brief closings (Figs 1*c*, 2*a*), although some long openings showed no apparent intervening closings (Fig. 2*c*). Also, there seemed to be more brief openings than expected from an exponential distribution (Fig. 2*c*). A quantitative examination was made by forming histograms of open and closed time distributions; Fig. 3 illustrates data from 832 channel openings recorded from one membrane patch. The present results are consistent with previous findings that both the open and closed time distributions of single glutamate channels can be fitted reasonably by single exponentials[5,6] and that open times are exponentially distributed[3], except that at short intervals (<200 μs) there is a considerable excess of both channel openings and closings (Fig. 3*b*, *d*), which are probably too brief to have been detected in previous patch-clamp studies having a narrower frequency range.

Figure 3*a*, *c* shows the distributions of brief openings and closings on an expanded time scale. In both cases an excess of events over a single exponential distribution becomes apparent at intervals of <~300 μs, and increases steeply with shorter intervals, except for a falloff in the shortest histogram bin (0–50 μs). A duration of 50 μs is about the limit of resolution of the recording system, so the falloff in this bin is probably due to very brief events remaining undetected.

We attempted to estimate roughly the total numbers of brief openings and closings by assuming they are distributed exponentially, and fitting the observed distributions by the sum of two exponentials corresponding to the 'brief' and 'normal' events. In the case of channel closings, the data (Fig. 3*c*) can be fitted by exponentials with time constants $\tau_{\text{fast}} = 100$ μs, $\tau_{\text{slow}} = 2$ ms. The predicted total excess of brief closings (=area under fast exponential) is 383, compared with 616 closings fitted by the slow exponential. It is clear therefore that channel openings generally occurred in bursts, with brief intervening closings within bursts and, on average, longer closings between bursts. For the events in Fig. 3 the mean number of closings per burst is

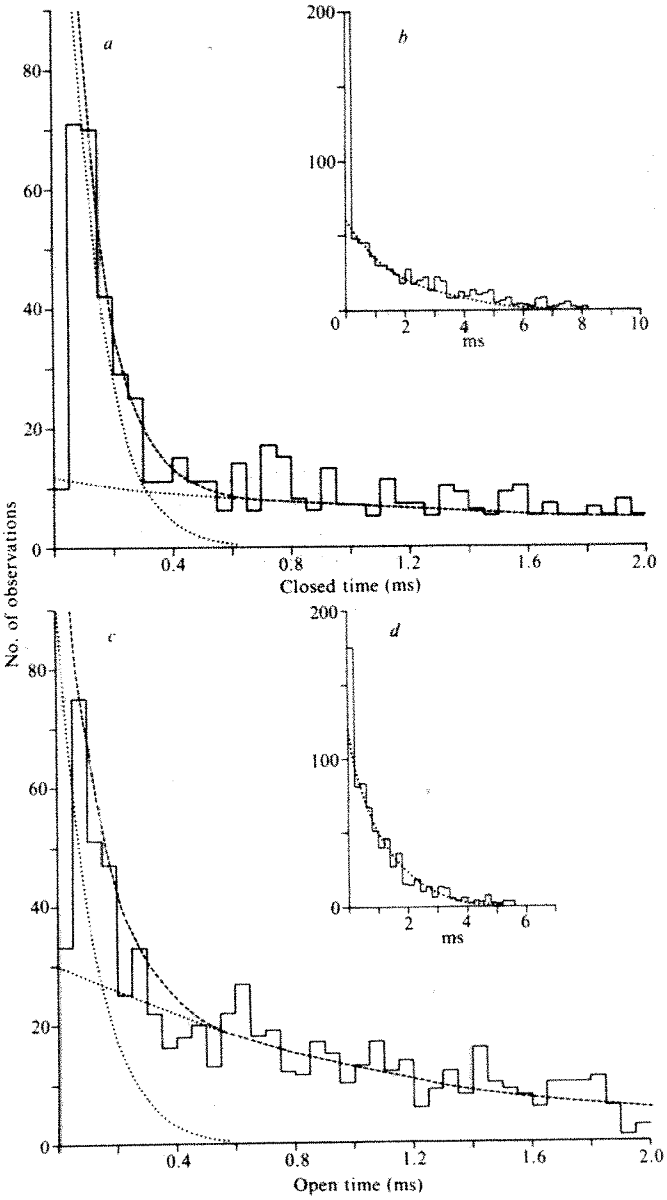

Fig. 3 Histograms of distributions of single channel closed (*a*, *b*) and open (*c*, *d*) times illustrating the excess of brief events. Data are measurements from 832 channel openings recorded from one membrane patch where only one channel appeared to be present. During the entire recording period the channel was in the 'normal' kinetic state[6]. Insets (*b*, *d*) show the same data as the main histograms, but on a different time scale. The distributions in *a* and *c* have been manually fitted by the sum of two exponentials; the component exponentials are indicated by dotted curves and the sum by dashed curves. Only the slow exponentials are shown in the insets. Time constants of the exponentials are: open times, $\tau_{\text{fast}} = 120$ μs, $\tau_{\text{slow}} = 1.5$ ms; closed times, $\tau_{\text{fast}} = 100$ μs, $\tau_{\text{slow}} = 2$ ms. Area under the exponentials are: open time, fast = 220, slow = 717; closed time, fast = 383, slow = 616. In preliminary experiments with different glutamate concentrations, estimated time constants for the closed time were: 100 μM, $\tau_{\text{fast}} = 110$ μs, $\tau_{\text{slow}} = 6.8$ ms; 600 μM, $\tau_{\text{fast}} = 117$ μs, $\tau_{\text{slow}} = 0.86$ ms (mean values from 5–7 patches).

~0.6 and hence the mean number of openings per burst is 1.6. The mean open time per burst can be estimated from the total area under the open time distribution (dashed line in Fig. 3*a*) divided by the number of inter-burst intervals and is 1.64 ms. Hence, the total burst length is ~1.7 ms and the mean duration of the openings within a burst ~1.0 ms. This estimate includes both the fast and slow components of the open time distribution. If the brief intra-burst closings were not detected, the apparent 'channel lifetime' would correspond to the mean burst length, and previous estimates of channel lifetime from noise analysis[3] and patch-clamp recording[5,6] are in reasonable agreement with our estimate of the mean burst length.

Considering next the excess of brief openings, the mean lifetime of this component estimated from the fitted fast exponential is 120 μs, and the predicted number in the recording period is 220, compared with 717 'normal' openings. Thus, about one-quarter of all channel openings were due to the brief component, but because of their short duration they would have carried only ~3% of the total current.

Records from seven other membrane patches (four muscles) using 200 μM glutamate were similar: a mean value of 1.6 ± 0.03 (s.e.) openings per burst, with a mean channel open lifetime of 0.97 ± 0.12 ms. However, in view of possible errors and assumptions in fitting the fast exponential functions to the tails of poorly resolved distributions, these values should be regarded as provisional.

Brief intervening closings during channel openings and an excess of brief openings have been observed from acetylcholine-receptor channels in frog twitch muscle[8] and the existence of intra-burst closings has been inferred from noise analysis in frog slow muscle fibres[9]. It seems likely therefore that these features may be general to most drug-activated channels. One possible mechanism for the intra-burst closings is that the channel is transiently blocked in a manner analogous to the action of local anaesthetics[10,11]. If this blocking resulted from glutamate molecules plugging the channel, then the number of brief closings would be expected to increase directly with glutamate concentration. In preliminary experiments we found that the number of brief closings per millisecond of open time showed little change over a range of glutamate concentrations (100, 200, 400, 600 μM). A more attractive possibility, which has been predicted from model reaction schemes[12,13], is that the intra-burst closings result from re-isomerization of the channel to the open configuration after closing, without dissociation of the bound agonist molecules. A simple two-step model for channel opening is:

$$\mathrm{A}+\mathrm{T} \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} \mathrm{AT} \underset{\alpha}{\overset{\beta}{\rightleftharpoons}} \mathrm{AR} \qquad (1)$$

where A = agonist molecule, T = closed channel and R = open channel. In this scheme, intra-burst closings result from the transitions $\mathrm{AR} \rightarrow \mathrm{AT} \rightarrow \mathrm{AR}$, and their mean duration is $1/(\beta + k_{-1})$. For our data $\beta \approx 4 \times 10^3\ \mathrm{s}^{-1}$. Similarly, $\alpha \approx 1/$channel lifetime $\approx 10^3\ \mathrm{s}^{-1}$. The mean number of openings per observed burst $= (1+\beta/k_{-1}) = 1.6$; hence $k_{-1} \approx 6 \times 10^3\ \mathrm{s}^{-1}$. In fact, this two-step model is probably an over-simplification; for example, opening of the glutamate channel seems to involve binding of two or more agonist molecules[6,14]. Such a cooperative model is expected to give rise to a three-component distribution of closed times[13]. The intermediate component (due to brief closings via the singly bound state) may be partially included in our estimated fast component, but calculations based on a cooperative model indicate that the maximum contribution would be smaller than our experimental error. The rough estimates of α, β and k_{-1} are therefore applicable to both cooperative and non-cooperative models.

The origin of the excess brief openings is more mysterious. One possibility, which may be readily discarded, is that two separate channels of different mean lifetimes, were present under the patch pipette. If this were the case, 47 simultaneous openings would have been expected in the record of Fig. 3, and the probability of observing zero simultaneous events is $\approx 10^{-20}$; none was observed. Another possibility, which has been suggested to explain similar brief openings of acetylcholine-receptor channels[8], is that they arise from channel openings when only one agonist molecule is bound. Important clues as to the origins of both the brief openings and closings should be given by their dependence on agonist concentration and species of agonist. It is hoped to explore these possibilities further using internally perfused patch-clamp pipettes[6,14].

We thank the MRC for support.

T-cell colonies recognize antigen in association with specific epitopes on Ia molecules

Robert B. Clark, Joe Chiba, Stephen E. Zweig & Ethan M. Shevach

Laboratory of Immunology, National Institute of Allergy and
Infectious Diseases, National Institutes of Health, Bethesda,
Maryland 20205, USA

The products of the *I* region of the major histocompatibility complex have a role in many immunological processes and are intimately involved with, if not identical to, the genes controlling specific immune responses (*Ir*). Alloantibodies to *I* region-associated (Ia) antigens have proved extremely useful in defining the relationship between Ia antigens and *Ir* gene product function[1]. We have recently reported data which suggest that monoclonal anti-Ia antibodies interact with different epitopes (antigenic determinants) on macrophage Ia molecules and that distinct epitopes, though on the same Ia molecule, are recognized by T cells in association with different antigens or antigen fragments[2]. We have now used these monoclonal xenogeneic antibodies to guinea pig Ia antigens together with antigen-specific T-cell colonies to analyse further the role of macrophage Ia antigens in T-cell activation. We demonstrate here that the proliferative responses of individual antigen-specific T-cell colonies were often completely inhibited by only one of several anti-Ia monoclonal antibodies. These results strongly support the notion that monoclonal anti-Ia antibodies can be used to define epitopes on Ia molecules that have unique functions in the activation of antigen-specific T cells, and that individual T-cell colonies recognize antigen in association with functionally distinct epitopes on Ia molecules.

Antigen-specific T-cell colonies were prepared from lymph node cells of guinea pigs primed *in vivo*, using a modification of the soft agar cloning technique described elsewhere[3]. Over 80% of the colonies that were picked from the agar could subsequently be expanded to testable numbers of cells, and ~95% of these colonies proliferated specifically when challenged with the soluble protein antigens used to generate the colonies, but not in response to other antigens to which the T-cell donor had been primed (data not shown). Furthermore, it is likely that the initial colonies picked from soft agar represen-

501	Strain 13	Strain 13	PPD	<10	13,391	13,503

Antigen-specific T-cell colonies were generated from inbred strain 2, strain 13 or $(2\times13)F_1$ regional lymph node nylon wool-purified T cells obtained from animals which had been primed *in vivo* with ovalbumin (OVA) (Miles) in complete Freund's adjuvant (CFA) (Difco). T cells (4×10^6) were cultured with X-ray irradiated (2,500 R) non-immune, unfractionated mineral oil-induced PECs (1×10^6) and 100 μg ml^{-1} PPD (Connaught) or OVA for 4–7 days in 24-well plates (Costar) in RPMI-1640 (Gibco) containing 300 μg ml^{-1} L-glutamine, 100 U ml^{-1} penicillin, 100 μg ml^{-1} streptomycin, 1 μg ml^{-1} 5-fluorocytosine, 5×10^{-5} M 2-mercaptoethanol (complete medium), and 5% heat-inactivated normal guinea pig serum. After this period of liquid culture, the antigen-stimulated T cells were plated onto a double layer of soft agar. The lower layer of agar, prepared 24 h before the upper layer, consisted of 0.5% Noble agar (Difco), 100–300 μg ml^{-1} PPD or OVA, with or without 25% T-cell growth factor (TCGF) and 10% heat-inactivated fetal calf serum (FCS). The TCGF used consisted of crude supernatants of concanavalin A-stimulated guinea pig lymph node cells and always contained 20 mg ml^{-1} α-methylmannoside (Calbiochem-Behring). The upper layer of agar consisted of 0.32% Noble agar, 10% heat-inactivated FCS, fresh PECs (2×10^5) and antigen-stimulated T cells (4–8×10^5). After 3–5 days on agar, colonies consisting of ~50 cells were picked off with a Pasteur pipette and then liquid-cultured in complete medium with 5% heat-inactivated FCS, 100 μg ml^{-1} PPD or OVA, 10^4 PECs and 25% TCGF in 96-well flat-bottomed microtitre plates (Costar). Expanding colonies were transferred to 24-well plates and fed twice weekly with 5×10^5 PECs, 200 μg ml^{-1} PPD or OVA and 25% TCGF. Antigen-induced proliferation of T-cell colonies (10^4) was measured by incubation with 10^5 PECs and 100 μg ml^{-1} PPD or OVA in 0.2 ml of complete medium with 5% heat-inactivated FCS and 10% TCGF in flat-bottomed microtitre wells. After 3 days, the contents of each well were divided into three new flat-bottomed, microtitre plates, each containing 0.2 ml of complete medium with 5% heat-inactivated FCS, 10% TCGF, 100 μg ml^{-1} PPD or OVA and fresh PECs (10^5). After an additional 48 h of culture, 1.0 μCi of tritiated thymidine (^{3}H-TdR: specific activity 6.7 Ci mmol^{-1}; NEN) was added to each well and after 18 h the amount of radioactivity incorporated into the cellular DNA was determined using a semi-automated microharvesting device (Mash II; Microbiological Associates). The results of triplicate cultures are expressed as total c.p.m. with antigen – c.p.m. without antigen (Δ c.p.m.). The s.e.m. of triplicate samples was rarely >10% of the mean, and for simplicity, only the mean of triplicate samples is given. ND, not determined.

ted true T-cell clones and not mixed cell populations because almost all T-cell colonies derived from $(2\times13)F_1$ donors that had been selected and expanded with F_1 peritoneal exudate cells (PECs) demonstrated an antigen-specific proliferative response in the presence of one but not the other parental strain of PEC (Table 1, colonies 10, 31, 124 and 126). $(2\times13)F_1$ T-cell colonies that had been generated and expanded with strain 2 PECs, and T-cell colonies derived from inbred strain 13 T cells that had been expanded with syngeneic PECs, also demonstrated a strict genetic restriction in their proliferative response to the appropriate strain of PEC (Table 1, colonies 62, 63, 131, 500 and 501).

The production and characterization of the murine monoclonal antibodies to guinea pig Ia antigens have been described in detail elsewhere[4]. Both monoclonals 22C4 and 27E7 reacted with all Ia antigens identified by a strain 2 anti-strain 13 serum (anti-Ia 1, 3, 7). However, in sequential immunoprecipitation studies with a strain 13 anti-strain 2 serum (anti-Ia 2, 4), monoclonal 27E7 reacted only with the Ia 2-bearing molecule while monoclonal 22C4 reacted with all the Ia molecules identified by the anti-Ia 2, 4 serum (ref. 4 and S.E.Z. and E.M.S., in preparation). Monoclonal antibodies 25E11 and 13S1 reacted with alloantigenic determinants of strain 2 and strain 13 Ia molecules, respectively.

These monoclonal antibodies were studied for their effects on the proliferative responses of the antigen-specific T-cell colonies; as a control population we used short-term lines of antigen-specific T cells which had been prepared by stimulation with antigen in liquid culture but which had not been separated into distinct colonies on agar. Colonies 62, 63 and 131 are strain 2-restricted, purified protein derivative of tuberculin (PPD)-specific, $(2\times13)F_1$ T-cell colonies. As seen in Table 2, colony 62 was inhibited only by monoclonal antibody 22C4, which is directed against an Ia determinant present on all strain 2 and strain 13 Ia molecules. Colony 63 was inhibited only by monoclonal antibody 25E11, which is directed against a strain 2 alloantigenic determinant. Colony 131 was inhibited by monoclonal antibodies 25E11 and 27E7, the latter being directed against a determinant present on all strain 13 and on some, but not all, strain 2 Ia molecules. Thus, while monoclonal 22C4 reacts with all strain 2 and strain 13 Ia molecules, it inhibits the response of colony 62 but not that of colonies 63 and 131. This indicates that colony 62 recognizes PPD in association with a region or epitope on the restricting Ia element different from that recognized by colonies 63 and 131. It is also likely that the latter colonies recognize PPD in association with distinct epitopes, as colony 63 was blocked only by 25E11 whereas colony 131 was blocked by both 25E11 and 27E7. As competitive binding studies have demonstrated partial inhibition of the binding of 25E11 by 27E7, the determinants identified by these monoclonal antibodies are probably adjacent to each other on the Ia molecule (S.E.Z. and E.M.S., unpublished observations). Thus, colony 131 may react with PPD in association with an epitope of strain 2 Ia located between the sites defined by 25E11

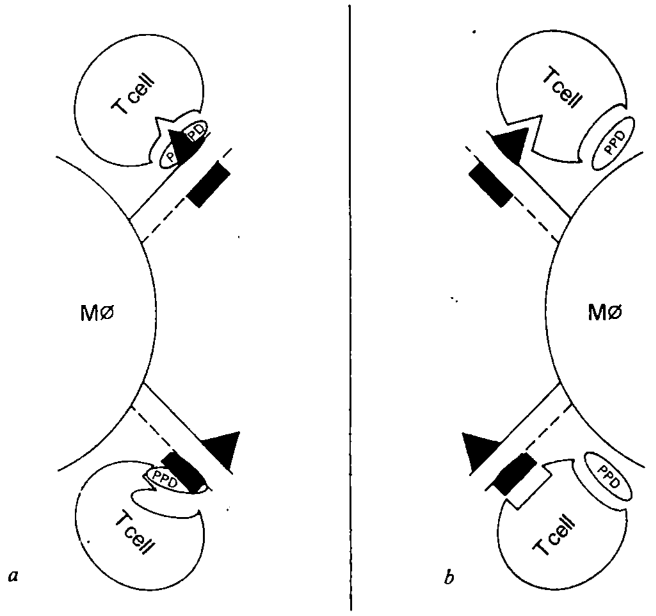

Fig. 1 *a*, Model of antigen presentation in which distinct epitopes on macrophage Ia molecules interact with conventional antigens and determine the orientation of antigenic determinants presented to the responding T cells. *b*, Model of antigen presentation in which distinct epitopes on Ia molecules and conventional antigens are recognized separately by two distinct receptors on responding T cells.

Table 2 Effect of monoclonal anti-Ia antibodies on the antigen-specific proliferative responses of T-cell colonies and T-cell lines

			Δ c.p.m. ^{3}H-TdR incorporation in the presence of monoclonal anti-Ia antibody			
Responder	PPD-pulsed macrophage (MØ)	Control	25E11	27E7	22C4	13S1
Colony 62	Strain 2	2,178	3,906	2,669	643	ND

T-cell line (strain 13)	Strain 13	13,031	13,465	3,105	11,490	1,832

Antigen-specific T-cell colonies were generated as described in Table 1 legend. Short-term T-cell lines were generated as follows: nylon wool column-purified T cells were obtained from regional lymph nodes of inbred strain 13 or $(2\times13)F_1$ guinea pigs which had been primed *in vivo* with OVA in CFA. T cells (4×10^6) and irradiated, non-immune mineral oil-induced PECs (1×10^6) were cultured in complete medium containing 5% heat-inactivated normal guinea pig serum and 100 μg ml^{-1} PPD for 1 week before testing. $(2\times13)F_1$ T cells were cultured with parental strain 2 PECs. Inbred strain 13 T cells were cultured with strain 13 PECs. Antigen-induced proliferation of short-term T-cell lines or antigen-specific T-cell colonies was measured by incubation with antigen-pulsed PECs. For antigen pulsing, unfractionated, mineral oil-induced, non-immune, irradiated PECs $(10\times10^6$ ml$^{-1})$ were incubated in complete medium at 37 °C for 1 h in the presence of 100 μg ml^{-1} PPD. The cells were then washed three times to remove unbound antigen. These antigen-pulsed PECs (1×10^5) were incubated in 0.2 ml of complete medium with 5% heat-inactivated FCS and 5% TCGF, together with cells from T-cell lines or T-cell colonies (2×10^3) for 3 days in a round-bottomed microtitre plate (Linbro Chemical). To measure inhibition of antigen-specific proliferation by the monoclonal anti-Ia antibodies, ascitic fluids produced from the individual hybrid cell lines were added to the above microtitre wells at a final concentration of 1%. As all the monoclonal antibodies used were either of the IgM or IgG1 isotype[4], we used as control ascitic fluid, a hybrid myeloma line (provided by Ms R. Lieberman) which secreted an IgM antibody directed against inulin in addition to the parental IgG1 antibody of the P3×63Ag8 myeloma line. All the ascites containing monoclonal anti-Ia antibody had previously been found to have peak binding or cytotoxicity values when used at 0.1% or 0.01%. ^{3}H-TdR (1.0 μCi) was added to each well after 48 h of culture and 18 h later the amount of radioactivity incorporated into cellular DNA was determined using a semi-automated microharvesting device, Mash II. The results of triplicate cultures are expressed as total c.p.m. with antigen-pulsed PECs plus ascites – total c.p.m. with unpulsed PECs plus ascites (Δ c.p.m.). The s.e.m. of triplicate samples was rarely >10% of the mean, thus for simplicity only the mean of triplicate samples is given. ND, not determined.

and 27E7, while colony 63 reacts with PPD in association with an epitope close or identical to that defined by 25E11. Colonies 500 and 501, both derived from PPD-immune strain 13 T cells, were also inhibited by different monoclonal anti-Ia antibodies (Table 2). Despite the fact that monoclonal 27E7 reacts with a determinant present on all strain 13 Ia molecules, colony 500 was significantly inhibited by 27E7 whereas colony 501 was inhibited significantly only by monoclonal 13S1, which is directed against an alloantigenic determinant on strain 13 Ia molecules.

In contrast to the inhibition profiles of the colonies, the PPD-specific response of the short-term line of $(2\times13)F_1$ T cells was inhibited only moderately by 25E11, 27E7 and 22C4 (Table 2). The short-term line of inbred strain 13 PPD-specific T cells was significantly inhibited by 27E7 and 13S1 (Table 2). Thus, both short-term T-cell lines demonstrated some inhibition by more than one monoclonal antibody. These results are identical to those observed for T cells stimulated directly after being taken from the animal, without previous short-term culture[2].

Our results are consistent with the hypothesis that the monoclonal anti-Ia antibodies inhibit T-cell proliferation by masking individual Ia epitopes and that individual antigen-specific T-cell colonies recognize antigen in association with such distinct epitopes on Ia molecules. In agreement with this hypothesis, the unseparated T-cell lines, containing multiple antigen-specific clones, were inhibited by more than one monoclonal antibody, and this inhibition was often only moderate. We have recently demonstrated similar differential inhibition by these monoclonal antibodies of alloreactive T-cell colonies, thus these results are not unique to antigen-specific T-cell colonies[5]. It is very difficult to exclude the possibility that our results actually represent inhibition of T-cell recognition by masking of the entire Ia molecule rather than by masking of distinct epitopes on the same Ia molecule. However, the former explanation seems unlikely because several of the monoclonal antibodies which recognize determinants present on all guinea pig Ia molecules inhibit the response of only some of the colonies. Similarly, the differential inhibition by monoclonal antibodies that recognize monomorphic Ia determinants makes it unlikely that monoclonal anti-Ia antibodies inhibit T-cell proliferation by a generalized capping and shedding of Ia antigens. We have so far been unable to reclone any of our antigen-specific T-cell colonies, but the significance of our demonstration that individual antigen-specific T-cell colonies show fine differences in genetic restriction at the level of Ia epitope recognition, is not dependent on rigorous proof of the monoclonality of these putative clones.

The results presented here are most consistent with the theories of *Ir* gene function proposed by Rosenthal *et al.*[6] and Benacerraf[7], in which Ia molecules on macrophages interact with antigens and determine the orientation of antigenic determinants presented to the responding T cells. In this case, monoclonal anti-Ia antibodies would selectively inhibit T-cell activation by masking one of the sites of interaction of the Ia molecules with conventional antigen (Fig. 1*a*). However, the results are also compatible with the theories[8] proposing that the T cell has two receptors, one for self-Ia and the other for conventional antigen. In the latter case (Fig. 1*b*), monoclonal anti-Ia antibodies would inhibit T-cell proliferation by masking the recognition of individual Ia epitopes seen by the anti-self-Ia receptor on the T cell.

These results have important implications for the relationship between Ia antigens, *Ir* genes and disease susceptibility. As suggested by Schwartz *et al.*[9], the frequently noted associations between disease susceptibility and HLA antigens in man may, in fact, be associations between disease susceptibility and distinct epitopes on those HLA antigens. Determination of such disease–MHC epitope associations could have great practical and theoretical value by allowing more accurate detection of those individuals at highest risk for developing certain diseases and by furthering our understanding of the relationship between the immune system and disease susceptibility.

We thank Mrs Clare Horton for technical assistance and Ms Shirley Starnes for assistance with the manuscript. S.E.Z. is a Fellow of the Arthritis Foundation.

Progesterone monoclonal antibody blocks pregnancy in mice

L. J. Wright, A. Feinstein, R. B. Heap, J. C. Saunders, R. C. Bennett & M.-Y. Wang

ARC Institute of Animal Physiology, Babraham,
Cambridge CB2 4AT, UK

Production of monoclonal antibodies by hybrid cell lines[1] provides a method potentially superior to conventional techniques for raising antisera[2] in respect of titre and specificity. Many lines have been prepared[3] that secrete antibody to cell-surface and soluble antigens and to viruses, but the products of hybridomas that recognize steroid haptens have not yet been exploited. Progesterone, the hormone of pregnancy, is essential for the establishment and maintenance of gestation in all mammalian species so far studied in detail[4], and we describe here the production and characterization of an anti-progesterone monoclonal antibody which blocks the establishment of pregnancy in mice.

Adult male BALB/c mice from a colony maintained at this Institute were immunized against progesterone-11α-succinyl–bovine serum albumin (BSA) conjugate (molar ratio of steroid to protein, 26:1) prepared using carbodiimide as the coupling agent. The spleen cells from these animals were fused with the mouse myeloma cell line NSI[5,6]. Immediately after fusion the cells were cultured in selection medium containing hypoxanthine–aminopterin–thymidine (HAT) and subsequently HT[5], and the supernatants were screened by a binding assay (see Table 1) for the presence of progesterone-binding antibodies. Vigorous growth of hybrids was observed but the supernatant of only one well displayed marked anti-progesterone activity. Of 14 subcultures established from this well, four remained active and stable over a 5 month period (AA1, BA2, 2A3, AB1). After cloning the hybrid AA1 on soft agar[7], one colony was selected for further study (III A4.1) and was recloned. Seventeen subcultures grew well and anti-progesterone antibody was detected by a high binding activity in the supernatants of all 17 wells. This, together with later evidence, suggests that III A4.1 is a clone. Ascites fluid formed after cells of clone III A4.1 were injected into mice was found to contain a high concentration of anti-progesterone monoclonal antibody (up to 15 mg ml^{-1}) by immunoelectrophoresis and analytical ultracentrifugation. It was also shown to possess precipitating activity against steroid–BSA conjugate, but not against BSA alone. Specific antisera showed it to be of mouse IgG1 sub-class. The results of similar tests on ascites fluid prepared with cells of subculture AA1 were identical. When tested by the binding assay (see Table 1), 50% binding of radioligand was obtained at dilutions of ascites fluid ranging from 1:3,000 to 1:43,000. Anti-progesterone antibody (AA1, ascites fluid) had an association constant of 0.4×10^9 M^{-1} (Scatchard analysis).

The specificity of binding in ascites fluid (AA1 and III A4.1) was compared with that obtained for an antiserum (provided by Dr A. P. F. Flint) raised against the same antigen by the conventional procedure in a sheep. The anti-progesterone monoclonal antibody was less specific than the average of the polyclonal antibodies in antiserum 18.2 (Table 1) as noted by others[8]. However, the high concentration of clonal IgG available in the ascites fluid preparation, its relatively low contamination with other proteins and the preservation of clone III A4.1 in liquid nitrogen provided a long-term reproducible source of a suitable reagent for testing anti-fertility properties.

The anti-implantation properties of the monoclonal antibody (clone III A4) were tested in BALB/c mature virgin mice. Five daily injections of ascites fluid (15 μl) blocked implantation in all animals, whether given intraperitoneally (i.p.) or intravenously (Table 2: route). To determine the time at which the monoclonal antibody blocked pregnancy most effectively, mature virgin BALB/c mice were given a single i.p. injection at 32 and 109–130 h post-coitum (p.c.). Monoclonal antibody blocked implantation in all 13 mice treated at 32 h ($P < 0.001$, Table 2: time) and in a further four mice treated at 65 h p.c. (Table 3). Pregnancy was also blocked in 9 of 11 mice treated 109–130 h p.c. but implantation occurred and pregnancy appeared to progress normally in two animals (Table 2: time). Control ascites fluid from mouse myeloma McPc 1748 had no effect on pregnancy when injected at 32 h p.c., but when given at later stages (109–130 h) reduced fertility (Table 2: time).

In mice receiving five daily injections, the mean concentration of plasma progesterone was higher in the experimental than the control group of animals on day 10 p.c., but the difference was not statistically significant. The high concentration was associated with a marked increase in the amount of ^{3}H-progesterone bound by plasma *in vitro* ($P < 0.001$, Table 3). The number of

Cross-reactivity was determined using monoclonal antibody III A4.1 and polyclonal antiserum 18.2 at a dilution in phosphate buffer of 1:15,500 and 1:1,400 respectively. At this dilution each preparation bound ~50% of the radioligand used in the binding assay. A high concentration of monoclonal antibody was obtained by the injection of cells of clone III A4.1 into BALB/c mice primed with pristane (2,6,10,14-tetramethylpentadecane) 14 days before injection i.p. of $\sim 7 \times 10^6$ cells. The binding assay consisted of 100 μl supernatant incubated overnight at doubling dilutions with 100 μl [1,2,6,7-^{2}H]progesterone (89 Ci mmol^{-1}; 20,000 d.p.m. per 100 μl phosphate buffer; Amersham). For screening purposes, supernatants were diluted 1:1 (v/v) with phosphate buffer. Unbound radioligand was absorbed by the addition of 200 μl dextran-coated charcoal, and 20 min later charcoal-bound radioligand was separated from antibody-bound radioligand by centrifugation. Radioactivity in the supernatants indicative of antibody binding was measured by liquid scintillation spectrometry[15]. The nonspecific binding of the assay (culture medium with no antibody) was 5.2±0.8% (mean±s.e.m.) of the added radioligand. Competitive binding studies were carried out using increasing amounts of the compounds listed (25–25,000 pg in 25 μl buffer) and a constant amount of ^{3}H-progesterone (100 μl buffer containing 20,000 d.p.m.). Incubation conditions and the method of separation of antibody-bound and unbound radioactivity were identical to those used in the binding assay. Cross-reactivity was calculated as the amount of progesterone required to reduce the amount of radioligand bound by one-half, divided by the amount of competing steroid that produced a similar displacement (×100)[16].

Table 2 Effect of the route and time of administration (h p.c.) of anti-progesterone monoclonal antibody on blocking of pregnancy in mice

Group		No. pregnant/ no. treated	Total no. of implantations
Route: five daily injections			
Intraperitoneal	Experimental	0/6*	0
	Control	4/6	20
Intravenous	Experimental	0/6*	0
	Control	4/6	39
Time: single injection			
32 h p.c.	Experimental	0/13*	0
	Control	13/14	109
109–130 h p.c.	Experimental	2/11	20
	Control	7/12	75

Route: BALB/c mice were injected daily at ~10.00 h on days 1, 2, 3, 4 and 5 (day 1 = day of copulation plug; coitus ~02.00 h). Injections consisted of 200 µl 0.9% NaCl containing 15 µl ascites fluid (cloned hybrid III A4.1, experimental), 15 µl ascites fluid (mouse myeloma McPc 1748, control) or 15 µl non-immune mouse serum. Ascites fluid from the cloned hybrid III A4.1 diluted 1:42,000 bound 50% of radioligand when incubated with ^{3}H-progesterone (~20,000 d.p.m.). Ascites fluid from McPc 1748 or non-immune serum showed no detectable binding of ^{3}H-progesterone. Autopsy was performed on day 10 p.c. Time: BALB/c mice were given a single injection i.p. at the times shown (0 h = estimated time of coitus, ~02.00 h of the morning when a copulation plug was found, day 1). Injections consisted of 200 µl 0.9% NaCl containing 15 µl ascites fluid (cloned hybrid III A4.1, experimental) or 15 µl ascites fluid (mouse myeloma McPc 1748, control, see above). Autopsy was performed on days 11–15 p.c.

* Difference between experimental and control group was significant ($P<0.001$) when tested after the calculation of exact significance probabilities using the randomization procedure first proposed by Fisher[17].

corpora lutea counted in serial sections of ovaries removed at autopsy was similar in experimental (10.0 ± 0.7, mean ± s.e.m.) and control (9.0 ± 2.0) groups, though the corpora lutea were frequently small and regressed in mice treated with anti-progesterone antibody. Thus the high concentration of progesterone in peripheral plasma was probably due to the retention of antibody-bound steroid in circulation, and the decline of luteal function to a lack of pituitary and/or placental luteotropin arising from the failure of implantation.

Plasma progesterone levels in mice treated with a single dose of anti-progesterone antibody at 32 or 65 h p.c. and killed on day 11–15 p.c. were less than one-half those found in mice treated daily for 5 days, presumably due to the further decline of luteal secretion of progesterone. The mean plasma progesterone concentration in mice injected at 109–130 h p.c. was similar to that in control animals; in two animals that remained pregnant the values were high (64 and 94 ng ml^{-1}) whereas in a further two mice which were not pregnant values were low (2 and 14 ng ml^{-1}). Circulating monoclonal antibody was still present at autopsy in mice injected only once with cross-reacting IgG as judged by the greater amount of radioligand bound by plasma *in vitro* (47.3 ± 2.3%) compared with values obtained in control mice (15.5 ± 1.8%, $P<0.001$, Table 3). The binding observed in plasma from control animals was attributed to corticosteroid-binding globulin[9] as when plasma was heated at 60 °C for 20 min the value was reduced to levels similar to the nonspecific binding values of the assay, whereas in monoclonal-treated animals it was only reduced to 36% due to the presence of anti-progesterone IgG (Table 3).

The results show that anti-progesterone monoclonal antibody given as single or repeated injections during preimplantation will prevent implantation in mice. It was estimated that at equilibrium, anti-progesterone antibody reduced the concentration of readily available progesterone in circulation by >95% during the critical preimplantation stage, when a precise hormonal sequence of progesterone and oestrogens is normally required to sensitize the endometrium for implantation[10] which begins at ~90 h p.c. The finding that a single injection of monoclonal anti-progesterone IgG (200 µg; 10 mg per kg) prevented pregnancy in all 17 mice treated between 32 and 65 h p.c. and that its effect was slightly reduced when it was administered later, may be associated with the limited capacity of antibody to reduce circulating progesterone levels in the face of increasing luteal secretion[11,12]. The results obtained with this monoclonal preparation in mice showed a substantial improvement compared with those obtained with a polyclonal antiserum in rats in which anti-progesterone antiserum (10 mg; 50 mg per kg) delayed implantation by at least 24 h but blocked pregnancy in only 6 of 14 treated animals[13].

The mechanism by which this anti-progesterone monoclonal antibody reduced fertility in mice probably differs according to the time of treatment. When injected at 32 h p.c. transport along the Fallopian tubes may have been affected, whereas when injected 109–130 h p.c. the process of implantation itself seemed to be inhibited. Ligand specificity of the monoclonal anti-progesterone antibody used in this study was relatively inferior to that of a conventional antiserum, certain steroids structurally dissimilar to progesterone (such as aetiocholanolone) competing successfully with progesterone for the monoclonal binding site. Whether or not these cross-reactivities are an essential feature of the anti-implantation efficacy of this antibody remains to be established, but products of suitably selected anti-progesterone clones should prove invaluable for further studies of the regulation of fertility.

We thank Professor E. C. Amoroso, Drs A. P. F. Flint, J. C. Howard and D. E. Walters for help and valuable discussions, and Mrs E. Tredget, Miss M. Hamon, Miss P. Hansford and Mr I. R. Fleet for technical assistance.

Note added in proof: It has been demonstrated that an anti-progesterone monoclonal antibody can be prepared with high specificity[14].

Table 3 Effect of anti-progesterone monoclonal antibody on progesterone levels and binding of progesterone in plasma during pregnancy

Treatment	Group	No. pregnant/ no. treated	Progesterone: Plasma conc. (ng ml^{-1})	Progesterone: % Bound, Before heating	Progesterone: % Bound, After heating
Five daily injections	Experimental	0/6	35.7 ± 12.6 (6)	54 ± 9* (6)	ND
	Control	4/6	11.1 ± 3.8 (4)	10 ± 4 (4)	ND
One injection, 32 h p.c.	Experimental	0/4	16.5 ± 4.1*	45 ± 3* (4)	33 ± 3* (4)
	Control	4/4	38.8 ± 2.3 (4)	19 ± 2 (4)	8 ± 1 (4)
One injection, 65 h p.c.	Experimental	0/4	8.7 ± 5.2 (4)	52 ± 4 (4)	40 ± 2 (4)
	Control	2/4	31, 32 (2)	14, 15 (2)	6, 8 (2)
One injection, 109–130 h p.c.	Experimental	2/4	43.5 ± 21.5	45 ± 6* (4)	ND
	Control	3/4	34.3 ± 3.3 (3)	13 ± 2 (3)	7 ± 1 (3)

Details of treatment are given in Table 2 legend. Blood was collected from mice under ether anaesthesia on days 10–15 and plasma progesterone concentration was measured by radioimmunoassay. Values of % bound were obtained by the addition of a known amount of ^{3}H-progesterone (100 µl phosphate buffer containing 20,000 d.p.m.) to 100 µl plasma diluted 1:10 with phosphate buffer. In selected cases plasma was heated at 60 °C for 20 min to inactivate binding associated with the presence of corticosteroid-binding globulin[9]. Conditions of incubation and the method of preparation of antibody-bound and unbound radioactivity are described in the text. The amount of radioligand bound in plasma was expressed as a percentage of the total amount of ^{3}H-progesterone added. Results are given as mean ± s.e.m.; numbers of animals are shown in parentheses. ND, not determined.

* Difference between experimental and control group was significant ($P<0.001$) using Student's unpaired *t*-test.

Maryland 20205, USA

Polypeptides classified as transforming growth factors (TGFs) have been found in various neoplastic cells and tumour tissues[1–5], and most recently in many non-neoplastic tissues[6]. These TGFs are low-molecular-weight (7,000–20,000) acid-stable polypeptides, which induce anchorage-dependent non-neoplastic indicator cells to form progressively growing colonies in soft agar. Certain extracellular TGFs isolated from conditioned medium derived from both rodent sarcoma virus-transformed cells and several human tumour cell lines have been shown to compete with epidermal growth factor (EGF) for membrane receptors[1,3,4,7]. By direct extraction from Moloney sarcoma virus (MSV)-transformed cells, we have isolated two distinct classes of intracellular TGFs, one of which competes with EGF for receptor binding sites, whereas the other does not. We report here that after purification by HPLC, the colony-forming activity of the TGFs that do not compete with EGF for receptor binding was enhanced 100-fold by the addition of EGF. This ability to enhance the growth-stimulating effects of the TGFs is specific to EGF, as insulin, the insulin-like growth factors, platelet-derived growth factor and nerve growth factor do not show this property. In contrast, the colony-forming activity of TGFs that compete with EGF for receptor binding is not potentiated by EGF.

Direct extraction of MSV-transformed 3T3 cells with acid–ethanol has been shown[2] to yield TGFs which, when chromatographed on Bio-Gel P-30, seem to behave similarly to the extracellular sarcoma growth factor (SGF) isolated from conditioned medium derived from these cells[1]. However, other experiments have shown that the major soft-agar colony-forming activity in the unfractionated acid–ethanol extract of MSV-transformed cells is potentiated by EGF[6]. Using reverse-phase HPLC for further purification, we now demonstrate the heterogeneous nature of these intracellular TGF preparations.

As seen in Fig. 1, the TGF fraction from Bio-Gel P-30 columns (10,000–12,000 molecular weight) can be separated into two major components by HPLC on C_{18} μ Bondapak columns using a linear acetonitrile gradient in 0.1% trifluoroacetic acid. One component, which we term the EGF-potentiated TGF, elutes later (38% acetonitrile) than marker EGF (35% acetonitrile), and together with EGF (2 ng ml^{-1}) results in the formation of large colonies (>3,140 μm^2) in soft agar (Fig. 1*a*). The other component elutes earlier (32% acetonitrile) and induces formation of smaller colonies (>840 μm^2) in soft agar in the absence of added EGF (Fig. 1*b*). Binding competition studies using ^{125}I-labelled EGF showed that only the latter component competes strongly with EGF (Fig. 1*c*); this is designated 'intracellular SGF', as its behaviour is similar biologically to the extracellular SGF of conditioned medium[1,7]. In radioimmunoassays using anti-murine EGF antiserum, all these fractions were shown to be free of native EGF (data not shown). The intracellular SGF peak contained 3.7% of the total recovered absorbance at 280 nm and ~80% of the total colony-forming units assayed in the absence of EGF; the EGF-potentiated TGF peak contained 4.2% of the recovered absorbance units and ~90% of the total colony-forming units assayed in the presence of EGF.

The growth-stimulating effect of EGF and each of the two classes of TGFs on NRK cells, clone 49F (ref. 8), was quantified in the soft-agar system described previously[2]. Cells were stained and analysed for colony formation 1 week after seeding in the presence of TGF and/or EGF. Colony size was determined quantitatively using a Zeiss microscope and Videcon television camera coupled to a Bausch and Lomb Omnicon image analysis system and a data terminal. The field of view was displayed in two dimensions and all parameters were derived from the area

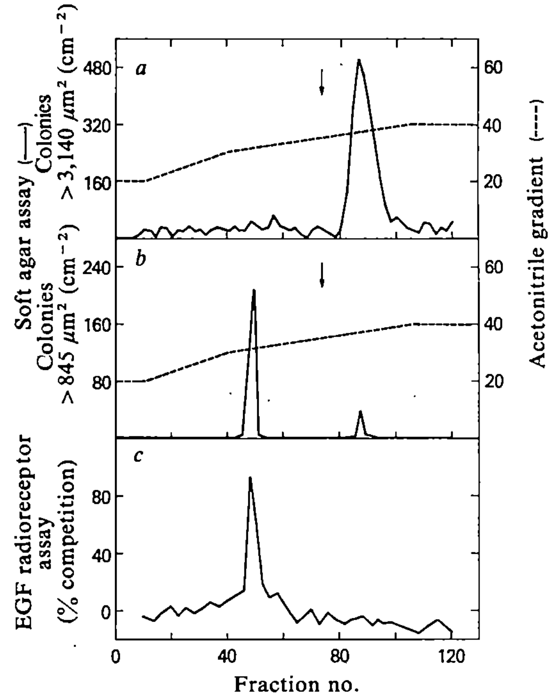

Fig. 1 HPLC purification of TGFs from MSV-transformed 3T3 cells. The acid–ethanol extract of MSV-transformed cells was purified initially on Bio-Gel P-30 in 1 M acetic acid as described elsewhere[2]. EGF was obtained by similar extraction of male mouse salivary glands[6]. The TGF pool (20 mg) was dissolved in 2 ml 0.1% trifluoroacetic acid (TFA), applied to a μ Bondapak C_{18} column (7.8×300 mm; Waters Associates) and eluted at a flow rate of 0.8 ml min^{-1} with a gradient of acetonitrile in 0.1% TFA as shown. Aliquots (40 μl; 5%) were lyophilized and assayed for activity in the soft-agar assay: *a*, in the presence of 2 ng ml^{-1} murine EGF; *b*, without EGF. *c*, Duplicate aliquots (40 μl) were assayed for inhibition of ^{125}I-EGF-receptor binding in mink lung epithelial cells (CCL 64) as described elsewhere[7] (3.5 ng ml^{-1} EGF resulted in 50% competition). Arrow indicates position of elution of marker murine EGF (*a*, *b*).

0028–0836/82/050417—03$01.00

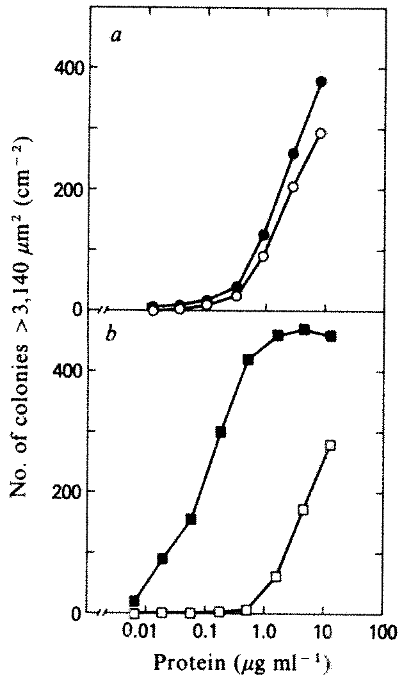

Fig. 2 Effect of EGF on the dose–response curves of the two classes of TGFs. *a*, EGF-independent TGF that competes with EGF for binding (Fig. 1, fractions 49–53) or *b*, EGF-potentiated TGF that does not compete with EGF (Fig. 1, fractions 88–98) was assayed in the absence of EGF (open symbol) or presence of 2 ng ml^{-1} murine EGF (solid symbol). The background level of colonies >3,140 μm^2 (51 per cm^2) that was observed in response to EGF alone has been subtracted. An identical response was seen for EGF prepared by the method of Savage and Cohen[24] and for receptor grade EGF (Collaborative Research).

of the colony cross-section. The system was programmed to size and count colonies >500 μm^2 and to determine the mean colony size from the data obtained for each plate. The effect of EGF on the dose–response curves of the two classes of TGFs is shown in Fig. 2*a*, *b*. If the background of colonies formed in response to EGF alone (2 ng ml^{-1}) is subtracted, it is apparent that there is no enhancement by EGF of the intrinsic colony-forming activity of the intracellular SGF (which competes for EGF receptor binding) (Fig. 2*a*). In contrast, the addition of EGF (2 ng ml^{-1}) to the culture medium caused the NRK cells to be ~100-fold more sensitive to the EGF-potentiated class of TGFs, as measured by the number of colonies >3,140 μm^2 (Fig. 2*b*). In the presence of EGF, soft-agar colony-forming activity was detected in 6 ng ml^{-1} protein from the EGF-potentiated TGF peak after HPLC purification.

The effect on colony size of EGF added to sub-optimal levels of the EGF-potentiated TGF is shown in Fig. 3. EGF alone (2 ng ml^{-1}) induced the NRK cells to form numerous small colonies of mean size 3,300 μm^2, in agreement with the data of Topp *et al.*[9], whereas TGF alone (4.6 μg ml^{-1}) caused the cells to undergo only a few divisions, to give a mean colony size of 1,800 μm^2. The simultaneous addition of EGF and TGF resulted in the formation of a large number of colonies of mean colony size 7,700 μm^2. The numbers of colonies per cm^2 greater than 3,140 μm^2 were 51 and 5, respectively, for EGF and TGF alone, whereas the two factors combined gave 470 colonies, suggesting cooperative effects. The potentiating effect of EGF in the soft-agar assay was optimal at concentrations of 0.4–10 ng ml^{-1}; higher or lower concentrations had less effect. The response of the NRK cells to EGF alone differed from the response to EGF plus EGF-potentiated TGF; colonies reached a plateau of 2,000–3,000 μm^2 mean colony size in the presence of optimal concentrations of EGF alone, whereas colonies formed in response to the two factors combined reached colony sizes of 13,000–19,000 μm^2.

Soft-agar assays (data not shown) in which EGF and/or the EGF-potentiated TGF were added sequentially as an overlay 1 week later showed that the order in which EGF or TGF is added is not important for the potentiation of the colony-forming response of the cells, and that the mean colony size attained after sequential addition is not significantly different from that after simultaneous addition of the two factors. In contrast, cells treated initially with EGF alone were refractory to further EGF added 1 week later, and cells treated initially with TGF responded to a further addition of TGF with only a doubling in mean colony size. Other growth factors were investigated for their ability to amplify the anchorage-independent growth response induced by this TGF. Platelet-derived growth factor, nerve growth factor, insulin and the insulin-like growth factors, each tested over a 1,000-fold concentration range, had little effect on the colony-forming response to sub-optimal levels of the EGF-potentiated TGF. By themselves, these factors caused very few cells to undergo even a single division in the soft-agar medium.

The potentiating effect of EGF is specific for a class of TGFs that do not compete with EGF for receptor binding, possibly implicating interaction of two distinct membrane receptors. In model systems, platelet-derived growth factor and pituitary fibroblast growth factor, while not competing for EGF-receptor sites, can induce a transient down-regulation of the EGF receptor, suggesting co-internalization of the receptors for these hormones[10]. Phorbol ester tumour promoters[11,12] and vasopressin[13] can alter the affinity of EGF receptors, and EGF can alter the response of rat pituitary cells to thyroid hormone and hence alter the hormonal control of growth hormone and prolactin synthesis by these cells[14].

Assuming that anchorage-independent growth correlates with neoplasia[15,16], the results reported here suggest a mechanism for some of the observed promoter-like effects ascribed to EGF. EGF can increase viral transformation of cells[17,18] and promote methylcholanthrene-induced papillomas in mouse skin[19]. It can also increase the anchorage-independent growth of adenovirus-transformed rat embryo cells, as measured by increases in both colony size and number[20]. Each of these effects could be mediated by EGF potentiation of sub-optimal levels of a class of EGF-responsive TGFs resembling those described here.

Results similar to those presented here for the cellular extracts of MSV-transformed mouse cells have also been obtained from both non-neoplastic and neoplastic tissues of man, mouse, chicken and cattle[21]. In every case, the major TGF activity does not compete with EGF for receptor binding but is markedly potentiated by EGF to induce growth of large colonies in soft agar. The presence in these extracts of TGFs that compete with EGF for receptor binding but are not enhanced by EGF in

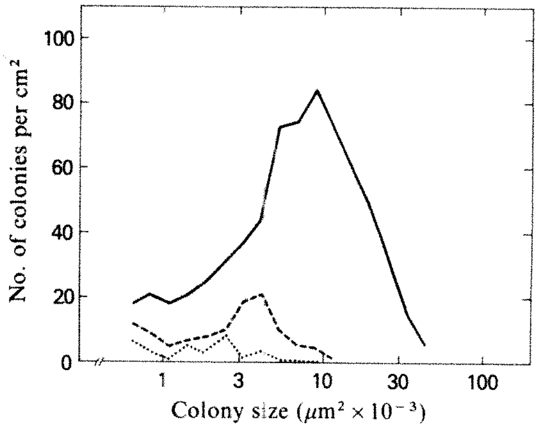

Fig. 3 Size distribution curves of colonies formed in response to EGF and/or sub-optimal concentrations of the EGF-potentiated TGF. The size distribution of colony area, as determined by image analysis, for 4.6 μg TGF (Fig. 2*b*) is represented on a logarithmic scale. · · · ·, TGF alone (4.6 μg ml^{-1}); ——, TGF at the same concentration in the presence of EGF (2 ng ml^{-1}); and - - - -, EGF alone (2 ng ml^{-1}) as a control.

the induction of anchorage-independent growth has not yet been conclusively demonstrated. Recent data of Moses *et al.* on TGF production in chemically transformed cells also demonstrate the existence of several TGFs, only one of which competes for binding to the EGF receptor[5]. The physiological significance of the interaction between EGF and this new class of TGFs is unknown, but it is possible that, in addition to a role in malignant transformation, these factors may function in the natural mechanism of wound repair and in embryogenesis, where both EGF[22] and the TGFs[23] have been postulated to play a part.

We thank Dr P. Nissley for assaying the mouse insulin and insulin-like growth factors, Dr R. Humbel for providing the insulin-like growth factors, Dr H. Antoniades for platelet-derived growth factor, Dr R. Bradshaw for nerve growth factor, Dr J. E. De Larco for helpful discussions, and Ms Ellen Friedman and Ms Ruth Morsillo for typing the manuscript.

Stimulation of tyrosine-specific phosphorylation by platelet-derived growth factor

Bo Ek*, Bengt Westermark†, Åke Wasteson* & Carl-Henrik Heldin*

* Institute of Medical and Physiological Chemistry, Biomedical Center, Uppsala University, Uppsala, Sweden
† The Wallenberg Laboratory, Uppsala University, Uppsala, Sweden

Recent studies have shown that tyrosine-specific protein kinases may be involved in both virus transformation and growth stimulation with polypeptide growth factors. Thus, several *onc* gene products possess such kinase activity[1–9] and, further, binding of epidermal growth factor (EGF)[10] to A-431 cells stimulates phosphorylation of tyrosine residues of both membrane and cytoplasmic proteins[11–16]. Platelet-derived growth factor (PDGF), a 30,000 molecular weight (M_r) polypeptide, is the major growth-promoting factor in serum for connective tissue-derived cells and glial cells in culture[17–22]. High-affinity binding of ^{125}I-PDGF to a specific receptor on such cells has recently been demonstrated; thus, human foreskin fibroblasts were found to have some 300,000 PDGF receptors per cell, with an affinity constant of 1 nM (ref. 23). The addition of PDGF to human glial cells and fibroblasts produces various phenotypic changes, similar to those induced by EGF[24] and tumour viruses[25], which include rapid induction of membrane ruffling, reduction in cell adhesion, change in structure of the actin cytoskeleton and increased mitotic activity (B.W. *et al.*, unpublished data). These considerations suggested that PDGF binding to cellular receptors might similarly stimulate kinase activity. The present report demonstrates such an effect: when incubated with plasma membranes from human fibroblasts or glial cells, PDGF induces the phosphorylation of tyrosine residues of membrane proteins with apparent molecular weights of 175,000 and 130,000.

Membranes were prepared from cultured human foreskin fibroblasts or glial cells as described previously[26] and incubated at 0 °C with ^{32}P-ATP and pure PDGF[21]. After 10 min incubation, the resulting phosphoprotein pattern was analysed by SDS-polyacrylamide gel electrophoresis (PAGE).

As Fig. 1 shows, PDGF stimulated the incorporation of ^{32}P into membrane proteins of both fibroblasts (Fig. 1*a*) and glial cells (Fig. 1*b*), promoting, in particular, the phosphorylation of a 175,000-M_r and a 130,000-M_r protein, in comparison with the

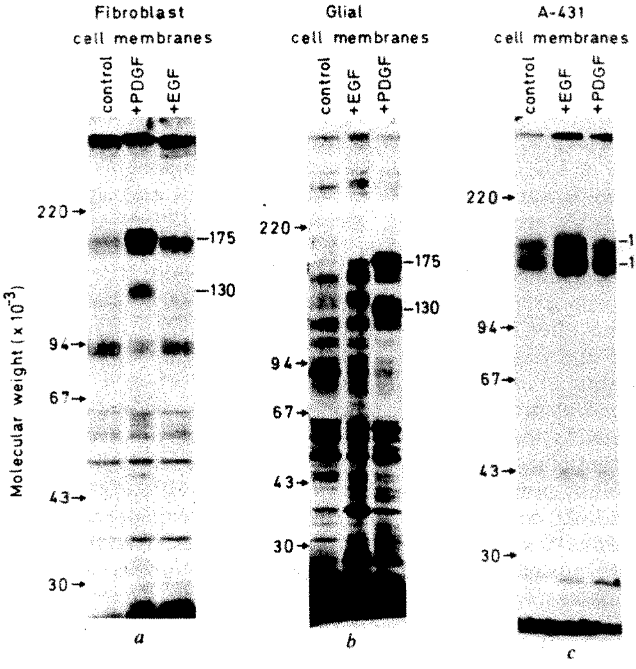

Fig. 1 Effect of PDGF and EGF on the phosphorylation of fibroblast (*a*), glial (*b*) and A-431 (*c*) cell membrane proteins. Cell membranes were prepared from serum-starved cultures of human foreskin fibroblasts (cell line AG 1523, obtained from the Human Genetic Mutant Cell Repository, Institute for Medical Research, Camden, New Jersey), human normal glia-like cells (cell line 1508 CG from our own laboratory) and A-431 cells (obtained from J. E. De Larco, National Cancer Institute, Bethesda, Maryland) according to Thom *et al.*[26] as modified in ref. 12, and were stored in aliquots suspended in 20 mM HEPES *p*H 7.4 at −70 °C for up to 2 months. The phosphorylation reaction was carried out at 0 °C in a final volume of 40 µl containing 40 µg (*a*, *c*) or 10 µg (*b*) of cell membrane protein (determined according to Bradford[31]), 20 mM HEPES *p*H 7.4, 3 mM $MnCl_2$, 0.1% bovine serum albumin, 15 µM (γ-^{32}P]ATP (33.3 kBq (*a*, *c*) or 333 kBq (*b*)) and 100 ng PDGF (76 nM) or 40 ng EGF (167 nM). PDGF was prepared according to Heldin *et al.*[21] and EGF was purchased from Collaborative Research. The cell membranes were preincubated with growth factors at 0 °C for 10 min before the phosphorylation reaction was started by adding ^{32}P-ATP. The reaction was terminated after another 10 min by adding 40 µl of SDS-sample buffer (80 mM Tris-HCl *p*H 8.8, 30% w/v sucrose, 3.6% SDS, 10 mM dithiothreitol and 0.01% bromophenol blue) and heating at 95 °C for 3 min. After alkylation with iodoacetamide the samples were subjected to SDS-PAGE as described elsewhere[32], using polyacrylamide gradients of 5–10% (*a*, *c*) or 3–10% (*b*) and gel dimensions of 170 × 1 mm. Gels were run at a constant current of 15 mA. After fixation in 20% 5-sulphosalicylic acid for 1 h, staining with Coomassie blue, destaining and drying under vacuum, the gels were autoradiographed using intensifying screens (DuPont, Lightning Plus) and pre-exposed Kodak X-Omat AR films[33]. Exposure was at −70 °C for up to 3 days. The following proteins were used as molecular weight standards: fibronectin (220,000), phosphorylase *b* (94,000), bovine serum albumin (67,000), ovalbumin (43,000) and carbonic anhydrase (30,000).

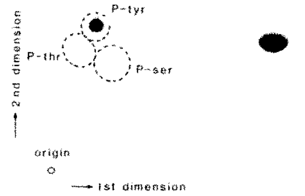

Fig. 2 Phosphoamino acid analysis after PDGF-stimulated phosphorylation. Glial cell membranes (10 µg) were incubated with ^{32}P-ATP and PDGF and the incubation mixture analysed by SDS-PAGE (see Fig. 1 legend). The phosphorylated 175,000-M_r component was localized by autoradiography and the corresponding region of the gel excised. The gel piece was hydrolysed under vacuum in 200 µl 6 M HCl at 110 °C for 2 h. After removal of HCl by evaporation under reduced pressure at 37 °C, the sample was resuspended in 20 µl of acetic acid/formic acid/water (78:25:897) containing 2 mg ml^{-1} each of phosphoserine (Sigma), phosphothreonine (Sigma) and phosphotyrosine (synthesized according to ref. 34). Two-dimensional chromatography was performed on cellulose thin layer plates (20 × 20 cm) as described previously[1], that is, electrophoresis at *p*H 1.9 in acetic acid/formic acid/water (78:25:897) at 1 kV for 3 h (first dimension) followed by ascending chromatography in isobutyric acid/0.5 M ammonia (5:3) (second dimension). Autoradiography was performed as described in Fig. 1 legend. Standards were visualized by ninhydrin staining. Broken lines: ninhydrin staining of phosphoserine (P-Ser), phosphothreonine (P-Thr) and phosphotyrosine (P-Tyr). The unidentified spot with the highest electrophoretic mobility probably consists of inorganic ^{32}P formed during the hydrolysis[1].

control incubation, in which no growth factor was added. Slight effects of PDGF were also seen in other components of the autoradiogram, associated with both increased (for example, a 36,000-M_r protein) and decreased (99,000 M_r) phosphorylation. In a separate experiment to determine the time and dose dependence of the phosphorylation reaction, stimulation of phosphorylation was observed after 1 min at 0 °C and was maximal after 5 min; it was detectable in the presence of 8 nM PDGF and was maximal at 40 nM (not shown).

A similar experiment investigated the effect of EGF on phosphorylation of human fibroblast and glial cell membrane proteins. In the presence of EGF, ^{32}P incorporation increased preferentially in a 170,000-M_r protein of the fibroblast membrane preparation (Fig. 1*a*) and in both a 170,000- and a 150,000-M_r component of the glial cell membrane preparation (Fig. 1*b*). This result is clearly distinct from that obtained with PDGF, indicating that different proteins serve as substrates for the kinases stimulated by the two factors. There is evidence that the EGF receptor proper is phosphorylated after stimulation with EGF[13], but whether PDGF binding induces phosphorylation of the PDGF receptor in an analogous manner remains to be clarified. PDGF seems to be more potent than EGF, producing a higher degree of phosphorylation in fibroblast as well as glial cell membranes. This might be due to the presence of three to five times more PDGF receptors than EGF receptors on both types of cells[23,27].

The epithelial cell line A-431, which has an unusually high number of EGF receptors[28], has been shown to lack high-affinity receptors for PDGF[23]. Membranes from this cell line were therefore incubated with ^{32}P-ATP and PDGF or EGF and the phosphorylation pattern analysed by SDS-PAGE (Fig. 1*c*). After incubation with PDGF the distribution of phosphoproteins was similar to that of the control carried out in the absence of growth factor. As expected, however, EGF was active in this system, increasing the phosphorylation of proteins in the 140,000–160,000-M_r region. The absence of an appreciable effect of PDGF on membranes from this PDGF receptor-negative cell line in conditions where membranes from PDGF receptor-positive cells did respond to PDGF indicates that the response to PDGF was mediated by binding to the PDGF receptor.

We also investigated the specificity of the PDGF-stimulated kinase activity with regard to the type of phospho-accepting amino acid residue involved. Human glial cell membranes were incubated with ^{32}P-ATP in the presence or absence of PDGF and the incubation mixture analysed on SDS-PAGE. The 175,000-M_r component was identified by autoradiography and the corresponding portion of the gel excised. After partial acid hydrolysis the phosphoamino acids were separated on cellulose thin layer plates by electrophoresis at *p*H 1.9 (first direction) and chromatography in isobutyric acid/0.5 M ammonia (5:3) (second direction)[1]. Figure 2 shows an autoradiogram from this experiment, which indicates that the 175,000-M_r component phosphorylated under the influence of PDGF contained only tyrosine-bound phosphate; no labelled phosphoserine or phosphothreonine was detected. An identical result was obtained with the 175,000-M_r ^{32}P-labelled product of fibroblast membranes. Analysis of the 130,000-M_r protein also showed the presence of phosphotyrosine, although some phosphothreonine and phosphoserine were detectable (not shown).

In conclusion, PDGF stimulates tyrosine-specific phosphorylation of two membrane components of human fibroblasts and glial cells with apparent M_rs of 175,000 and 130,000, distinct from the 170,000-M_r component phosphorylated in response to EGF. The precise relationship between the individual members of the growing family of tyrosine-specific protein kinases[9,29,30] remains to be elucidated. As they seem to be involved both in the cellular response to growth factors, like EGF and PDGF, and in tumour-virus induced transformation, including the expression of abnormal growth properties, it is reasonable to believe that this type of enzyme participates in the mediation of growth regulatory signals. Therefore, PDGF and EGF, although they bind to separate cell-surface receptors[23], may function via similar or identical intracellular events, that is, tyrosine-specific phosphorylation of certain growth-controlling proteins. The similarity in some of the phenotypic properties of virus-transformed cells and those of PDGF- or EGF-stimulated cells might then be explained by an overlapping substrate specificity of the respective protein kinases.

A hypothesis for the initiation of genetic recombination in eukaryotes

Paul Markham & Harold L. K. Whitehouse

Botany School, University of Cambridge, Downing Street,
Cambridge CB2 3EA, UK

Initiation of genetic recombination at meiosis in Ascomycete fungi is thought to occur from fixed sites, at least in the majority of events. The simplest way to initiate recombination from fixed sites would be if an endonuclease recognized them and cut one strand of the DNA duplex to allow formation of asymmetric hybrid DNA, as proposed in the Meselson–Radding model of recombination[1]. However data from the *Neurospora crassa his-3* gene[2] and the conversion patterns of a mutation in *Schizosaccharomyces pombe*[3] and one in *Sordaria brevicollis*[4], require this idea of initiation to be modified. Here we propose a hypothesis of initiation that will accommodate these experimental observations, which involves the recognition of initiation sites by an endonuclease capable of migrating along a DNA duplex and that cuts in *trans*.

Catcheside and Angel[2] have described a mutation in *N. crassa* in which the distal quarter of the *his-3* gene with respect to the centromere has been transferred from linkage group I to linkage group VII. On crossing a strain carrying this mutation with strains having a complete *his-3* gene, recombination events were observed in the section of the gene proximal to the break point, but which had been initiated from the distal *cog* site (see Fig. 1). From this they have inferred that recombination events initiated at the *cog* site[5], at the distal end of the gene, are capable of migrating down the gene and past the break point, before hybrid DNA formation. These observations require that the mechanism of initiation of recombination from fixed sites allows for the migration of the initiation event before hybrid DNA formation.

The single mutations M26 in the *ade6* gene of *S. pombe*[3] and YS17 in the *buff* gene of *S. brevicollis*[4] are characterized by high conversion frequency, dramatic elevation of levels of interallelic recombination when the alleles are present in a cross and ability to modify recombination polarity. Such behaviour can best be explained if the effect of the mutations has been to introduce fortuitously a site for the initiation of recombination in their respective genes. Both mutations are also converted predominantly to wild type, so that in crosses with wild-type strains, >95% of all aberrant asci produced have three wild-type products of meiosis and one mutant (see Table 1). This observation is clearly at odds with the simple idea of initiation of recombination, which would predict that if M26 and YS17 are initiation sites, they should be recognized by an endonuclease which would cut a single strand of their DNA duplex. This would provide a free single-strand end to invade one of the chromatids of the other parental type, as predicted by the Meselson–Radding model[1], which would result in either correction back to wild type in the invading strand, which would go undetected because it would restore the normal allele ratio, or persistence of the heteroduplex section. Persistence of the uncorrected invading strand would lead to postmeiotic segregation and a three wild-type plus five mutant spored ascus in *S. brevicollis* or an ascus generating one wild-type colony, one sectored colony and two mutant colonies in *S. pombe*. If correction to mutant occurred in the second strand of the invaded chromatid, then a two wild-type plus six mutant spored ascus would result in *S. brevicollis* or a one wild-type plus three mutant spored ascus in *S.*

pombe. This mechanism cannot explain the observed six wild-type plus two mutant spored asci in *S. brevicollis* and three wild-type plus one mutant spored asci in *S. pombe*. This pattern of behaviour is also observed in the *his-3* gene of *N. crassa*. When only one parental strain in a cross carries the more active form of the *cog* site (*cog*$^+$), the other carrying a much less active form (*cog*), then alleles of the *his-3* gene present on the molecule with the *cog*$^+$ site are preferentially converted to wild type with respect to alleles present on chromatids of the other parental type (*cog*), regardless of the normal gene polarity[5] (see Table 1). This therefore requires that the DNA strand carrying the initiation site becomes the recipient of hybrid DNA and not the donor.

To accommodate all these observations, we suggest that initiation of recombination from fixed sites occurs by the following mechanism (see Fig. 2). It is assumed that the two homologous DNA molecules, one from each parent, are closely paired before nuclease action. An enzyme complex with endonuclease activity recognizes the fixed site (Fig. 2*a*) and either cuts a single strand of a chromatid of the other parental type (Fig. 2*b*), or migrates along the duplex that it has recognized before cutting in *trans* at some random position removed from the initiation site (Fig. 2*c*). This provides the single-strand end capable of producing hybrid DNA as described by the Meselson–Radding model[1]. This hypothesis clearly allows for the migratory capacity necessary to explain the results of Catcheside and Angel[2] and also explains the results obtained with M26, YS17 and *cog*$^+$ by allowing for the cutting of a DNA strand of different parental origin from the initiation site. Catcheside and Angel[2] originally explained their observations by postulating that the nick or gap introduced at the initiation site was capable of being moved along the DNA strand by combined exonuclease and polymerase activity before giving rise to hybrid DNA. The migration of the initiating enzyme complex and the ability of a gap or nick to be moved along the DNA strand are not, of course, mutually exclusive, so it is useful to examine the idea of nick or gap movement in the light of our hypothesis. Catcheside and Angel[2] found that the presence of a fully active (*cog*$^+$) site in only one of the *N. crassa* parental strains in a cross involving the *his-3* interchange mutation affected recombination in the part of the gene beyond the break point. Recombination initiated from *cog*$^+$ was observed in this region only when *cog*$^+$ was in the chromosome carrying the complete *his-3* gene and not when it was in the chromosome carrying the interchange (see Fig. 1). This suggests that if the endonuclease does cut in *trans* then either the nick or gap cannot move along the DNA strand or if it does so it is not recombinogenic, and thus any gap or nick introduced into a complete *his-3* chromatid by an endonuclease recognizing a *cog*$^+$ site in a chromatid carrying the interchange cannot result in recombination beyond the interchange point.

The capacity of enzyme systems to carry out the functions required by this hypothesis has been demonstrated in different but closely related systems. Enzyme migration from a recognition site before acting has been postulated for the type I restriction endonucleases of *Escherichia coli* B and *E. coli* K-12[6-12]. A protein in the *recBC* recombination pathway of *E. coli* is believed to recognize a particular nucleotide sequence[13,14]. To account for the ability of this enzyme to promote recombination at a distance from such a hot spot, it has been suggested that the enzyme usually slides away from its binding site before nicking the DNA[15]. The inability of an intervening non-homologous region to lower the recombination frequency showed that the movement from site of recognition to site of action could not involve the second DNA molecule. Diffusion along the DNA has also been proposed for deoxyribonuclease I of *Ustilago maydis*[16]. Cutting in *trans* as a feature of recombination was proposed by Ross and Howard-Flanders[17,18] for repair in *E. coli* of DNA containing cross-links as a result of exposure to psoralen and 360 nm light. An investigation of recombination between phage λ DNA damaged in this way and undamaged prophage λ, showed that the damaged DNA led to cutting in *trans* of the undamaged homologous DNA. Homology of nucleotide sequence between the two

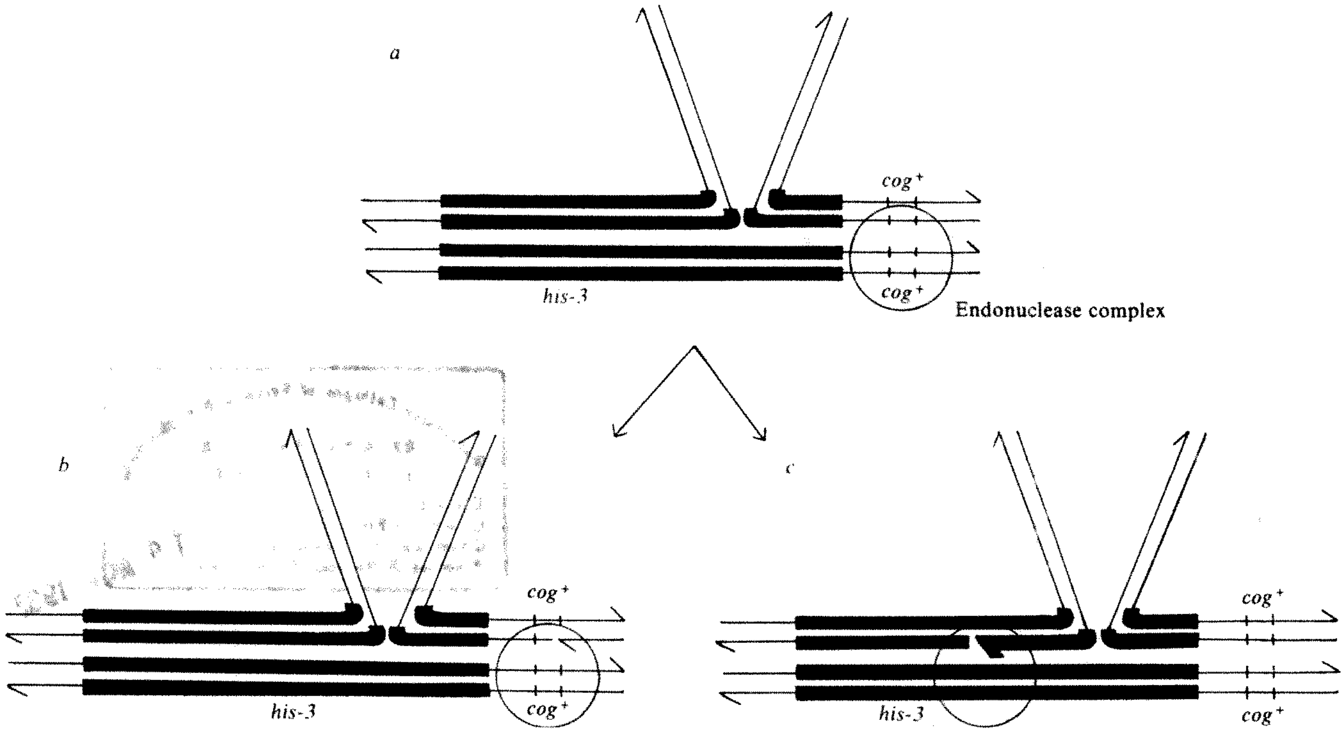

Fig. 2 Diagram illustrating the hypothesis for initiation of recombination. *a*, The endonuclease complex recognizes and binds to the initiation site. Then, either *b*, the endonuclease complex, while still bound to the initiation site, cuts in *trans* one strand of the second chromatid, or *c*, the endonuclease complex migrates along the chromatid which it originally recognized and cuts in *trans* one strand of the second chromatid at a position removed from the initiation site. In this case the enzyme migration leads to a cut being made beyond the interchange break in the second chromatid. After either of these alternative events, invasion of the unbroken chromatid by the free end of the cut strand may lead to hybrid DNA formation. The *his-3* region of *N. crassa* with the interchange break in one chromatid, as illustrated in Fig. 1, is used here to demonstrate the two major features of the hypothesis. The thick lines denote the *his-3* gene. Diagram not drawn to scale.

molecules was necessary for the cutting, which required the host *recA* gene function. Subsequently cutting in *trans* was demonstrated *in vitro* using damaged and undamaged molecules of phage $\phi X174$ DNA (replicative form I) and crude *E. coli* extracts[19].

Enzyme migration along the DNA from an initiation site, before hybrid DNA formation, offers an explanation for several features of eukaryotic recombination. First, it could account for the occurrence of crossing-over between the sites of alleles without either site apparently being included in hybrid DNA. Such crossing-over is frequent in some genes[20] but to account for the polarity often observed in recombination it is necessary to postulate initiation of recombination from fixed sites which appear to be outside genes, such as *cog*. Enzyme migration offers a solution to this paradox by allowing initiation from outside a gene to become manifest only within it on some occasions. Second, there is the mutant specificity of crossing-over between alleles (mutants 137 and 277 in series 46 of *Ascobolus immersus*[20] and mutants 4 and 4b at the *g* locus in *Sordaria fimicola*[21–23]). As there is no hybrid DNA at either mutant site with such crossing-over, it was not obvious how the mutant specificity came about. If a mutant had a molecular structure that interfered with heteroduplex formation, selection for recombinants might imply selection for meiotic cells in which enzyme migration had moved hybrid DNA formation beyond the site of the mutation as in the case of the interchange mutation of *his-3* in *N. crassa*. Work with spore colour mutants of *A. immersus* shows that mutations favouring crossing-over with an allele may be deletions. Thus, mutants 1028, 1130 and 49 of series 19 appeared to be deletions because they showed no recombination with two or more closely linked alleles that recombined with one another. They showed frequent crossing-over with more distant alleles[20]. Such multisite mutations might be expected to interfere with hybrid DNA formation. Third, enzyme migration would allow recombination of distal origin to effect conversion at a proximal site and vice versa, which may have some bearing on apparent cases of polarity reversal.

The Meselson–Radding model of recombination is seen as the most likely consequence of these initiation steps because it best explains data on recombination in eukaryotes. Nevertheless there are alternative mechanisms which could give rise to recombination following the proposed method of initiation.

Bacterial expression of an enzymatically active protein encoded by RSV *src* gene

J. P. McGrath & A. D. Levinson

Department of Molecular Biology, Genentech, Inc.,
460 Point San Bruno Boulevard, South San Francisco,
California 94080, USA

Genetic evidence indicates that the oncogenic potential of Rous sarcoma virus (RSV) resides in a single viral gene denoted *src*[1,2]. The product of this gene is a 60,000-molecular weight (M_r) phosphoprotein ($pp60^{src}$)[3–6] which is linked to the plasma membrane of RSV-infected cells[7–9] by an interaction at its amino terminus[10]. This protein is associated with a protein kinase activity[5,11] capable of phosphorylating tyrosine residues in acceptor proteins[12–15]. A closely related protein occurs in uninfected cells from a wide variety of vertebrates[16–18] and is presumably encoded by a cellular gene that is alleged to be the progenitor of *src*[16–19]. Because detailed enzymological characterization of $pp60^{src}$ has been hampered by a lack of sufficient quantities of purified material, we have produced a bacterial plasmid capable of expressing in *Escherichia coli* a protein closely related to $pp60^{src}$. We report here the construction of this vector, which directs the synthesis in *E. coli* of large quantities of a protein having the size and immunological properties characteristic of $pp60^{src}$. In addition, we have demonstrated tyrosine-specific protein kinase activity associated with the bacterially derived protein, an observation which greatly strengthens the claim that the kinase activity previously observed to be associated with $pp60^{src}$ represents a bona fide property of the protein.

The general approach used for the bacterial synthesis of $pp60^{src}$ was to express the protein as a fusion product involving the amino terminus of human growth hormone (HGH) (Fig. 1). HGH has been synthesized directly in *E. coli* under the control of both the *lac* promoter (pHGH107)[20] and the *trp* promoter (pHGH207-1)[21]. To minimize the involvement of HGH sequences while preserving the essential control elements of the plasmid (including promoter, ribosome binding site and start codon), we digested cloned pHGH207-1 DNA with *Pvu*II and *Bam*HI and isolated the 4,350-base pair (bp) fragment which contains pBR322 sequences, the *trp* promoter and the first 23 amino acids of HGH[20]. An *Eco*RI subclone of the Schmidt–Ruppin strain of RSV containing the entire *src* gene (pSRC-RI)[22] was cut with *Hae*II and *Bam*HI, and the 2,334-bp fragment (encoding all of $pp60^{src}$ except the first 14 amino acids) was ligated into the *trp* expression plasmid. From the known sequence of HGH[20] and $pp60^{src}$ (ref. 22), such a construction was expected to join the HGH and $pp60^{src}$ sequences in the proper reading frame; this was verified by DNA sequence analysis across the HGH-src junction (R. Najarian and P. Seeberg, unpublished results). After screening and

0028–0836/82/050423—03$01.00

identification of the appropriate recombinant molecules, one such clone (pSRCex16) was tested for the expression of the 60,000-M_r HGH–src protein (p60) in *E. coli*. Because the *trp* promoter is induced by a lack of tryptophan in the medium, it was expected that p60 would be induced in pSRCex16-transformed cultures as depletion of tryptophan occurred. As a specific test of this, cultures of *E. coli* K12 strain 294 were transformed with either pBR322, pHGH207-1 or pSRCex16 and grown to $A_{550} = 0.25$ or 1.00 in either LB broth (rich medium) or M9 broth (minimal medium). Tryptophan depletion, and consequent activation of the *trp* promoter, have been shown to occur by $A_{550} = 1.0$ in M9 medium[21,23]. Total cellular extracts were then prepared and the proteins visualized by Coomassie blue staining after electrophoresis on SDS-polyacrylamide gels (Fig. 2). As expected, no overall change in the protein profile occurred in cells transformed with pBR322 regardless of the growth state (Fig. 2*a*). However, in the pHGH207-1 extract (Fig. 2*b*), a prominent protein of 22,000-M_r appeared after induction in M9 medium (lanes c, d); this protein was not observed after corresponding times in LB medium, in which tryptophan is abundant (lanes a, b). This protein represents mature HGH when synthesized under *trp* control[21]. Figure 2*c* demonstrates that in bacteria transformed with pSRCex16, a protein of 60,000-M_r was induced in M9 medium; this corresponds to the size of the protein encoded by *src*[22]. The protein appeared selectively during late growth phase in M9 medium in bacteria transformed with pSRCex16 (Fig. 2*c*, lanes c, d), but not in similar cultures grown in rich medium (LB) (lanes a, b), strongly suggesting that it represents the translational product of the *src* gene under the control of the *trp* promoter. We estimate that when induced, this protein represents ~5% of total bacterial protein (170,000 molecules per cell).

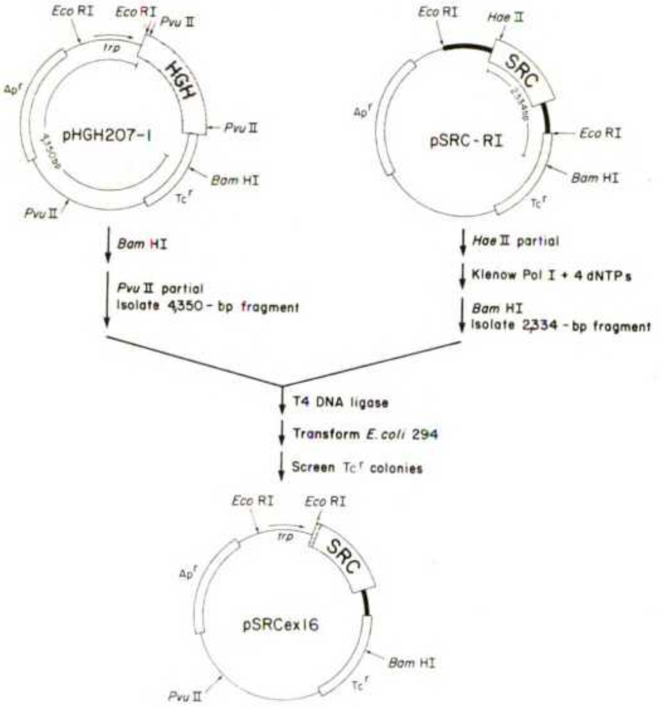

Fig. 1 Construction of a plasmid (pSRCex16) expressing p60. Cloned pGHG207-1 DNA[21] was partially digested with *Pvu*II, then digested to completion with *Bam*HI. The 4,350-bp fragment containing the *trp* promoter, most of pBR322, and the first 69 nucleotides of HGH was isolated from polyacrylamide gels by electroelution[32]. Plasmid pSRC-RI (ref. 22) was partially digested with *Hae*II, and the 3′ single-stranded cohesive termini removed using DNA polymerase I (Klenow fragment) in the presence of four dNTPs. The products were then digested to completion with *Bam*HI, and the 2,334-bp fragment representing 375 base pairs of pBR322 and all but 42 nucleotides of the coding region of pp60^{src} was isolated. The two isolated fragments were ligated to each other using T4 DNA ligase and transformed into *E. coli* 294 (ref. 33). Transformants were selected on LB plates containing 5 $\mu g\ ml^{-1}$ tetracycline (Tc) and screened for recombinant plasmid DNA by digestion with restriction enzymes. (Enzymes were from either New England Biolabs or BRL and were used according to manufacturer's instructions.)

To characterize this protein further, we labelled cultures of *E. coli* transformed with either pBR322 or pSRCex16 with ^{35}S-methionine, and prepared lysates for immunoprecipitation. The specificity and efficacy of this procedure have been well documented[3,5]. Figure 3*a* illustrates that antiserum reactive against pp60^{src} (TBR serum) specifically precipitated a protein of 60,000 M_r from labelled extracts derived from the 294/pSRCex16 culture (lane d). No corresponding protein was seen with control serum, nor was this protein precipitated when TBR serum was used with an extract derived from a 294/pBR322 culture (lane b). As a further test of specificity, we analysed the bacterially derived 60,000-M_r protein by partial hydrolysis with the V8 protease of *Staphylococcus aureus*, according to the procedure of Cleveland *et al.*[24]. The digestion products of bacterially produced p60 are virtually identical to those of RSV-encoded pp60 produced in transformed vertebrate cells, when analysed either by ^{35}S-methionine labelling or by Coomassie blue staining (A.D.L. and Hermann Oppermann, unpublished data).

There is much evidence which suggests that the protein kinase activity observed in preparations of pp60^{src} purified from RSV-transformed vertebrate cells represents an inherent property of the protein[14,15,25]; direct evidence, however, has proved elusive. We therefore assessed the enzymatic activity of bacterially derived p60. We prepared lysates of recombinant *E. coli* strains

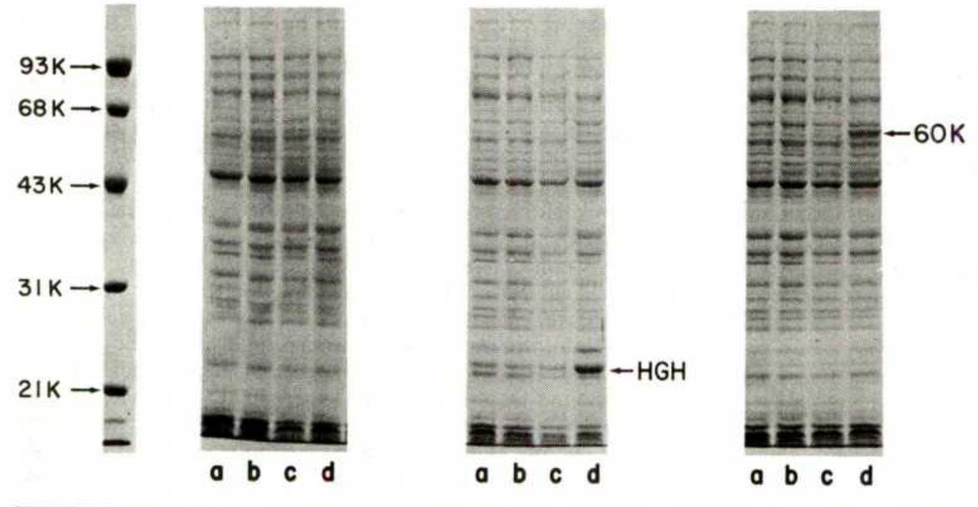

Fig. 2 Analysis of total cellular proteins in *E. coli* transformed with recombinant vectors. *E. coli*, transformed with pBR322 (*a*), pHGH207-1 (*b*), or pSRCex16 (*c*) were grown to $A_{550} = 0.25$ (lanes a, c) or $A_{550} = 1.0$ (lanes b, d) in rich medium (lanes a, b) or minimal medium (lanes c, d) and total cell lysates from 3×10^7 cells were prepared for SDS-gel electrophoresis[34] as described elsewhere[20]. Proteins were visualized by Coomassie blue staining. Molecular weight markers (obtained from BioRad) were electrophoresed in parallel. K represents 1,000 M_r.

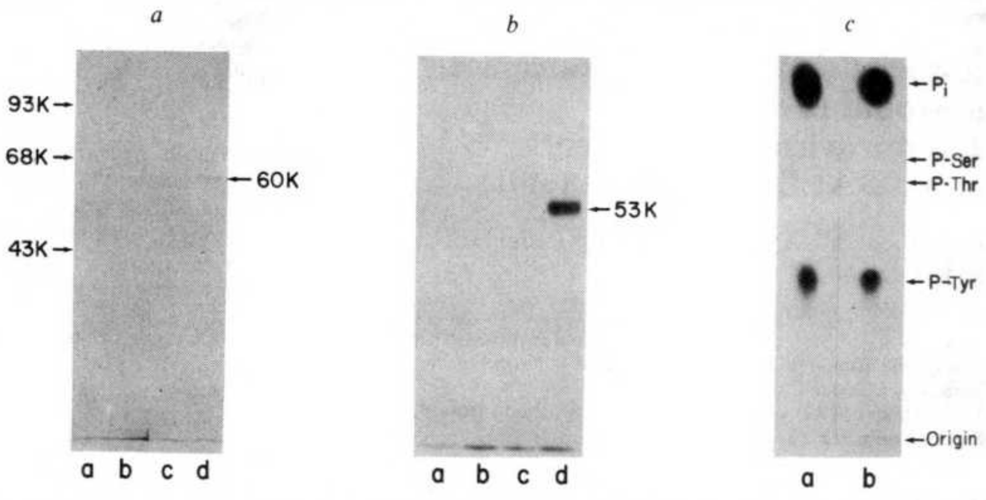

Fig. 3 Analysis of *E. coli* strains transformed with recombinant vectors. *a*, Immunoprecipitation of p60 synthesized by *E. coli*. Cultures (2 ml) of *E. coli* strains transformed with either pBR322 (lanes a, b) or pSRCex16 (lanes c, d) were grown to $A_{550} = 1.0$ in M9 medium (10^9 cells) containing 5 μg ml^{-1} tetracycline, pelleted, washed, re-pelleted and suspended in 2 ml of M9 supplemented with 0.2% glucose, 1 μg ml^{-1} thiamine, 20 μg ml^{-1} standard amino acids (except methionine, which was 2 μg ml^{-1} and tryptophan which was excluded) 5 μg ml^{-1} tetracycline and 20 μCi ml^{-1} ^{35}S-methionine (1,200 Ci mmol^{-1}; NEN). After incubation at 37 °C for 30 min, bacteria were pelleted, resuspended in 0.2 ml 25% sucrose, 50 mM Tris *p*H 8.0. Lysozyme was added to 1 mg m^{-1}. After incubation at 4 °C for 10 min, the extract was adjusted to 0.5% NP-40, 0.4 M NaCl, 5 mM $MgCl_2$ and DNase added to 100 μg ml^{-1} (Worthington). The extract was incubated at 4 °C for 15 min to reduce the viscosity, clarified by centrifugation at 10,000*g* at 4 °C for 5 min, and 10% of the supernatant immunoprecipitated with normal baby rabbit serum (lanes a, c) or TBR serum (lanes b, d) and analysed by electrophoresis in polyacrylamide gels as described elsewhere[5]. The autoradiogram was exposed for 3 h. *b*, Immunoprecipitation of a *src*-specific protein kinase activity from recombinant *E. coli* strains. Cultures (1 ml) of *E. coli* strains transformed with either PBR322 (lanes a, b) or pSRCex16 (lanes c, d) were grown to $A_{550} = 1.0$ in M9 medium containing 5 μg ml^{-1} tetracycline. The bacteria were pelleted and lysates prepared as in *a*. Samples were immunoprecipitated with normal baby rabbit serum (lanes a, c) or TBR serum (lanes b, d) and IgG kinase assays performed and analysed as described elsewhere[17]. *c*, Identification of amino acids phosphorylated by viral pp60^{src} and bacterially derived p60. Immunoglobulin heavy chains phosphorylated by pp60^{src} from RSV-transformed rat cells[15] (lane a) and p60 isolated from *E. coli* (lane b) (see Fig. 2*b*) were isolated, subjected to partial acid hydrolysis and analysed on cellulose thin-layer plates as described elsewhere[12]; 4,500 c.p.m. from each heavy chain were applied to the origin (marked by an arrow). Autoradiography was performed using a fluorescent screen for 8 h. Markers (P-Ser, phosphoserine; P-Thr, phosphothreonine; P-Tyr, phosphotyrosine) were run as internal standards and visualized by ninhydrin staining. (Phosphoserine and phosphothreonine were from Sigma; phosphotyrosine was provided by H. Oppermann.)

harbouring either pBR322 or the p60 expression plasmid (pSRCex16), and kinase activity capable of phosphorylating anti-pp60^{src} antibody was assayed after purification by immunoprecipitation as described elsewhere[5]. Figure 3*b* (lane d) demonstrates that such a protein kinase activity is present in bacteria expressing p60. No activity was present in bacteria not synthesizing p60 (lanes a, b), nor was activity observed in either case when normal serum was used (lanes a, c).

Previous evidence[12–15] has indicated that the kinase activity associated with pp60^{src} phosphorylates acceptor proteins at tyrosine residues rather than at serine and threonine residues, which more typically serve as targets of protein kinase action. To examine the substrate specificity of p60 produced in *E. coli*, we characterized the amino acid on the IgG molecule phosphorylated by bacterially derived preparations of p60. ^{32}P-labelled IgG was isolated and subjected to acid hydrolysis, and the resulting free amino acids separated by TLC[12]. Figure 3*c* reveals that all detectable incorporation of label into antibody occurred at tyrosine residues following reactions using either pp60^{src} derived from RSV-transformed rat cells[15] as a control[12] (lane a), or p60 derived from *E. coli* (lane b). We have attempted to label *E. coli* harbouring the p60 expression plasmid with ^{32}P *in vivo* to identify possible bacterial targets of p60 action, but have so far been unsuccessful. Similarly, we have been unable to detect any 'self' phosphorylation of p60 *in vivo*.

The specificity of the IgG kinase assay has been well documented[5,11,16,17], and has provided the basis for the conclusion that pp60^{src} possesses protein kinase activity. However, the possibility that pp60^{src} specifically interacts with and activates a cellular protein kinase responsible for this activity has not been excluded. Our demonstration that bacterially derived p60 also exhibits protein kinase activity addresses this issue, as given the considerable evolutionary divergence between bacteria and vertebrates, and more specifically the lack of any detectable homology between the *src* gene and DNA from *E. coli*[19], we would expect no specific interaction between the avian gene product (p60) and protein kinases of *E. coli*. Furthermore, *E. coli* has been reported to exhibit no[26–28], or only a very low level[29–31] of protein kinase activity that is specific for phosphorylation at serine and threonine residues[29,30]. We therefore consider that this demonstration of tyrosine-specific protein kinase activity in a highly purified bacterially derived preparation of p60 lends considerable support to the conclusion that this enzymatic activity represents an intrinsic property of the molecule.

We thank J. M. Bishop for providing the pSRC-RI clone and for helpful discussions, H. Opperman for TBR sera and assistance with the phosphoamino acid analysis, F. Fields for technical assistance, D. Goeddel and D. Kleid for advice, and R. Swanson for support and encouragement.

Note added in proof: Since the submission of this letter, similar results have been published by Gilmer and Erikson[35].

Association between a transposed α-globin pseudogene and retrovirus-like elements in the BALB/c mouse genome

Kira Lueders*, Aya Leder†, Philip Leder†‡ & Edward Kuff*

* Laboratory of Biochemistry, National Cancer Institute, and

‡ Department of Genetics, Harvard Medical School, Boston, Massachusetts 02115, USA

Mice have three functional α-globin genes and two closely related pseudogenes[1-5]. In BALB/c mice, the functional genes are known to be clustered on chromosome 11, but the pseudogenes, designated $\alpha\psi3$ and $\alpha\psi4$, are located on chromosomes 15 and 17, respectively[5]. One of the pseudogenes, $\alpha\psi3$, has precisely lost the intervening sequences characteristic of the functional genes[3,4], as if it had been generated from a processed RNA intermediate. It has been suggested that retroviral functions could have been instrumental in the formation of this 'spliceless' pseudogene[6] and its integration at a novel chromosomal locus[5]. We report here that retrovirus-like elements are located on both sides of the $\alpha\psi3$ gene.

The genome of *Mus musculus* contains, in addition to endogenous type B and C retroviral genes, 1,000–2,000 copies of retrovirus-like elements related to the mouse intracisternal type A particle (IAP)[7-10]. The IAP-related sequences are associated with many if not all of the mouse chromosomes[7]. We have isolated multiple examples of IAP genes from BALB/c DNA as recombinants in λ phage Charon 4A[9,10]; a common form is about 7.3 kilobases (kb) long, colinear with the IAP 35S genomic RNA and bounded by 0.3–0.4 kb of terminal repeated sequences (LTRs). Deleted forms of the IAP genetic units have also been observed[8,10].

As IAP genes are abundant and widely distributed throughout the mouse genome, and as integrated retroviruses can have important effects on nearby genetic elements[11], we (K.K.L. and E.L.K.) have been systematically searching for proximities between IAP and other known mouse genes. Originally, we found IAP-related sequences associated with 1% of recombinants in a mouse genomic library consisting of ~15 kb inserts in λ phage[9]. Since then, we have tested 98 recombinants selected because they contained an identifiable mouse gene (unrelated to IAP genes). Five of these clones gave positive reactions when the DNAs were spotted on nitrocellulose membranes and hybridized with ^{32}P-labelled DNA prepared from an isolated IAP gene, MIA14 (refs 9, 10). Among 13 recombinants containing the various α-globin genes and pseudogenes[5], positive reactions were confined to 2 containing the $\alpha\psi3$ sequences. As described below, the spatial relationships between IAP and pseudogene regions were then determined by examining heteroduplexes between these clones and two representative recombinants that contain IAP genes in known orientation and position with respect to the λ arms[9].

Some structural aspects of the recombinants used for heteroduplexing are indicated in Fig. 1*a*, *b*. The IAP isolates do not share flanking sequences and have no known topographical relationship to one another. The two $\alpha\psi3$-containing clones represent overlapping fragments that span about 22 kb of the mouse genome[5]. In $\alpha\psi3$-1, a deletion (Δ) has interrupted the pseudoglobin sequence and brought the truncated gene into juxtaposition with DNA sequences that are located at some distance downstream in the intact genome. In $\alpha\psi3$-2, the original relationships of the $\alpha\psi3$ gene to its flanking sequences have been maintained; this clone shares sequences with $\alpha\psi3$-1 in the region of overlap to the left of the pseudogene (see also Fig. 1*g*).

Representative heteroduplexes are shown in Fig. 1*c*, *d*, while

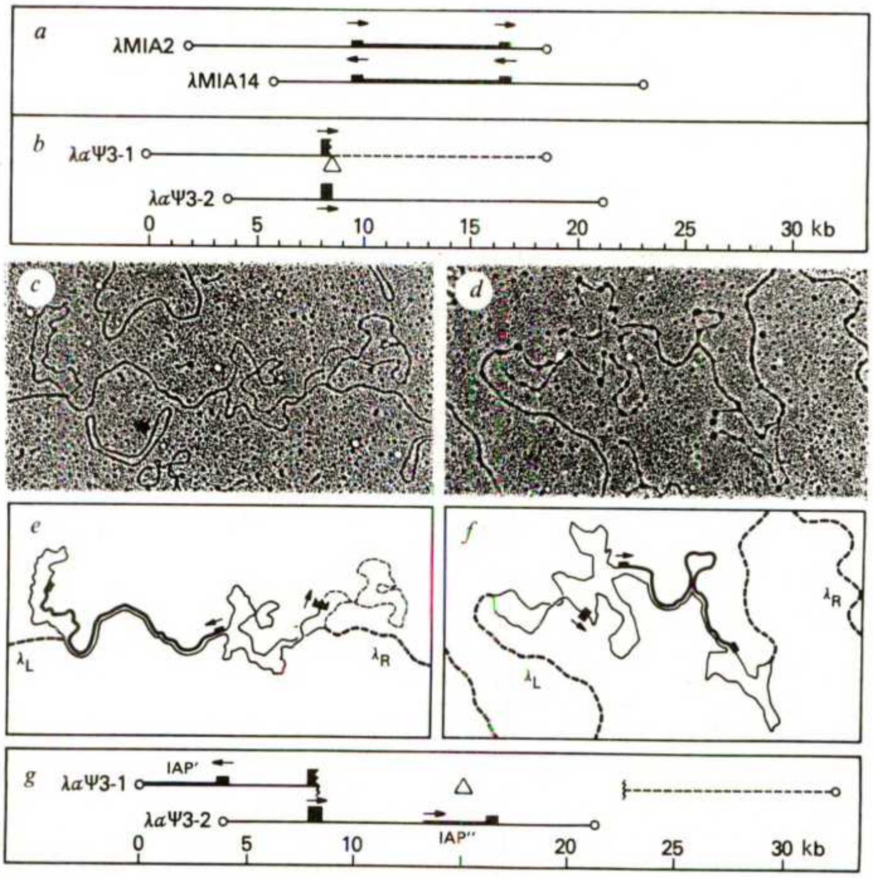

Fig. 1 Heteroduplex mapping of IAP sequences in BALB/c genomic clones containing the pseudo α-globin gene $\alpha\psi3$. The cloned genomic fragments were derived from mouse embryo DNA by partial *Hae*III digestion and inserted into λ Charon 4A via *Eco*RI linkers. All the inserts are shown in the same orientation with respect to the phage arms, that is, with the left arm towards the left of the figure. The 5′–3′ orientations of the genes themselves are indicated by arrows. The λ arms are not shown. The heteroduplexes were prepared and examined as described previously[9,10]. *a*, Diagrams of two previously mapped recombinants[9,10] containing 7.3 kb IAP genes in opposite orientations. The IAP sequences are indicated by heavy lines with thickened ends representing the LTRs. The flanking sequences in the two clones (thin lines) are unrelated. *b*, Two recombinants known[5] to contain $\alpha\psi3$ gene sequences (filled bars) in the indicated locations. The cloned fragments represent overlapping segments from the same region of the mouse genome[5]; however, in $\lambda\psi3$-1, a cloning deletion (Δ) has interrupted the $\alpha\psi3$ gene (jagged edge) and brought it into continuity with more distant downstreams flanking sequences (light broken line). *c*, Typical heteroduplex between $\lambda\alpha\psi3$-1 and λMIA14. A relaxed SV40 DNA molecule (*) provides a 5.2 kb size standard. *d*, Heteroduplex between $\lambda\alpha\psi3$-2 and λMIA2. *e*, *f*, Semi-diagrammatic representations of the heteroduplexes in *c* and *d*, respectively, showing the known positions of the IAP and $\alpha\psi3$ sequences on the individual strands. The λ arms are indicated by heavy broken lines. *g*, The two $\alpha\psi3$-containing clones, showing the positions and orientations of the IAP sequence elements. In $\lambda\alpha\psi3$-1, the presence of the cloning deletion (Δ) is indicated and the right-hand flanking sequences are detached to show that they occupy a position downstream in the intact mouse genome[5].

0028-0836/82/050426—03$01.00

Fig. 1*e*, *f* show the individual strands of each heteroduplex, on which we have indicated the known locations of the IAP and pseudoglobin sequences. In Fig. 1*c*, *e*, the $\lambda\alpha\psi3$-1 strand shows 4 kb of homology with the IAP gene in λMIA14 before being interrupted at the junction with the λ arm. The IAP and $\alpha\psi3$ sequences in this clone have opposed 5'–3' orientations. $\lambda\alpha\psi3$-2 also has a major region of homology with the IAP gene in λMIA2 (Fig. 1*d*, *f*). The IAP sequences in this clone show two major alterations with respect to the complete IAP gene; one involves the loss of 0.8–1 kb of 5' sequence including the 5' LTR; the other represents the deletion of 3 kb of internal sequence. It is unlikely that these deletions are artefacts produced in cloning because deletions of similar size and position have been seen in several other IAP gene isolates[8,10]. In fact, three of the other IAP genes found in association with known mouse genes contained deletions (K.K.L. and E.L.K., unpublished observations). Figure 1*g* summarizes the locations of the IAP and $\alpha\psi3$ sequences in the $\lambda\alpha\psi3$ clones. The structures of the clones as deduced from the heteroduplexes were confirmed by restriction enzyme analysis and hybridization with specific probes derived from selected regions of the IAP gene (data not shown).

Figure 2*a* shows a reconstruction of the genomic region encompassing the $\alpha\psi3$ gene in BALB/c mice. This putative arrangement, in which the gene is bracketed at a distance of ~4 kb on either side by IAP sequences (IAP' and IAP"), was verified by direct restriction analysis of cellular DNA. The individual $\alpha\psi3$-containing clones were first mapped with respect to several restriction endonuclease sites and these sites were positioned on the reconstructed genomic segment (Fig. 2*b*). The predicted restriction fragments were then sought in digests of BALB/c embryo DNA using hybridization probes (see Fig. 3 legend) derived from the 4.7 kb $\alpha\psi3$-containing *Eco*RI fragment shown in Fig. 2*b*. The results (Fig. 3) were entirely consistent with the proposed gene order. The 11.5 kb *Sst*I fragment provided the most direct evidence for this arrangement because it is defined by sites located in the two IAP sequences themselves (Fig. 2). *Sst*I fragments of the same size were detected with the $\alpha\psi3$ probe in the DNAs from several other mouse strains and cell types (livers of AKR/N, C3H, A, C57BL and NIH Swiss mice, BALB/c myeloma and 3T3 fibroblasts), suggesting that the gene order may be a general property of *M. musculus* laboratory strains and is relatively stable in conditions of continued cell division.

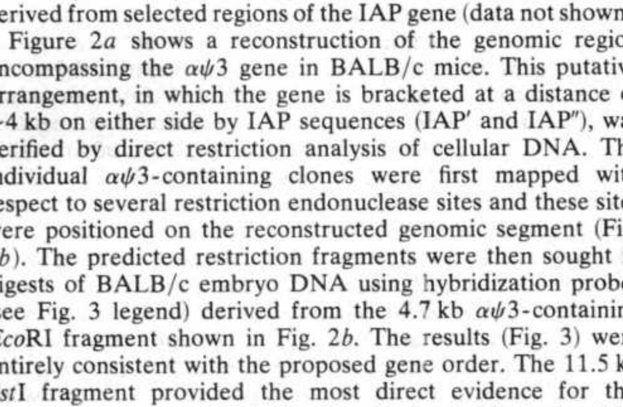

Fig. 2 Putative arrangement of $\alpha\psi3$ and IAP sequences in the BALB/c genome and some restriction endonuclease fragments predicted from this arrangement. *a*, The continuous bar represents a 23 kb segment of genomic DNA reconstructed from the two individual $\alpha\psi3$ clones shown in Fig. 1g. The expanded gene sequences at the top show the positions of the IAP LTRs and the two deletions in IAP". The vertical broken lines in the $\alpha\psi3$ gene indicate the positions of two intervening sequences found in the closely related functional adult α-globin genes but absent in this pseudogene[3]. *b*, Putative locations of *Sst*I, *Pvu*II, *Bst*EII and *Eco*RI restriction endonuclease sites in the regions flanking the $\alpha\psi3$ gene. The individual $\lambda\alpha\psi3$ clones were first mapped with respect to the enzymes, using probes derived from the 4.7 kb $\alpha\psi3$-containing *Eco*RI fragment separately cloned in λgtWES[3]. When these sites were then positioned on the reconstructed genomic region, they yielded the indicated set of predicted fragments.

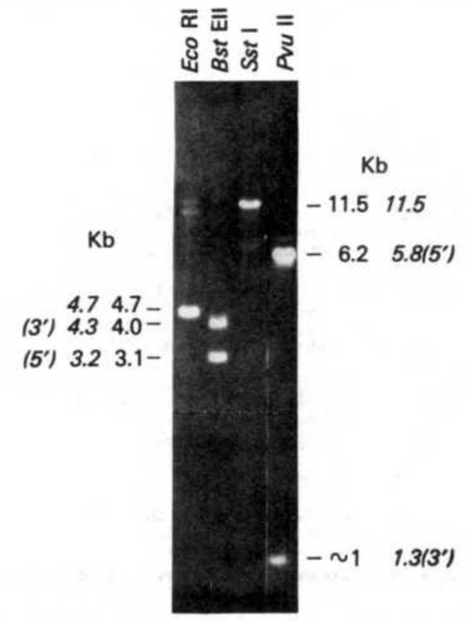

Fig. 3 Comparison of observed genomic restriction endonuclease fragments with those predicted from the sequence arrangement shown in Fig. 2. BALB/c embryo DNA was digested to completion with the indicated enzymes and digests equivalent to 20 μg of DNA were applied to each lane for electrophoresis in 1.2% agarose gels. After transfer to nitrocellulose membranes the fragments were hybridized sequentially with ^{32}P-labelled fragments derived by *Bst*EII cleavage of the 4.7 kb $\alpha\psi3$-containing *Eco*RI fragment (cloned in λgtWES) shown in Fig. 2*b*. The blots were autoradiographed after each hybridization step. In this way, the reactive fragments in the *Bst*EII and *Pvu*II genomic digests were identified in terms of their 5' or 3' position with respect to the $\alpha\psi3$ gene. The observed sizes of the reactive restriction fragments are shown in upright numerals, the predicted sizes in italics.

Retroviruses are known to acquire and transmit cellular genes[6,12,13] and Goff *et al.*[6] have emphasized that such transfer can result in the loss of intervening sequences within the acquired gene after one cycle of virus infection. The topographical relationships shown in Fig. 2 lead us to ask whether IAPs could have had a role in generating the $\alpha\psi3$ gene and/or bringing it to its present location. Because the observed organization of the IAP sequence elements on either side of the $\alpha\psi3$ gene does not permit us to construct a straightforward model for the events in question, it cannot be ruled out that the observed spatial association is fortuitous. On the other hand, although IAPs are not horizontally infectious, they do have several retrovirus-like properties, and their LTRs have a retroviral type of organization[10,14] and contain signal sequences appropriate for the initiation and termination of RNA transcription (L. A. Smith and E. L. Kuff, unpublished observations). In addition, IAPs are expressed in pre-implantation embryos[15–17], that is, at a developmental stage that would facilitate integration of a recombinant provirus into germ-line DNA.

Perhaps the evolutionary aspects of the situation offer the best hope of resolving this problem. It has been estimated that a functional precursor of the α3 pseudogene may have been generated about 24 Myr ago and eventually become inactive as long ago as 17 Myr[18]. Even allowing for major uncertainties inherent in such calculations, these intervals are large with respect to the estimated time of divergence of mouse and rat species from a common ancestral form[19,20]. IAP-related sequences are found not only in these[21,22] but in other more distant rodent species such as gerbil and Syrian hamster[23], so that it is likely that IAP genes or their evolutionary precursors were extant at the time the ancestral α3 pseudogene was formed. Comparative observations using gene libraries prepared from other species may clarify the possible role of IAPs in the evolution of the pseudo α-globin gene.

Note added in proof: Evidence has recently been obtained for the presence of $\alpha\psi3$ genes in the DNAs of other species of *Mus* and of other more distantly related rodents such as rat, gerbil and hamster (R. Taub and A. Leder, unpublished observations).

Structural alterations in J regions of mouse immunoglobulin λ genes are associated with differential gene expression

Jim Miller, Erik Selsing & Ursula Storb

Department of Microbiology and Immunology, University of Washington, Seattle, Washington 98195, USA

Immunoglobulin λ light chains in the mouse comprise three types: λ1, λ2 and λ3 (refs 1–3 respectively) and are encoded by three constant region (Cλ) and two variable region (Vλ) genes. The Cλ2 and Cλ3 protein sequences differ at only 5 amino acid positions whereas Cλ1 differs from both by about 30 amino acids. The Cλ1 and Cλ3 genes are closely linked[4], separated by ~3 kilobases (kb) of DNA. The Cλ2 gene is closely linked to a Cλ4 gene, but is an unknown distance from the Cλ3–Cλ1 cluster[4,5]. Although the Cλ4 gene shares homology with Cλ1, we show here that it represents a pseudogene. Only two germ-line V genes appear to be expressed in mouse λ chains: Vλ1 is used in association with either Cλ1 (ref. 1) or Cλ3 (ref. 6), while Vλ2 has only been found with Cλ2 (ref. 2). Differential gene expression is observed in the λ locus. Among mouse serum antibodies, λ1 chains occur 10 times more frequently than λ2 (ref. 7) or λ3 (ref. 3) chains while λ4 chains have not been identified. We have now searched for structural differences between Cλ genes which could explain this differential expression. Our nucleotide sequence analysis indicates that Cλ4 is not expressed due to an inactive RNA splice site. Although no structural defects were found in Cλ2 or Cλ3, substitutions in the rearrangement recognition sequences associated with Jλ2 and Jλ3 segments, together with nearby competing pseudo recognition sequences, may explain the relatively low levels of Cλ2 and Cλ3 gene expression.

Immunoglobulin gene expression requires the recombinational joining of V and C gene segments via a small joining (J) DNA segment[8–11]. J segments characteristically display V–J joining and RNA splicing recognition sequences separated by a short coding sequence (13 amino acids). We have found J segments 1.2–1.4 kb 5′ of each Cλ gene (Fig. 1). In each Jλ segment, sequences showing homology to V–J joining and RNA splice sites are observed (Fig. 2). In the Jλ1, Jλ2 and Jλ3 genes the coding sequences correspond exactly to the J peptide segments in λ1, λ2 and λ3 light chains respectively (refs 2, 12 and H. Eisen, personal communication).

The J region associated with Cλ4 was of particular interest because λ4 proteins have not been observed among mouse light chains; comparison of the Jλ4 sequence with the closely homologous Jλ1 sequence suggests an explanation for this observation (Fig. 2). Relative to Jλ1, Jλ4 has both a deletion of two nucleotides near the beginning of the coding sequence and a nucleotide substitution in a critical position of the RNA splice site. The substitution changes the G-T, found in all 5′ intron sequences[13], to an A-T. Even if this unconventional splice site (*a* in Fig. 2) were used, the 2-base pair (bp) deletion at the beginning of Jλ4 would result in a shortened, and possibly nonfunctional, mRNA. A possible alternative splice site for Jλ4 (*b* in Fig. 2) results in termination codons in all mRNA reading frames, either in Jλ4 (Fig. 2) or in Cλ4 (E.S., J.M., R. Wilson and U.S., in preparation). Apparently, rearranged Vλ2–Jλ4–Cλ4 genes would not result in an active mRNA. Thus, Cλ4 represents a nonfunctional pseudogene.

Although the events leading to the inactivation of the Cλ4 gene cannot be ordered unambiguously, it is possible that, like Jκ3 in the κ gene complex[8,9], Jλ4 initially became inactive due to an alteration in its RNA splice site. Subsequent evolutionary drift could have resulted in the 2-bp deletion.

Mouse κ and H chain C genes are associated with four functional and one nonfunctional J gene segment[8–11]. Known λ protein chains only contain one type of J segment: Jλ1 for λ1, Jλ2 for λ2 and Jλ3 for λ3 (refs 12, 2 and H. Eisen, personal communication, respectively). A corresponding J segment is present 5′ of each of the Cλ genes (Fig. 1). No additional J segments were found in the regions 250–350 bp 3′ of Jλ1, Jλ2, Jλ3 or Jλ4, that is, at the distance J segments are spaced in κ and H chain genes.

However, there is another J-like region 601 nucleotides 3′ from the end of Jλ3 (see Fig. 1). Identified by sequences homologous to V–J recombination and RNA splice sites, this J also contains a potential coding region of the appropriate length, in which all three possible reading frames are open (Fig. 2). Nevertheless, certain characteristics of J regions are missing. First, the recognition sequence contains a poorly matched heptamer. Second, the nucleotides in the potential coding region have little resemblance to those of known J segments. Furthermore, this resemblance is no greater when these nucleotides are translated into amino acids in any of the three open reading frames. We conclude that this is a pseudo J region (ψJλ3). ψJλ3 differs in structure from the recently detected ψJH, which contains in-phase termination codons[10].

Although we find a pseudo J sequence associated with Cλ3, in the analogous position relative to Cλ2 there is no well matched V–J recombination or RNA splice site (d (downstream) Jλ2 in Fig. 2). Sequences similar to V–J joining sites are found 117 and 113 bp 3′ of Jλ1 and Jλ4 (dJλ1 and dJλ4 in Figs 1, 2). It appears possible, therefore, that, like Cκ and CH genes, Cλ genes once had associated multiple Jλ sequences but these have been partially lost during evolution.

Do the primary DNA sequences of λ genes suggest a basis for the differential serum concentrations found for λ1, λ2 and λ3 protein chains? Comparison of Cλ1 and Cλ3 is most straightforward because both are associated with Vλ1 in the respective light chains. As only the very conservative substitutions, Trp–Val in Jλ1 compared with Phe–Ile in Jλ3, are found in the third hypervariable region[14] of germ-line λ1 and λ3 genes (Fig. 2), it seems unlikely that differential expression of λ1 and λ3 results from different affinities for antigen. In addition, we have found normal RNA splicing and translation termination signal sequences associated with Cλ2 and Cλ3 as well as with Cλ1 (the sequencing strategy for the Cλ genes is shown in Fig. 1; data will be presented elsewhere: E.S., J.M., R. Wilson and U.S., in preparation). Thus, the low levels of Cλ2 and Cλ3 proteins in mouse serum are not due to any apparent faulty processing signals associated with the Cλ2 and Cλ3 exons.

Although preferential association of the Cλ1 protein region with CH regions cannot be ruled out, structural features in the DNA sequences flanking the J genes could explain the differential gene expression. All J segments associated with mouse κ[8,9], H[10,11] and λ[15] genes and human κ genes (P. Hieter, J. Maizel and

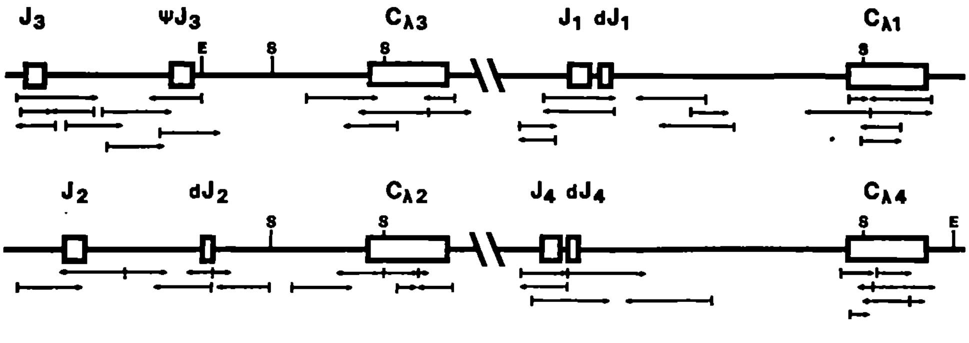

Fig. 1 Organization and sequence analysis of the four Cλ genes. Sequencing strategy of the four Cλ genes and their corresponding J regions (open boxes). Clones containing either the Cλ3–Cλ1 (ref. 4) or the Cλ2–Cλ4 (E.S., J.M., R. Wilson and U.S., in preparation) gene clusters were obtained from a BALB/c kidney DNA library. The distance between Cλ3 and Cλ1 is 3.2 kb, that between Cλ2 and Cλ4 is 3.0 kb. The sequence was determined by the dideoxynucleotide termination method[22] as described previously[23] or in conjunction with M13 cloning vectors[24]. The direction and extent of the sequence determinations are indicated by arrows. The pseudo (ψ) and downstream (d) J regions are described in the text. E, *Eco*RI; S, *Sac*I.

P. Leder, personal communication) are preceded 5′ by two blocks of conserved 'recognition' sequences presumed to be involved in V–J joining: a nanomer with the consensus sequence GGTTTTTGT separated by a spacer of 12 (λ) or 21–24 (κ and H) nucleotides from a heptamer with the consensus sequence CACTGTG. Differences in the Jλ1 and Jλ3 recognition sequences could explain the unequal expression of λ1 and λ3 genes, assuming homology with the consensus recognition sequence determines the frequency of V–J joining. The recognition sequences of both Jλ1 and Jλ3 exhibit three mismatches when compared with the consensus sequence (Fig. 2). However, the mismatches in Jλ3 are all clustered at the 3′ end of the nanomer whereas those in Jλ1 are distributed over both the nanomer and heptamer. No Jκ or JH recognition sequences exhibit multiple mismatches at the 3′ end of the nanomer.

Also striking in the Jλ3 recognition sequence is the presence of 'interfering' nanomers. The ψJλ3 gene possesses a nanomer which shows greater homology to the consensus sequence than does the Jλ3 nanomer. Also, extraneous nanomers occur in the recognition sequence spacers of both Jλ3 and ψJλ3 V–J joining sites (Fig. 2), which are also more homologous with the consensus nanomer than is the functional Jλ3 nanomer. No other JH, Jκ, or Jλ (except Jλ2, see below) exhibits a nanomer sequence in the recognition site spacer. These extra recognition sequences surrounding the Jλ3 region might create substrate competition for putative V–J recombination proteins, which could then interfere with correct recombination to Jλ3, and so decrease the ratio of Vλ1–Jλ3 to Vλ1–Jλ1 rearrangements.

Although it is not known whether λ2 containing immunoglobulins have less affinity for common antigens than those containing λ1, the low level of λ2 expression could result from the same structural defects as in λ3. For example, there are deviations from the consensus sequence clustered at the 3′ end of the Jλ2 nanomer and an interfering nanomer exists in the recognition site spacer which is more closely matched to the consensus than is the Jλ2 nanomer. In addition, Jλ4 and dJλ4 could compete with Jλ2 for Vλ2 rearrangements. As both Jλ4 and dJλ4 lack functional RNA splice sites, any rearrangement into these J regions would lead to a nonfunctional transcription unit. These structural features, in and around Jλ2, could interfere with proper Vλ2–Jλ2 joining and result in decreased expression of λ2.

Jλ1 is also associated with an interfering recognition sequence (dJλ1, see Figs 1, 2). This sequence is not as well matched to the consensus as is Jλ1 and, therefore, less likely to interfere with λ1 expression. Thus, the differential expression of the λ isotypes in normal mouse serum correlates well with the structural integrity of the J region associated with the individual Cλ genes.

The λ gene family not only shows variation in isotype expression, but as a whole represents only 5% of mouse serum immunoglobulin light chains[7,16]. Studies of individual immunoglobulin-producing cells have also indicated that the rearrangement frequency is much lower for λ genes than for κ genes[17,18]. Note that all functional J segments associated with Cλ genes exhibit a 3′-terminal C or G residue in their recognition sequence nanomers. Because this position is invariably a T in all other Jκ and JH segments, it is tempting to speculate that these substitutions might particularly affect the V–J joining rate. However, as several components may differently affect λ and κ genes (such as antigenic selection, specific mechanisms which might rearrange κ genes before λ genes) it would be premature to implicate a specific position in the nanomer sequence. In particular, the ratio of λ and κ rearrangements may only reflect the different numbers of V genes (50–2,000 for κ[19,20] compared

Fig. 2 Comparison of the λ J region DNA segments. The DNA sequences were obtained as described in Fig. 1 legend. Rearrangement recognition sequences and RNA splice sites are in capital letters. Differences from the consensus sequences (see text) are underlined. *a* And *b* indicate possible RNA splice sites in Jλ4. dJλ1, dJλ2, dJλ4: recognition sequences located 117, 600 and 113 bp respectively 3′ of the beginning of the nanomer preceding Jλ1, Jλ3 and Jλ4. * Indicates positions of the J recognition sequences which are invariant in functional κ and H genes. →, Only reading frame of Jλ4 which, using RNA splice site *a*, would also be open in Cλ4.

with 2 for λ) associated with these families. If recombination occurs equally at λ and κ recognition sites and functional recombinations represent only a portion of these events, then the observed λ/κ rearrangement ratio could merely be a statistical phenomenon. Further investigation will be required to clarify this point.

Our studies suggest that differences in the J regions may have profound effects on the level of immunoglobulin gene expression. In particular, clustering of mismatches at the 3′ end of J gene recognition nanomers and competition by interfering recognition sequences may be important. The degree of alteration of the Jλ regions is well correlated with their respective frequency of expression. Such alterations may also explain the *cis*-dominant defect that results in very low levels of λ1 expression in the SJL mouse strain[21]. In addition, we have found that the J region associated with the Cλ4 gene, whose product has not been found among λ chains, has lost its 3′ RNA splice site by a point mutation. Thus the Jλ4–Cλ4 gene represents a pseudogene. Because each Cλ gene is associated with only a single J region, unlike κ and H chains[8-11], the inactivation of a Jλ region would cause the entire gene to become nonfunctional.

We thank R. Wilson and R. Gelinas for help with M.13 cloning, M. McMullen, P. Engler and J. Voss for the isolation of some of the λ gene containing clones, and B. Arp for some of the DNA sequence. This work was supported by NSF grant PCM78-13205 and NIH grants CA/AI25754 and DE02600. J.M. is supported by NIH training grant GM07270.

Nucleotide sequence of a macronuclear gene for actin in *Oxytricha fallax*

Brian P. Kaine* & Brian B. Speart†

Section of Biological Sciences, Department of Biochemistry,
Molecular and Cell Biology, Northwestern University, Evanston,
Illinois 60201, USA

The hypotrichous ciliated protozoan *Oxytricha fallax* possesses a mechanism for processing its genome into a collection of small, gene-sized, transcriptionally active sections. Macronuclear DNA is arranged as short achromosomal sections, 0.5–22 kilobase pairs (kbp) long, while micronuclear DNA has a typical chromosomal organization[1,2]. Macronuclear DNA is derived from micronuclear DNA by a process of polytene chromosome fragmentation with a resultant decrease in DNA sequence complexity[3,4]. The isolation of intact macronuclear DNA sections enables the study of specific structural units of genetic material that occur naturally in the organism. We have previously described[5] the construction of a recombinant plasmid, pOfACT (1.6), which contains an intact 1.6-kb length of macronuclear DNA (Fig. 1) homologous to a yeast actin gene[6]. We now present the complete nucleotide sequence of the cloned DNA molecule and the derived sequence of the actin protein which it encodes. As the sequence is that of a complete, naturally occurring DNA molecule, it shows all *cis*-active regulatory regions in addition to the coding region. The actin protein encoded differs considerably from other known actins.

The complete nucleotide sequence of the cloned 1.6-kb macronuclear DNA section, determined by the chemical procedure of Maxam and Gilbert[7], is shown in Fig. 2. The overall length of the 1.6-kb insert from plasmid pOfACT(1.6) is 1,561 bp, measured from the *Pst*I cleavage sites which flank the cloned sequence. This length includes the cleavage sites and the polynucleotide tails which were added enzymatically during construction of the plasmid. Incubation of macronuclear DNA with terminal transferase and cloning in *Escherichia coli* added 24 dG bases to the 5′ end and 26 dC bases to the 3′ end of the 1.6-kb section.

DNA sequencing has demonstrated an inverted repeat sequence at both ends of the cloned 1.6-kb macronuclear section. This sequence takes the form of a repeating octanucleotide 3′-GGGGTTTT...5′. Subsequent sequencing of total native macronuclear DNA (A. F. Pluta, B.P.K. and B.B.S., in preparation) has confirmed the presence of this terminal sequence on all macronuclear DNA molecules. Similar sequences have been found at the macronuclear termini of other related species[8,9]. The repeat sequences does not appear at any internal locations in the 1.6-kb clone.

The nucleotide sequence 5′ to the actin-coding region but 3′ to the terminal repeat is 183 bases long. Several possible promoters for RNA polymerase have been identified in this region. Three sequences beginning at positions 8, 137 and 154 (Fig. 2) resemble the 'Hogness box' sequence, TATAAAA. This sequence (or others closely related to it) has been found in 5′ regions flanking numerous eukaryotic genes and is believed to be a transcriptional promoter[10,11]. Surprisingly, the 'Pribnow box' prokaryotic transcriptional promoter sequence, TATGATG[12], occurs at position 20. If this sequence is indeed a functional promoter, it is possible that *O. fallax* possesses an RNA polymerase similar to that of prokaryotic organisms.

A second group of putative regulatory signals resembles the pentanucleotide CCAAT, which has also been implicated in the control of transcription[13]. These sequences occur at positions −2 (beginning with the last two bases of the terminal repeat on the anti-sense strand), 101, 129 and 152 (Fig. 2). A similar sequence, CCAAA, forms part of the terminal repeats upstream from the actin-coding region. The significance, if any, of this sequence occurring in the repeats is unknown.

The DNA sequence 3′ to the termination codon but 5′ to the terminal repeats is 186 bases long. Like the 5′ region, the 3′-flanking region also contains several possible control signals. The pentanucleotide AATAA occurs downstream from the termination codon at positions 1,412 and 1,424. This sequence may be a potential signal for polyadenylation and is commonly found near the end of the 3′-untranslated region of eukaryotic mRNAs[14,15]. A sequence that serves as a transcriptional termination signal for type III genes, TTTT[16], occurs 3′ to the termination codon at position 1,433. This tetranucleotide also occurs as part of the terminal repeats at the 3′ end of the anti-sense strand. As with the CCAAA pentanucleotide in the 5′-terminal repeats, it is unknown whether the TTTT tetranucleotide in the 3′ repeats has an actual role in RNA synthesis.

The 3′-flanking region contains a sequence similar to that

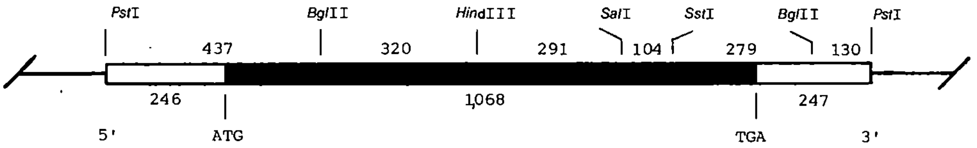
Fig. 1 Restriction map of plasmid pOfACT(1.6). The restriction sites shown are those used in sequencing. ■, *O. fallax* actin-coding sequence; □, *O. fallax* non-coding sequence; ——, pBR322 sequence. Sizes are shown in base pairs.



found near the origin of DNA replication on the polyoma virus chromosome. The sequence in *O. fallax*, between positions 1409 and 1436, consists of the palindromic sequence TTTAATAATTT (1,409–1,419) and an adjacent 15-base sequence, AAAATAACTTATTTT (1,422–1,436), capable of forming a self-complementary hairpin loop. The polyoma virus sequence consists of an A+T-rich palindrome located near a 15-base G+C-rich hairpin[17]. Recently, several stretches of DNA referred to as autonomously replicating sequences (ARS) have been isolated[18]. When linked to a bacterial plasmid, these elements are capable of replication in yeast. The sequence of one ARS element contains an 18-base A+T-rich region of perfect symmetry which is capable of forming a hairpin loop[19]. These similarities suggest that the origin of replication of the *O. fallax* macronuclear DNA molecule may be the region 1,409–1,436.

The overall length of the coding region on the 1.6-kb macronuclear DNA molecule is 1,068 bases from the initiation codon ATG (position 184) to the termination codon TGA (position 1,255). The amino acid sequence encoded (see Fig. 3) has 65.4% sequence homology with that of yeast actin[6], calculated as the number of amino acid residues in common divided by the number of co-linear amino acids. Similarly, the nucleotide sequence homology between the yeast and *O. fallax* actin genes is 65.7%. There are no intervening sequences in the *O. fallax* actin gene. However, this does not rule out the possibility of interruptions in the actin-coding sequence as it exists in the micronuclear DNA; such intervening sequences could be removed during macronuclear development.

The *O. fallax* actin sequence is 356 amino acids long whereas actins from other organisms, including yeast, consist of 374 or 375 amino acids. This is due primarily to the absence of 18 amino acids that, in yeast, would occupy the region containing residues 65–82. Restriction mapping has demonstrated that the corresponding 54-bp deletion occurs in macronuclear DNA as well as in pOfACT(1.6) and thus is not an artefact of cloning. The *O. fallax* actin sequence is also one amino acid shorter at the N terminus than yeast and has one additional internal residue (Leu 258).

The macronuclear gene appears to be expressed, rather than being an inactive pseudogene. *O. fallax* RNA, ranging in size from 7 to 15S, was labelled with ^{32}P and hybridized to pOfACT(1.6) that had been cut with *Pst*I. The RNA hybridized strongly to the *O. fallax* actin sequence but not to pBR322 (Fig. 4). The conditions of hybridization were sufficiently stringent so that the actin DNA could bind only to its homologous RNA sequence[5]. Therefore, the 1.6-kb actin sequence must be transcribed, and we presume that it is also translated, as it has a continuous open reading frame.

Fig. 2 The complete nucleotide sequence of the 1.6-kb macronuclear DNA insert from plasmid pOfACT(1.6). The sequence shown is that of the anti-sense strand. Directions are assigned with respect to the orientation of the actin-coding sequence on the DNA molecule. Bases are numbered starting with the first base occurring internally to the inverted terminal repeat at the 5′ end of the molecule. Putative regulatory signals are underlined.

Fig. 3 The amino acid sequence encoded by the cloned 1.6-kb *O. fallax* macronuclear actin gene. Regions differing in homology from the yeast actin sequence[6] are boxed, with the yeast residues given in the upper half of each box. Positions of deleted residues are indicated by broken lines.

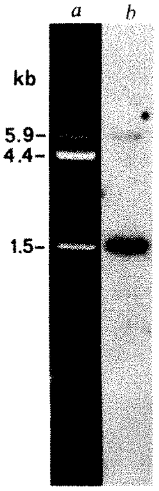

Fig. 4 Hybridization of *O. fallax* RNA to pOfACT(1.6). The plasmid pOfACT(1.6) was digested to near completion with *Pst*I, the fragments were separated by electrophoresis in a 1.2% agarose gel and then blotted on to nitrocellulose. *O. fallax* 7–15S RNA was cleaved by brief alkaline hydrolysis and labelled with ^{32}P using polynucleotide kinase and ^{32}P-ATP. Hybridization was carried out for 42 h at 65 °C with 1 M [Na$^+$] in conditions described previously[5]. The filter was washed in 2×SSC, 0.1% SDS, 0.1% Na-pyrophosphate at 65 °C. The input RNA was shown to be alkaline hydrolysable, thus ruling out DNA–DNA hybridization. *a*, DNA stained with ethidium bromide showin the *O. fallax* actin sequence at 1.5 kb, pBR322 at 4.4 kb and linear plasmid at 5.9 kb. *b*, Hybridization of *O. fallax* RNA.

The actins are a strongly conserved family of eukaryotic proteins. Actin isolated from the slime mold *Physarum polycephalum*, for example, differs from mammalian cytoplasmic actin in only 17 out of 375 amino acid residues—95.5% homology[20]. However, the *O. fallax* actin encoded by the 1.6-kb long macronuclear DNA differs considerably in structure from these proteins. It is possible that the *O. fallax* actin has become highly specialized in function. Ciliated protozoans are complex cells having a highly ordered anatomical structure, including such features as ciliary rows, an oral apparatus and a cytoproct (cell anus)[21]. It would not be unusual for these organisms to have proteins modified for use in such specialized structures.

Ciliate actin has not been well characterized. A protein that co-migrates with muscle actin has been isolated from *Tetrahymena thermophila*[22] but is absent from *Tetrahymena pyriformis* (N. E. Williams, personal communication). Recently, a fibre-forming protein (FFP-38) has been found in both *Tetrahymena* species[23] that co-precipitates with muscle myosin and is found in contractile regions of the cell. However, FFP-38 is smaller than muscle actin and is biochemically and antigenically distinct. It is possible that FFP-38 may be homologous to the *O. fallax* sequence.

A second *O. fallax* macronuclear DNA molecule has been detected that hybridizes to the yeast actin gene[5]. This molecule is 1.4 kb long and differs substantially in nucleotide sequence from pOfACT (1.6). However, the 1.4-kb molecule hybridizes no more readily to the yeast actin sequence than does the 1.6-kb molecule, and the melting temperatures of the hybrids produced are similar. It is unlikely that the 1.4-kb molecule is any more a true actin gene than the 1.6-kb molecule. Rather, we view the actin genes in *O. fallax* as a multigene family, as in most other eukaryotes[24].

The unusual *O. fallax* actin might also reflect a large evolutionary distance between the ciliates and other eukaryotes. Such an interpretation has been supported by other experimental evidence[25–27] and it has been suggested[20] that the ciliates formed a distinct phylogenetic group which may have been the first to separate from the main eukaryotic stem. Our results support this hypothesis.

From the sequence of the *O. fallax* actin gene we conclude that, in hypotrichous ciliates, first, only a small amount of DNA is necessary to make up the noncoding regions of a complete genetic unit, which, in this case is only ~200 bp at each end. Second, the sequenced DNA molecule clearly contains only a single gene. Thus the earlier hypothesis of Prescott and Murti[1] that the macronucleus is a collection of single-gene DNA molecules lacking non-genic spacer sequences seems correct.

Agrobacterium rhizogenes inserts T-DNA into the genomes of the host plant root cells

Agrobacterium rhizogenes, which induces hairy root disease of dicotyledonous plants[1], is closely related to _Agrobacterium tumefaciens_, the causative agent of crown gall disease[1–3]. Virulence in both species is conferred by large plasmids[4–7]. Infected plant tissue synthesizes novel metabolites, opines[8–11], that are not found in normal plant tissues. The pattern of opines synthesized is determined by the type of virulence plasmid in the bacterium, and in general virulence plasmids confer on the host bacterium the ability to catabolize the same opines (refs 8, 12, 13 and A.P. _et al._, in preparation). Opine synthesis persists when the affected plant tissue is cultivated _in vitro_ in the absence of the pathogenic bacterium[9–11,14,15], which in the case of crown gall tumours is a consequence of gene transfer from the pathogen to the plant cells. A small specific part of the tumour-inducing (Ti) plasmid of _A. tumefaciens_, termed T-DNA (transferred DNA), is incorporated into host plant nuclear DNA[16–21] and transcribed into mRNA[18,22–25]. A specific region of T-DNA confers the ability to synthesize the characteristic opine[26,27]. Synthesis of opines is thus a natural example of genetic engineering in which the agent is the Ti plasmid of, _A. tumefaciens_. The discovery of opines in roots induced by _A. rhizogenes_ (ref. 11 and A.P. _et al._, in preparation) suggested that they too might contain T-DNA derived from the virulence plasmid of the pathogen. We report here DNA hybridization studies that confirm this hypothesis.

A. rhizogenes strain 8196 (from Dr J. Lippincott) contains three plasmids, the intermediate-sized one being the virulence plasmid, isolated in transconjugant C58C1 (pRi 8196) (Fig. 1). Similar data have been reported by White and Nester[7] for *A.*

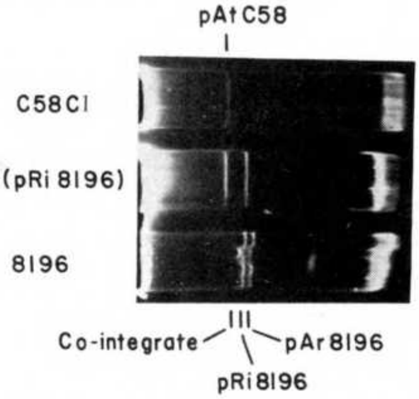

Fig. 1 Eckhardt gel[39] analysis of plasmids of *A. rhizogenes* 8196 and C58C1 (pRi 8196). Transconjugant strain C58C1 (pRi 8196) was obtained by conjugation of *A. rhizogenes* 8196 with *A. tumefaciens* C58C1, a strain cured of its Ti plasmid[4]. The donor strain was grown overnight in AT medium[40] with *N*-(1-mannityl)-glutamic acid ($2\ g^{-1}$)[11] as the sole carbon source; the recipient strain was grown overnight in AT medium with mannitol as sole carbon source. Recipient bacteria (10^8) were spread on AT agar with *N*-(1-mannityl)-glutamic acid as sole carbon source, rifampicin ($100\ \mu g\ ml^{-1}$) and streptomycin ($500\ \mu g\ ml^{-1}$) (drugs to which only the recipient is resistant). Donor bacteria (5×10^7) were applied to the lawn as a drop of liquid culture. Transconjugant colonies were picked after 8 days at 25 °C, and cloned on selective medium. Plasmids were visualized by a modification[41] of the Eckhardt gel technique. Strain 8196 contained three plasmids whose relative amounts varied between experiments. The two smaller plasmids (visible here) were sometimes impoverished and a larger plasmid (almost invisible here) predominant. We presume the larger plasmid to be a co-integrate of the smaller ones, analogous to the plasmids of *A. rhizogenes* strain 15824 (ref. 7). The transconjugant strain possesses the larger of the two small plasmids of the donor strain, and is virulent. It also contains the large cryptic plasmid of strain C58C1 (ref. 42).

rhizogenes 15834. As expected, plasmid DNA isolated[29] from C58C1 (pRi 8196) exhibits only a subset of the *Bam*HI fragments of plasmid from the parent 8196 strain (see Fig. 2). The giant cryptic plasmid of C58C1 (isolated in extremely poor yield because of its size) is present only as a trace contaminant in this preparation of pRi 8196. We propose the designation Ri for root-inducing virulence plasmids[11], analogous to Ti for tumour-inducing plasmids[30,31]. Contour length measurements by Constantino *et al.*[32] have shown pRi 8196 to have a molecular weight (MW) of $137 \pm 2 \times 10^6$.

In our experiments we used carrot disks inoculated with $\sim 10^9$ bacteria in 0.1 ml H_2O. Roots appeared after 2–3 weeks. Terminal pieces 10–15 mm long were excised and planted on Monier medium[11] without hormones, solidified with 1–1.5% agar. Explants were incubated in darkness at 25–27 °C and grew vigorously as roots. Those without visible bacterial contamination were transferred every 2–3 weeks and subcultured in Monier liquid medium without hormones (80 ml per Petri dish). Sterility of the cultures was assessed by plating macerates of the cultures on rich medium[11]. The cultures studied here were derived from single root tips; such cultures could be either cellular clones or chimaeras. Normal root cultures used as controls were established from roots of axenic carrot seedlings.

DNA was isolated from axenic root cultures previously induced by strains 8196 ('8196 root DNA') and C58C1 (pRi 8196) ('8196TC root DNA'), and from normal carrot roots cultivated similarly. The DNA isolation procedure is described in Fig. 3 legend. Southern blot hybridization analysis was performed on these DNA samples to determine the presence of any fragments homologous to the virulence plasmid. Plant DNA samples digested with *Bam*HI, as well as undigested samples, were electrophoresed in horizontal agarose gels. As controls, two parallel lanes were run with a low concentration of pRi 8196 digested to completion with *Bam*HI; the concentration used was calculated to be the amount of plasmid DNA expected per 5 μg of carrot DNA if the transformed roots contained one or three copies of the virulence plasmid per diploid nucleus. A Southern blot of the resulting agarose gel was hybridized with pRi 8196 DNA labelled *in vitro* by nick translation[33]. The autoradiogram of the blot (Fig. 3) shows hybridization bands in the lanes containing digests of transformed root DNA, but not in the lane containing normal carrot DNA. T-DNA was therefore present in the roots transformed by pRi 8196.

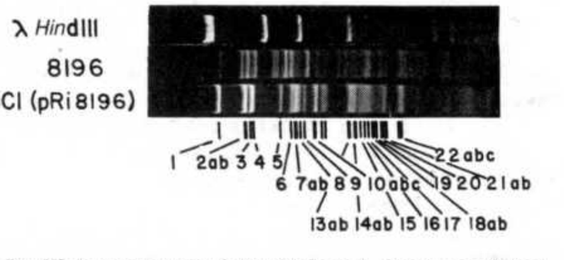

Fig. 2 *Bam*HI cleavage pattern of plasmids from *A. rhizogenes* 8196 and C58C1 (pRi 8196). *Bam*HI digests of plasmid DNA (2 μg samples) were electrophoresed in a horizontal agarose gel (0.7%)[31]. The line drawing indicates our assignment of fragment numbers, which was based in part on other studies in which digests were electrophoresed for longer.

Two prominent hybridization bands in the 8196TC root DNA digest co-migrated with bands 6 and 19 of the pRi 8196 digest and with hybridization bands in the 8196 root DNA digest. We interpret these T-DNA bands as 'internal fragments'[17–21] consisting entirely of pRi 8196 DNA. Six additional faint hybridization bands in 8196TC root DNA have no counterpart in 8196 root DNA, which in turn has four unique bands. We

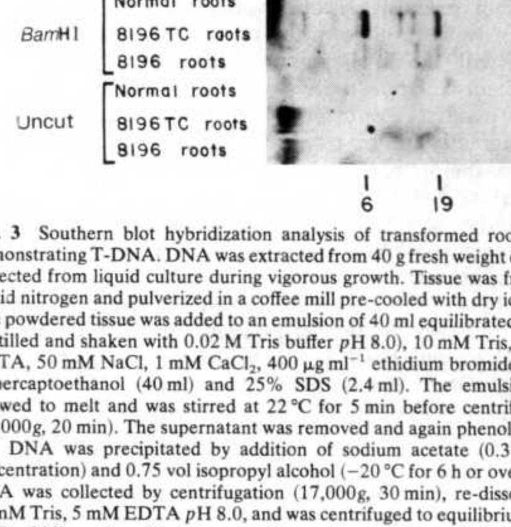

Fig. 3 Southern blot hybridization analysis of transformed root DNA demonstrating T-DNA. DNA was extracted from 40 g fresh weight of roots, collected from liquid culture during vigorous growth. Tissue was frozen in liquid nitrogen and pulverized in a coffee mill pre-cooled with dry ice chips. The powdered tissue was added to an emulsion of 40 ml equilibrated phenol (distilled and shaken with 0.02 M Tris buffer *p*H 8.0), 10 mM Tris, 50 mM EDTA, 50 mM NaCl, 1 mM $CaCl_2$, $400\ \mu g\ ml^{-1}$ ethidium bromide, 5 mM β-mercaptoethanol (40 ml) and 25% SDS (2.4 ml). The emulsion was allowed to melt and was stirred at 22 °C for 5 min before centrifugation (17,000*g*, 20 min). The supernatant was removed and again phenol-extracted. DNA was precipitated by addition of sodium acetate (0.3 M final concentration) and 0.75 vol isopropyl alcohol (−20 °C for 6 h or overnight). DNA was collected by centrifugation (17,000*g*, 30 min), re-dissolved in 10 mM Tris, 5 mM EDTA *p*H 8.0, and was centrifuged to equilibrium in six CsCl–ethidium bromide step gradients in a Spinco SW50.1 rotor (35,000 r.p.m. at 15 °C for 48 h). DNA bands were visualized using long-wavelength UV light and were removed by syringe. After repeated extractions with isopropyl alcohol to remove dye, the DNA solution was diluted with an equal volume of water, adjusted to 0.3 M sodium acetate and precipitated with 0.75 vol isopropyl alcohol. DNA was spooled on a rod, re-dissolved in 10 mM Tris, 1 mM EDTA *p*H 8, then dialysed briefly against the same buffer before restriction endonuclease cleavage. All glassware used for plant DNA isolation was either new or acid-cleaned and/or autoclaved to eliminate accidental contamination of the sample with native bacterial or plasmid DNA. Plant DNA and pRi 8196 were digested to completion with *Bam*HI (Boehringer-Mannheim). Plant DNA (5 μg per well), either digested or undigested, and pRi 8196 plasmid DNA digest (1.6 or $0.5 \times 10^{-3}\ \mu g$) (equivalent to three or one copies, respectively, per diploid carrot DNA equivalent based on a genome of MW 1.2×10^{12} (ref. 43)) were electrophoresed in horizontal 0.8% agarose gels. DNA was blotted on to cellulose nitrate (Schleicher & Schuell)[44] and hybridized with pRi 8196 DNA, labelled to a specific activity of 90×10^6 c.p.m. μg^{-1} by nick with [α-^{32}P]dCTP (Amersham) using a commercial kit (Amersham). Labelled DNA (1 μg) was incubated for 36 h with the Southern blot in 3 × SSC, 5 × Denhardt's solution at 68 °C as described by Thomashow *et al.*[45]. Blots were washed[45] to remove unhybridized probe and were subjected to autoradiography on Kodak RP X-omat film at −80 °C for 8 h with two intensifying screens.

interpret these bands as 'border fragments' analogous to those seen in T-DNA studies of crown gall tumour DNA[17-21], consisting of T-DNA covalently joined to host plant DNA. The six and four border fragments observed in these autoradiograms suggest that the transformed root cultures contained, respectively, three and two copies of T-DNA. The possibility of additional copies is not excluded. The various T-DNA copies may not be contained in the same cell, as the root cultures used here were not cloned from single cells.

Uncleaved DNA from the transformed roots, but not that from normal carrot roots, hybridized to the labelled probe DNA at the position of the high molecular weight plant DNA in the original gel. T-DNA does not migrate as a sharp band on the gel, as expected for a free replicon of fixed size. A very large free replicon would, however, escape detection because of fragmentation during DNA isolation. Our isolation method would certainly have broken covalently closed circular DNA molecules.

When we used the mixture of plasmids from *A. rhizogenes* strain 8196 (Fig. 2) as probe in a similar hybridization to transformed root DNA digests, we detected the same T-DNA fragments (data not shown), which confirms that all T-DNA is situated on pRi 8196.

Roots containing T-DNA can give rise to plantlets via callus and embryogenesis. Root tissue was transferred to Monier medium containing 2,4-D (0.36 μM) and kinetin (0.72 μM) solidified with agar (0.8%). After 4 weeks, the resulting callus tissue was transferred to liquid hormone-free Monier medium and incubated on an orbital shaker (150 r.p.m.) at 22–25 °C. The callus dissociated into suspension culture, and after 1 month embryos differentiated from these suspensions. Embryos were further incubated in Petri dishes containing hormone-free Monier medium where they developed into plantlets. Adventitious embryogenesis was observed on the newly differentiated plantlets, which resulted in the formation of tufts but did not interfere with the development of the plantlets into vigorous plants of normal appearance.

Of 20 plantlets examined, all contained high levels of the opine characteristic of transformed roots, N^2-(1-mannityl)-glutamine (mannopine), which suggests that the transformed roots derived from single root tips may indeed be a cellular clone. Studies of T-DNA in the plants obtained will determine whether each contains the several T-DNA inserts found in the parental root culture.

The results presented here demonstrate that a new family of pathogenic plasmids, the Ri plasmids that induce hairy root disease, share with the Ti plasmids (crown gall agent) the ability to insert T-DNA into the host plant genome. The Ri plasmids studied thus far share little DNA homology with the T-DNA of the Ti plasmids[34,35]; thus they seem to represent separate pathogenic agents. The similarity of the molecular mechanism of plant cell transformation by Ti and Ri plasmids thus extends the T-DNA concept and suggests that additional examples of foreign gene transfer may be found in plant pathogens.

Because of their natural ability to insert T-DNA into plant cells, the Ti plasmids are being extensively investigated as vectors for use in plant genetic engineering[36,37]. Regeneration of complete plants from crown gall tissue has proved extremely difficult[38]. In contrast, the roots containing pRi 8196 T-DNA regenerate reproducibly into plants containing opines, and thus presumably containing T-DNA. The Ri plasmid is thus an attractive alternative to the Ti plasmid as a genetic engineering vector.

This research was funded by CNRS grants ATP and AI 032750 to J.T. and DOE contract ERa0889 and American Cancer Society grant NP194 to M.D.C. M.D.C. received travel and fellowship support from CNRS, DGRST and INRA.

Stratification and terminal differentiation of cultured epidermal cells

Fiona M. Watt*‡ & Howard Green*†

As keratinocytes move from the basal to the outer layers of a stratified squamous epithelium, they enlarge and terminally differentiate. Hence, the stage of terminal differentiation is correlated with both cell size and position. To determine whether position is an important signal in differentiation, we have now grown human keratinocytes in conditions that prevented stratification but not cell enlargement. Involucrin, a marker of terminal differentiation, was synthesized in such a monolayer, but only by large cells. We conclude that the onset of involucrin synthesis, while normally restricted to cells in a non-basal position, does not depend on this position for an essential signal; however, a signal associated with increased cell size is not ruled out. When monolayer cultures were induced to stratify, the large involucrin-containing cells preferentially adopted a suprabasal position, indicating that terminal differentiation is associated with a decrease in substrate adhesiveness. Suprabasal cell position is therefore a consequence rather than a cause of terminal differentiation.

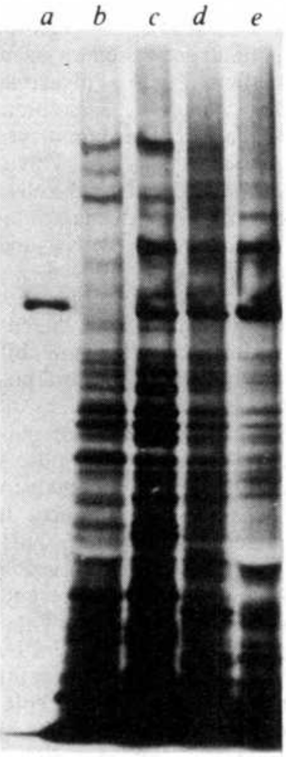

Fig. 1 Presence of involucrin in keratinocyte monolayers grown in low calcium medium. Second to fourth subcultures of human epidermal cells isolated from newborn foreskin were cultured in the presence of irradiated 3T3 feeder layers[9] in Dulbecco–Vogt medium supplemented with 10% fetal calf serum, 0.4 μg ml^{-1} hydrocortisone, 10^{-10} M cholera toxin[10], 5 μg ml^{-1} transferrin, 5 μg ml^{-1} insulin and 2×10^{-11} M tri-iodothyronine[3]. Epidermal growth factor was added to 10 ng ml^{-1} beginning on the third day after subculture[11]. The calcium concentration of control medium, determined by flame photometry, was 1.9 mM. When medium was prepared without calcium and supplemented with fetal calf serum that had either been dialysed against Ca-, Mg-free isotonic phosphate buffer (PBS) or treated with Chelex-100 resin[12], the final concentration of Ca^{2+} in the medium was about 0.1 mM (low calcium medium). Cells were labelled before collection with ~15 μCi ml^{-1} ^{35}S-methionine (Amersham, 600–1,300 Ci mmol^{-1}) for 24 h in medium containing 3 mg l^{-1} methionine. They were collected by scraping and sonicated in 10 mM EDTA, 50 mM Tris, *p*H 7.4. Insoluble material was removed by centrifugation for 2 min at 12,800*g*. *a*, Purified ^{35}S-involucrin marker. *b*, Extract of small cells selected by passage through a Nitex screen. Note the absence of involucrin. Small cells were plated out in control medium (*c*) or low calcium medium (*d*) and collected at confluence. *e*, Cells collected from the medium of a culture in low calcium by gentle aspiration 1 week after confluence. Only cells that were already detached or loosely attached to the monolayer were collected in this way.

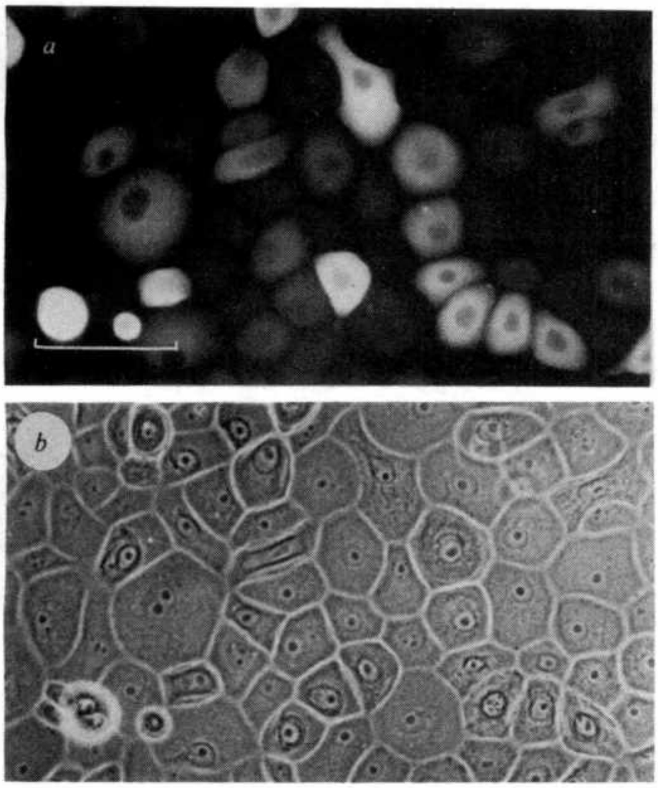

Fig. 2 Identification by immunofluorescence of involucrin-containing cells in keratinocyte monolayers grown in low calcium medium. Keratinocytes grown to confluence in low calcium medium and fixed with 3.7% formaldehyde in PBS (room temperature) for 8 min, in absolute methanol (−20 °C) for 4 min and in absolute acetone (−20 °C) for 2 min. The cells were incubated first with rabbit antiserum to involucrin (1:20 in PBS), then with fluorescein-conjugated goat anti-rabbit IgG (1:16 in PBS) (Miles). *a*, Immunofluorescence image. *b*, Phase image of the same field; scale bar 100 μm. Note mixture of involucrin-positive and -negative cells in the monolayer. Positive cells also seem to have better defined nuclear borders.

Involucrin is a soluble keratinocyte protein that becomes incorporated into the cross-linked envelope during terminal differentiation[1]. It is found in all human stratified squamous epithelia and cell cultures derived from them[2]. We have previously shown that the onset of involucrin synthesis is correlated with an increase in cell size[3] and with cell migration from the basal layer into the outer layers[1,2]. In culture, synthesis begins in the layers immediately suprabasal, while in intact tissues, cells migrate several layers beyond the basal layer before starting to make the protein[1,2]. Hennings *et al.*[4] have shown that cultivation of keratinocytes in medium containing a low concentration of Ca^{2+} prevents stratification by inhibiting desmosome formation, and this allows the relationship between cell position and involucrin synthesis to be tested.

Pre-confluent cultures of human epidermal keratinocytes derived from newborn foreskin were collected and passed through a screen of Nitex nylon monofilament cloth (type HC-3-11, Tetko). Only cells <15 μm in diameter passed through the screen; these cells did not contain involucrin, as judged by immunofluorescence and polyacrylamide gel electrophoresis (ref. 3 and Fig. 1*b*).

The small involucrin-free cells were collected in sterile conditions and plated in the presence of irradiated 3T3 cells in medium containing 0.1 mM Ca^{2+} (low calcium medium), grown into a confluent monolayer, then fixed and stained for indirect immunofluorescence, using antiserum raised in rabbits against purified involucrin[1]. As Figs 2 and 3 show, even though the cells were confined to a monolayer, the proportion of involucrin-positive cells was 30–50%, similar to the proportion found in stratified colonies cultured in control medium[3]. The presence of involucrin was confirmed by polyacrylamide gel electrophoresis of ^{35}S-methionine-labelled cell extracts (Fig. 1, compare *c* and *d*). Thus, terminal differentiation progressed to the stage of involucrin synthesis, even though stratification was prevented by the low Ca^{2+} concentration.

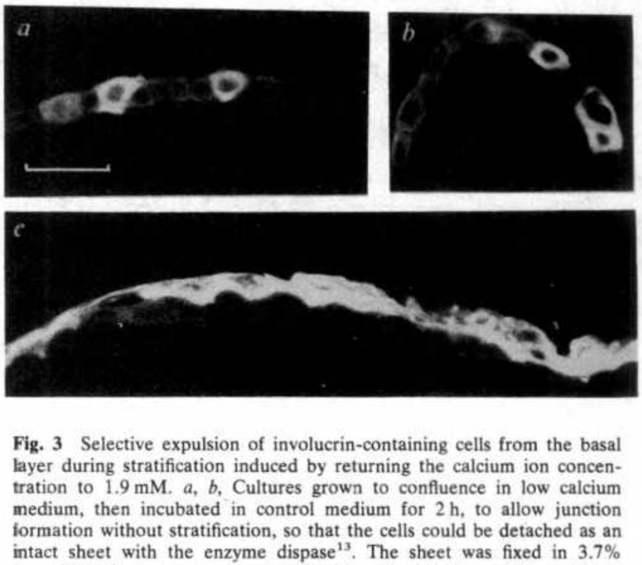

Fig. 3 Selective expulsion of involucrin-containing cells from the basal layer during stratification induced by returning the calcium ion concentration to 1.9 mM. *a*, *b*, Cultures grown to confluence in low calcium medium, then incubated in control medium for 2 h, to allow junction formation without stratification, so that the cells could be detached as an intact sheet with the enzyme dispase[13]. The sheet was fixed in 3.7% formaldehyde at room temperature for 1 h, embedded in paraffin, and 5 μm sections were cut at right angles to the surface of the epithelial sheet. The sections were prepared for immunofluorescence as described in Fig. 2 legend. Note that involucrin-positive and -negative cells are interspersed in the monolayer. *c*, Cells grown to confluence in low calcium medium, and transferred to control medium for 24 h before fixation, to induce stratification. The section was prepared as in *a* and *b*. Note that all the involucrin-positive cells have left the basal layer. *a*, *b*, *c* Are all at the same magnification; scale bar, 50 μm.

In control medium, the modal cell diameter was 12–13 μm and virtually all cells of ≥17 μm synthesized involucrin[3]. Cells grown to confluence in low calcium medium tended to be larger, the modal diameter increasing by 1–2 μm after 1 week in culture. In low calcium medium none of the involucrin-positive

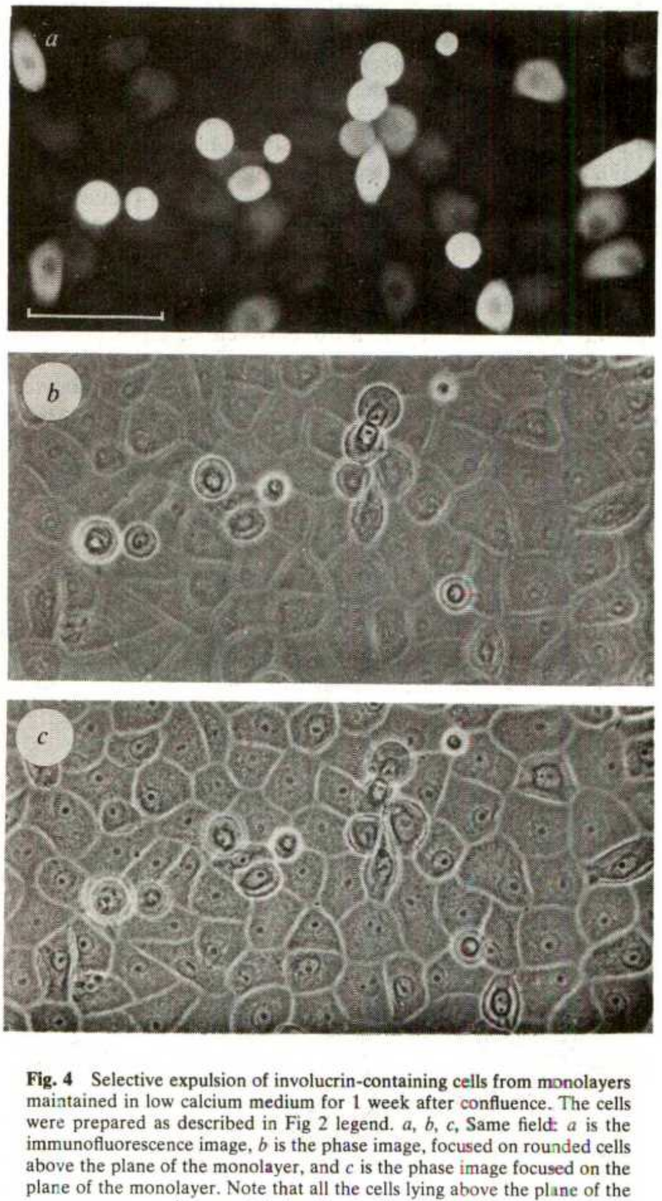

Fig. 4 Selective expulsion of involucrin-containing cells from monolayers maintained in low calcium medium for 1 week after confluence. The cells were prepared as described in Fig 2 legend. *a, b, c,* Same field: *a* is the immunofluorescence image, *b* is the phase image, focused on rounded cells above the plane of the monolayer, and *c* is the phase image focused on the plane of the monolayer. Note that all the cells lying above the plane of the monolayer contain involucrin. Scale bar, 100 μm.

cells was <17 μm in diameter, and 66% of cells >18 μm were positive. Although the absolute size at which involucrin synthesis began depended to some extent on the culture conditions, the onset of synthesis in both monolayer and stratified cultures was correlated with an increase in cell size.

We also investigated the effect of returning the calcium concentration to 1.9 mM, thereby inducing stratification, to see whether the involucrin-positive and -negative cells would distribute randomly between the basal and outer cell layers or whether they would sort out. Within 24 h of raising the calcium concentration, stratification occurred (Fig. 3*c*): all the differentiating, involucrin-positive cells were found in the outer cell layers and the involucrin-negative cells remained in the basal layer. Thus, although the newly stratified cultures were only two to three layers thick, the distribution of involucrin was the same as in cultures grown in control medium[2]. This demonstrates that the cells sufficiently differentiated to synthesize involucrin were selectively expelled from the basal layer.

Monolayers of keratinocytes were also maintained in low calcium medium for 1–2 weeks after reaching confluence. Some cell division continued in the cultures and those cells forced out of the monolayer were rounded and either loosely attached to the surface of the monolayer, or detached into the medium. When such cultures were fixed and stained for immunofluorescence with antiserum to involucrin, it was clear that involucrin was present in all the rounded cells above the plane of the monolayer as well as in most cells detached and free in the medium (Fig. 4). Polyacrylamide gel electrophoresis confirmed that extracts of ^{35}S-methionine-labelled cells detached from the surface of the monolayer by gentle aspiration contained involucrin (Fig. 1*e*). This suggests that the terminal differentiation of epidermal cells is accompanied by a decrease in substrate adhesiveness, which could account for the sorting out of involucrin-positive and -negative cells observed when stratification is induced.

These observations show that cells need not achieve a suprabasal position in the stratified epithelium to synthesize involucrin. Rather, the ability of involucrin-containing cells to sort out shows that cell position in the epithelium depends on properties established by the process of terminal differentiation. Selective expulsion of the more differentiated cells from the basal layer has been postulated to explain the kinetics of thymidine labelling in the superficial layers of intact epidermis[5]. Quantitative differences in adhesiveness are known to be sufficient to produce immiscibility between two cell populations[6]. A continuing gradient of surface adhesiveness linked to terminal differentiation and extending outwards from the basal layer would serve to maintain homogeneity of cells along a given plane in the epithelium by preventing the mixing of cells at different stages of differentiation. This is probably the basis for the ability of mixed epidermal cells at different stages of differentiation to reassemble histotypic structure, either in culture[7] or following their injection into animals[8].

These investigations were aided by NCI grants.

Unusual interactions of benzodiazepine receptor antagonists

David J. Nutt & Philip J. Cowen

Two compounds have recently been described which act as potent benzodiazepine (BDZ) antagonists *in vivo* and which, *in vitro*, show high affinity and selectivity for the BDZ receptor of the mammalian central nervous system (CNS). One, ethyl β-carboline-3-carboxylate (β-CCE), was extracted from human urine and may be related to an endogenous ligand for the BDZ receptor[1–3]. It reverses the effects of BDZs *in vivo*[4,5] and *in vitro*[6], but also has intrinsic activity, as it lowers the seizure threshold to drugs antagonistic to the action of γ-aminobutyric acid (GABA)[5,7]. The other compound, an imidazodiazepine (Ro 15-1788), which is also a potent and specific antagonist of

0028-0836/82/050436—03$01.00

BDZ binding *in vivo* and *in vitro*[8], blocked the sedative, hypnotic and anticonvulsant actions of conventional BDZs, without demonstrating any intrinsic activity[9,10]. Because of the different profiles of action of these two BDZ 'antagonists', we have here investigated their interactions in two well established systems for assessing BDZ activity: seizure thresholds *in vivo*[11] and the action of GABA on cervical sympathetic ganglia *in vitro*[12]. We find that Ro 15-1788 not only opposes the actions of BDZs but also is an effective antagonist of β-CCE in both systems. At high doses it has BDZ-like activity, suggesting that it may be a partial agonist at the BDZ receptor site.

Seizure thresholds in rats were determined by measuring the dose of drug, when infused at a constant rate through a tail vein, needed to elicit a seizure (see Table 1 legend), a method known to provide a reliable guide to the activity of certain anticonvulsant drugs[13]. Ro 15-1788 was prepared as a suspension in distilled water (DW) with 1 drop of Tween 40 per 10 ml and was injected intraperitoneally (i.p.) 15 min before infusion. All animals received a volume of 2 ml per kg, controls being given the Tween/DW vehicle.

Table 1 Effect of different doses of Ro 15-1788 on the seizure thresholds to PTZ, bicuculline and strychnine

Dose of Ro 15-1788 (mg per kg)	Seizure thresholds (mg per kg) PTZ	Bicuculline	Strychnine
Vehicle alone	30 ± 4 (5)	0.24 ± 0.02 (4)	2.2 ± 0.4 (5)
1	—	0.25 ± 0.02 (4)	—
10	29 ± 2 (6)	0.26 ± 0.03 (4)	—
50	36 ± 5 (6)*	0.29 ± 0.06 (4)*	2.1 ± 0.3 (6)
100	40 ± 5 (5)†	—	—

Seizure thresholds are expressed as mean ±s.d. with number of animals in parentheses. Rats were given either vehicle or Ro 15-1788 in a volume of 2 mg per kg i.p. and 15 min later convulsant was infused in a tail vein via a 25-gauge cannula, at a rate of 2.22 ml min^{-1}, and the time taken to the first seizure activity was recorded. Using this time and the concentration of infused drug and weight of the animal, the seizure threshold was computed. The concentrations of convulsant solutions used were PTZ 10 mg ml^{-1}, bicuculline 0.05 mg ml^{-1} and strychnine 1 mg ml^{-1}. PTZ and strychnine were dissolved in normal saline; bicuculline was dissolved in saline acidified to *p*H 3 with 0.1 M HCl. Significance was determined by Student's *t*-test: * $P < 0.05$; † $P < 0.01$, as compared with vehicle controls.

When tested alone on seizure thresholds to the GABA antagonist drugs pentylenetetrazol (PTZ) and bicuculline, Ro 15-1788 showed anticonvulsant activity at a dose of ⩾50 mg per kg, with a potency about 1/50th that of diazepam (Table 1). However, even at 50 mg per kg, Ro 15-1788 gave no protection against the seizures produced by the glycine antagonist, strychnine, suggesting that Ro 15-1788's anticonvulsant effect has a similar pharmacological specificity to that of the BDZs[14].

To determine the effect of Ro 15-1788 on the anticonvulsant effect of diazepam, rats were injected with diazepam, 5 mg per kg, and 15 min later with Ro 15-1788, 10 mg per kg (this dose was devoid of agonist effects, see Table 1). When PTZ was infused a further 15 min later the pronounced elevation of seizure threshold produced by diazepam was substantially reduced in the Ro 15-1788-treated group (Table 2).

The selectivity of this effect was determined by giving the same dose of Ro 15-1788 15 min after treatment with anticonvulsants thought to act at sites other than the BDZ receptor. As Table 2 shows, the anticonvulsant activity of phenobarbitone (40 mg per kg, i.p.), sodium valproate (400 mg per kg, i.p.) and progabide (200 mg per kg, i.p.), which raise seizure thresholds to PTZ by mechanisms which may involve GABAergic systems[15-17], was unaffected by Ro 15-1788.

The action of Ro 15-1788 on the previously reported proconvulsant action of β-CCE was evaluated by administering Ro 15-1788, 10 mg per kg, or Tween followed 10 min later by intravenous (i.v.) β-CCE, 1 mg per kg (1 mg ml^{-1} in propylene glycol/ethanol 2 : 1) and 5 min after this by PTZ infusion. The fall in seizure threshold produced by β-CCE was abolished by the Ro 15-1788 pretreatment (Table 2).

In the seizure threshold model, therefore, Ro 15-1788 at a dose of 10 mg per kg i.p. antagonized both the anticonvulsant effects of 5 mg per kg diazepam and the proconvulsant effects of 1 mg per kg β-CCE, without having any detectable effect of its own. This antagonistic effect seems to be selective for drugs acting at the BDZ receptor, as Ro 15-1788 did not reduce the anticonvulsant effects of phenobarbitone, sodium valproate or progabide.

GABA perfusion of the isolated rat cervical sympathetic ganglion induces depolarization which may be blocked by the GABA receptor antagonist, bicuculline. In this preparation the conductance change produced by GABA (an increase in chloride conductance) has been shown to correspond with those produced by GABA in the CNS[18]. Moreover, the binding characteristics of the ganglion and CNS GABA receptors are similar[19]. Figure 1 shows that, in agreement with previous studies[12] with BDZs, the water-soluble BDZ, chlordiazepoxide, increases the amplitude of the responses to GABA in the presence of bicuculline. Treatment of the ganglion with Ro 15-1788 (835 nm) abolished the effect of chlordiazepoxide (Fig. 1),

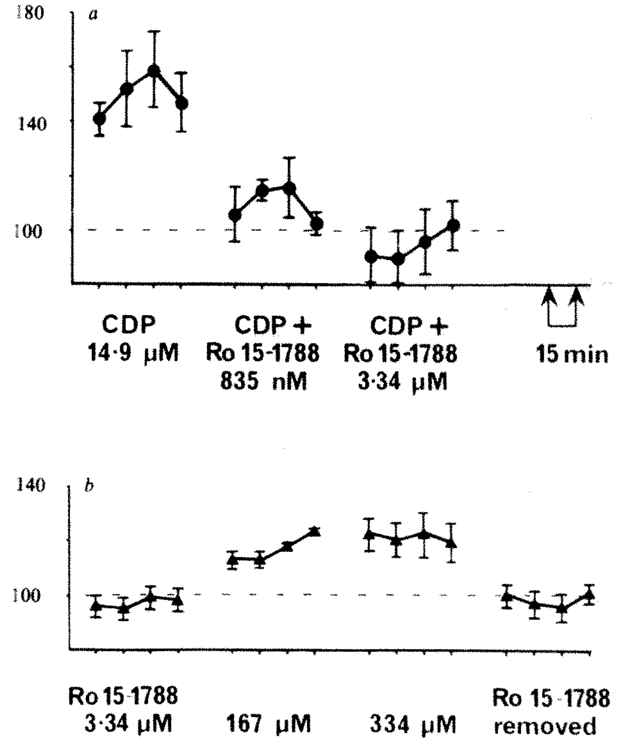

Fig. 1 The method used was that of Brown and Marsh[22] and involves superfusion of the isolated ganglion (1 ml min^{-1}) with extracellular recording of the postsynaptic potential changes. Application of GABA to the perfusion fluid for 2 min every 15 min was found to give steady control responses without desensitization. Four steady control responses to GABA (38.8 μM) were obtained in each experiment before the above treatments were applied. This concentration produces near-maximal responses to GABA in this preparation and the concentration of bicuculline used throughout (27.2 μM) reduced this to approximately half the maximum responses. These concentrations were similar to those used originally by Bowery and Dray[12] and were chosen to demonstrate the optimum changes in response amplitude. The results give the amplitude of the depolarizations produced by application of GABA, expressed as percentages of the mean of the four control values ($n = 5$ throughout). The compounds were added to the perfusion medium 15 min before GABA and were present throughout the treatment periods. Standard errors are included to give an indication of the variation. Analysis of variance performed on the original data showed that Ro 15-1788 (concentrations 835 nM and 3.34 μM) significantly antagonized the effects of chlordiazepoxide (CDP, $P < 0.01$). When applied alone, Ro 15-1788 caused significant increases in amplitude of responses at 167 μM and 334 μM ($P < 0.01$) but not at 3.34 μM. There was no further increase in response amplitude when the Ro 15-1788 concentration was raised to 835 μM. The mean amplitude of the control responses was 211 ± 19 μV. The drugs were made up in the following solutions: GABA and Ro 15-1788 in standard Krebs, chlordiazepoxide in distilled water, β-CCE in 0.03 M HCl, bicuculline in 0.1 M HCl titrated to *p*H 3.

Table 2 Effect of Ro 15-1788 on the changes in seizure threshold produced by diazepam, other anticonvulsants and β-CCE

	Seizure threshold to PTZ (mg per kg)		
Drug treatment	Vehicle (Tween)	Ro 15-1788 (10 mg per kg)	*P* value
Saline	34 ± 2 (5)	35 ± 3 (6)	N/S
β-CCE (1 mg per kg, i.v.)	26 ± 3 (5)	35 ± 3 (6)	<0.001
Diazepam (5 mg per kg, i.p.)	62 ± 14 (7)	39 ± 4 (5)	<0.001
Phenobarbitone (40 mg per kg, i.p.)	52 ± 5 (6)	56 ± 9 (6)	N/S
Valproate (400 mg per kg, i.p.)	57 ± 14 (5)	53 ± 10 (6)	N/S
Progabide (200 mg per kg, i.p.)	50 ± 6 (7)	55 ± 11 (7)	N/S

Diazepam, phenobarbitone, sodium valproate and progabide were given in the doses shown. Concentrations of solutions were diazepam 5 mg ml^{-1} in commercial vehicle (Roche), phenobarbitone 10 mg ml^{-1} and sodium valproate 100 mg ml^{-1} in normal saline, and progabide 100 mg ml^{-1} in Tween. Saline was given in a volume of 4 ml per kg. 15 min later Ro 15-1788, 10 mg per kg, was injected i.p. and a further 15 min later PTZ was infused (see Table 1 legend). With β-CCE, Ro 15-1788, 10 mg per kg in Tween, was given 10 min before an i.v. injection of 1 mg per kg β-CCE (1 mg ml^{-1} solution), with PTZ infused 5 min later. Seizure thresholds were expressed as mean ±s.d. with the number of animals given in parentheses. The *P* value refers to significance of differences between Ro 15-1788 and Tween vehicle-treated animals. There were no differences in seizure threshold between animals pretreated with saline, Tween, β-CCE vehicle or diazepam vehicle. Statistical analysis performed by Student's *t*-test. N/S, not significant.

while higher concentrations of Ro 15-1788 (167–835 μM) showed intrinsic activity in that they increased the responses to GABA (Fig. 1). The ratio of agonist and antagonist doses of Ro 15-1788 in this system was similar to that displayed in the seizure threshold model.

Barbiturates also increase the responses to GABA in the ganglion preparation[12], but as in the seizure threshold model, the effect of phenobarbitone (40% increase in the amplitude of GABA responses at 787 μM) was not antagonized by Ro 15-1788 at either 3.34 or 33.4 μM. These concentrations of Ro 15-1788 alone had no effect on the response to GABA.

When applied to the GABA–bicuculline-pretreated ganglion, 1 μM β-CCE showed opposite actions to BDZs in that it significantly ($P<0.01$) decreased the depolarization produced by GABA, 38.8 μM (results, expressed as in Fig. 1, were 85 ± 3% at 15 min, 78 ± 5% at 30 min, 85 ± 6% at 45 min and 83 ± 7% at 60 min). This effect was antagonized by Ro 15-1788 at the same concentration which blocked the effect of chlordiazepoxide (3.34 μM).

It thus seems that in two experimental systems in which specific BDZ activity may be assessed, β-CCE has the opposite effect to BDZs. Ro 15-1788 seems to be a selective and potent antagonist of both compounds in both systems. Investigations have failed to demonstrate specific binding of either β-CCE[1] or Ro 15-1788 (ref. 8) to CNS sites other than the BDZ receptor. In view of the selective and high-affinity BDZ receptor binding of β-CCE and Ro 15-1788, and the parallels between their binding and pharmacological activity, it is likely that the pharmacological effects observed are due to interaction at the BDZ receptor site.

We suggest three possible explanations for these findings. First, the partial agonist effect of Ro 15-1788 may be sufficient to account for its reversal of the actions of β-CCE. This seems unlikely because the concentrations of Ro 15-1788 that antagonized β-CCE had no agonist action when tested alone. However, it is possible that in the presence of β-CCE the BDZ receptor is altered so that Ro 15-1788 has a greater agonist effect.

The second explanation is that the functional interaction of ligands with the BDZ receptor may be unusual in that specific high-affinity ligands may produce opposite pharmacological effects and yet have a common antagonist. The possible existence of this type of receptor interaction has been predicted from receptor theory (see, for example, ref. 20). The allosteric models of receptor behaviour suggest that receptors exist in equilibrium between two states (which may be termed 'active' and 'inactive') and that this equilibrium is altered by ligand binding. If we apply this theory to our findings, BDZs would be considered to be agonists, binding to the active state, whereas Ro 15-1788 would be a conventional antagonist, binding to both forms without altering the equilibrium. If β-CCE bound preferentially to the receptors in the inactive state it would shift the equilibrium in the opposite direction. This form of antagonism has been predicted but not so far demonstrated.

A third explanation derives from results of ligand binding studies suggesting the existence of subclasses of BDZ receptors. These have identical affinities for the BDZs, including Ro 15-1788 (ref. 8), but differ in their affinities for the β-carbolines[2,21]. The pharmacological actions of the BDZs and β-CCE may thus be exerted through different subpopulations of BDZ receptors, and it is conceivable that the unusual interactions we have described represent a functional consequence of this differential binding.

We thank Dr B. Jones, Glaxo, and Dr Ian Martin, MRC Neurochemical Pharmacology Unit, Cambridge, for β-CCE, Dr W. Haefely, Roche, for Ro 15-1788, Synthelabo (Paris) for progabide, Professors Sir William Paton and D. G. Grahame-Smith and Dr A. R. Green for helpful advice and criticism and Mr C. Howard for technical assistance.

Errata

In the *Nature Directory of Biologicals 1982*, on page vi James Manley of Columbia University is incorrectly listed as Michael Manley under the heading 'Scientific Advisory Committees'.

In the letter 'Tree remains in a North York Moors peat profile' by I. G. Simmons & J. B. Innes, *Nature* **294,** 76–77 (1981), Figs 1 and 2 are transposed. Thus Fig. 1 is the pollen diagram shown on page 78.

In the article 'Magma chamber profiles from the Bay of Islands ophiolite complex' by J. F. Casey & J. A. Karson, *Nature* **292,** 295–301 (1981), NAM in Fig. 1 legend stands for North Arm Mountain. The received date for the article should read 29 September 1980.

Corrigendum

In the letter 'Mouse IgG3 antibodies are highly protective against infection with *Streptococcus pneumoniae*' by D. E. Briles *et al., Nature* **294,** 88–90 (1981), the dose of *S. pneumoniae* is given as 100 CFU in Table 2 and 150 in the text. This should read 100 CFU throughout.

BOOK REVIEWS

Tomorrow, the world

Brenda Maddox

Electronic Colonialism: The Future of International Broadcasting and Communication. By Thomas L. McPhail. Pp. 260. Hbk ISBN 0-8039-1602-7; pbk ISBN 0-8039-1603-5. (Sage: 1981.) Hbk $22.50, £15.50; pbk $9.95, £6.50. *Global Talk: The Marriage of the Computer, World Communications and Man.* By Joseph N. Pelton. Pp.336. Hbk ISBN 0-7108-0371-0; pbk ISBN 0-7108-0347-8. (Harvester: 1981.) Hbk £17.95; pbk £7.95.

ANY writer who sits down to try to explain the public policy issues embedded in complicated technology has two contradictory censors inside his head. "Don't get it wrong", demands one. "Don't make it boring", shouts the other. Because the dilemma is so common, a common solution has evolved: to be lofty. Cast the questions in terms of the survival of the race and the future of the planet; the technical experts will thus forgive you for skating over tedious details, while the lay reader will work extra hard and re-read tough pages rather than giving up.

To be sure, Mr McPhail, who teaches mass communication and journalism at Carleton University in Ottawa, has set his chisel to the hardest stone: Unesco and the issue of the New World Information Order. For at least a decade, the countries of the developing world have been demanding a New World Information Order. This fuzzy concept expresses a legitimate grievance — that most of their communication with the developed world flows in one direction only: in. Little news about them of their own choice flows out toward the wider world, and even less entertainment. They fear eventual cultural swamping and, at the present, resent what is seen as constant misinterpretation by Western news agencies.

To right this balance, these countries are using their numerical strength in the United Nations where each country has one vote. Their favourite battleground is Unesco. Unesco's secretariat has so taken up the Third World's campaign for a re-ordering of information (of news-gathering in particular), that it has come up with proposals which to Britain, the United States and other countries committed to a free (well, fairly free) press amount to nothing less than a Unesco endorsement of government control of the media. In 1980 at Unesco's general conference in Belgrade the West reluctantly, with many doubts and qualifications, allowed the barest acknowledgement that something like a New World Information Order may be needed.

All this sets a very demanding exercise for a writer, especially as Unesco obscures its own activities behind dense screens of jargon. Earnestness so permeates Mr McPhail's efforts that it is sad to have to declare that his book does not meet the challenge. For example, what did the West surrender in the way of press freedom at Unesco's general conference in Belgrade in 1980? The Western press tried analysis (duly quoted in Mr McPhail's text) and was hampered by the differing views, even between Britain and the United States, as to what happened. For its part, the developing world is not sure what it has achieved in securing within Unesco the creation of the International Programme for the Development of Communications: a talking shop, a funnel for practical aid or its own power base inside the secretariat? And neither is Mr McPhail. All he can conclude is that the New World Information Order is not going to go away.

For a book on the future of the media, Mr McPhail gets off to a disastrous start. In his very first two words, he spells a man's name wrong — and not just any man, but the legendary Lord Copper, the archetypal Fleet Street press baron of Evelyn Waugh's *Scoop*. Mr McPhail calls him Lord Cooper, somewhat spoiling Waugh's point. He then gets others wrong (President Kekkonen of Finland) but these could be the computer typesetting.

Another device which Mr McPhail's book would have been better without is the use of ponderous lists, with scarcely a verb at all:

> The questions of transnational data flows, computers, data processing, privacy, and computerization effects on the work place and labor are central to policy concerns of several industrialized nations.

The third stylistic flaw which makes the book unreadable is the excessive use of long quotations, with little guide as to how the extracted material furthers the author's argument.

At the start of his book, Joseph Pelton looks like falling into the same traps. *Global Talk,* he declares, "is only my third book on science policy and applications". But it was his hardest — because he says he has tried to be funny, and sophisticated too, without being as tedious as the *New York Times.* What a relief, therefore, to wade in and find that Mr Pelton, an executive of Intelsat, the International Telecommunications Satellite Organization, has assembled much hard-to-get and fascinating information — studies of telecommunications plans and expenditure in developing countries; similar statistical profiles of "the information societies" and on the technical and economic outlook for satellites.

Mr Pelton, too, dips into the slough of the UN conference — specifically the WARCs, the world radio conferences of the International Telecommunications Union. He knows, unlike Mr McPhail, that the "A" in WARC stands for "administrative" and not "administration" and he is, moreover, unafraid to use his own words, instead of quoted material, to draw conclusions. In the case of the 1979 WARC, his judgement is that, for their own purposes, more and more countries are willing to tax the ITU's cumbersome regulatory mechanisms — such as the mammoth WARC conferences — to the maximum, yet he sees this as no cause for despair. In spite of their complexity, the issues of international management of technology are no harder than those which international institutions have dealt with successfully in the earlier part of the century. Not a bold conclusion, perhaps, but a clear one.

In sum, Mr Pelton's grasp of his subject triumphs over his whimsy (although, in some cases, just barely: an excellent chapter on the worsening problem of incompatible international technical standards contains an awful poem, "Electronic Gumbo Stew"), and has allowed him to produce an ambitious and original work of reference. ☐

Tasteless behaviour

Mark Ridley

The Foundations of Ethology. By Konrad Z. Lorenz. Pp.380. ISBN 0-387-81623-2. (Springer-Verlag: 1981.) $21.95.

The Foundations of Ethology, a translation of a book that appeared in German a few years ago, is a monograph of Lorenzian ethology. The text reads well, unlike most translations, although "selfish", which becomes *egoistische* in German, returns in " 'The egoistical gene' has become the popular phrase. . .". All in all there is not much about natural selection in the book, for Lorenz founds ethology in the philosophy of *Gestalt* psychology, in physiology and in embryology. These three fill the main sections of the book: one on philosophy and methods, and two marked by Lorenz's controversial distinction between innate and acquired information. He repeats once again his argument for a fundamental distinction between innate and acquired information, and, in the present environment of debates about "genetic determinism", it is undoubtedly worth repeating. The fact that the behaviour of animals is adapted to their environments means that they must have "information" about their environment; it is this information (not behaviour) which Lorenz dichotomizes into genetic and acquired.

Lorenz could have written a book with the conceptual content of *Foundations of Ethology* 30 years ago. If it had been published then it would have become a classic alongside Tinbergen's *Study of Instinct* (Clarendon, 1951). Coming out now it appears awkwardly antediluvian. In his foreword, T.H. Bullock says that the book is intended as a contribution to the history of ethology. But to write a period textbook is not to write the history of a period. *Foundations of Ethology*, however, is not even simply a period textbook, for Lorenz is far too concerned with defending his concepts against later criticism. The fault with the book can be clarified by an analogy with historiography. By tracing back the pedigree of ideas that are interesting now, it is easy to distort history, because isolated ancestral ideas are rarely representative of contemporary thinking. Lorenz, by tracing forward and defending his ideas, produces an extraordinary futuristic distortion. For example, in his discussion of motivation he defends himself against Robert Hinde's criticisms and even presents an updated hydraulic analogy. But modern work on motivation is established on quite separate foundations, manifesting itself to most of us only as a fascinating and imposing castle, with sheer walls of solid algebra, surrounded by minefields of exegesis.

Lorenz's later books have tended to be increasingly concerned with human beings, but this one is almost entirely about animal behaviour. There is a typically nonconciliatory appendix on the uniqueness of mankind and a stricture or two against the deadly sins of civilized man. Our "innate releasing mechanisms", we are told on p.166, give us an unhealthy liking for chocolate and "even the most complete insight into the workings of our IRMs does not make it easy to avoid suicide by overeating". As a gastronomic experience, *Foundations of Ethology* is not so much suicidal as dry and unappetizing; it rather resembles three full courses of stale bread. Well before I had reached p.166, I had found that it went down best when taken with *religeuses* and *éclairs au chocolat.* ☐

Galactic sociology

John D. Barrow

Galactic Astronomy: Structure and Kinematics, 2nd Edn. By Dimitri Mihalas and James Binney. Pp.597. ISBN 0-7167-1280-6. (W.H. Freeman: 1981.) $29.95, £20.70.

THE story is told of a lecturer beginning his address on the structure of stars with the words "Stars appear to be very simple objects", whereupon someone in the audience retorted "You'd look pretty simple too at a distance of a hundred light years!". Because they are a good deal farther away than stars, astronomers used to think that galaxies were even simpler. Until very recently elliptical galaxies were thought to be uncomplicated and understood — just isothermal "gases" of stars whose various degrees of ellipticity were merely reflections of their differing rotation rates. During the past six years this naive picture has been obliterated and replaced by that complexity, masquerading as simplicity, that is the hallmark of all natural phenomena. Ellipticals have been revealed as complicated systems with three-dimensional dynamics that are neither isothermal nor rotating to any significant degree. Their flattening is a consequence of much more subtle dynamical properties.

Surprisingly, there has never been an authoritative advanced textbook on the structure of galaxies. There are indeed several good introductory texts and collections of review articles, either scattered around the literature or gathered into massive review volumes that send a shiver down your cheque book, but no single, detailed and up-to-date guide to all the relevant observational data and theoretical ideas — until now.

Mihalas and Binney have completed the first part of a two-volume treatise on the subject, this book being confined to observations and kinematics. The second volume, to be written by Binney and Tremaine, will be devoted to dynamics. By any standards this first volume is outstanding. Although advertised as a second edition of Mihalas and Routly's book of the same title, do not be misled, this is an entirely new book of more than double the length and considerably more depth than its prototype. After a brief history and introduction to astronomical concepts and vocabulary, it begins with a detailed overview of stellar evolution and the interstellar medium before describing the stellar content and kinematics of external galaxies and the Milky Way. The final chapters provide studies of the hydrogenic content of galaxies and their rotational properties. References to the original literature are always provided, although through a rather cumbersome system, and good tables and diagrams illuminate the text throughout.

This book is essential for any graduate course on galaxies. It is too advanced for undergraduate courses although lecturers and more able students will want to refer to it. Most graduate courses on galaxies divide their time equally between the material covered in this volume and the dynamical theory that will appear in Vol. 2, and together the two books should provide everything such students require. Unfortunately, it is hard to believe that many of them will be willing or able to pay the considerable price of both volumes — one hopes that a paperback edition will soon be available, as all astronomers should own and read this book. Perhaps also the authors and publishers might consider a third volume which would be an abridged combination of the two earlier volumes, with a length and level comparable to the original edition written by Mihalas and Routly.

John Barrow is a Lecturer in Astronomy at the University of Sussex.

Everything e^- can do ν can do better

P.W. Hawkes

Optical Information Processing: Fundamentals. Edited by S.H. Lee. Pp.308. ISBN 3-540-10522-0. (Springer-Verlag: 1981.) DM 99, $42.20.

How is optical information processing getting on? For nearly two decades now, the advantages of light for manipulating data have been attracting more and more attention, although, as Casasent says in this book, "optical processors are somewhat like discrete transistors before the dawn of LSI; they are truly in their infancy". These advantages may be summarized as parallel processing, high throughput and the ability to perform such operations as cross-correlation virtually instantaneously. Such features clearly make optical processors serious potential competitors of digital systems, though, to quote Casasent again, "the shortcomings of one system are the advantages of the other. The two technologies (optical and digital) are actually complementary rather than similar".

The present text, which should be regarded as a companion to an earlier volume in the same Springer series edited by Casasent (*Optical Data Processing: Applications*, 1978), gives an impressively complete account of the degree of sophistication that such optical systems have reached. About a third of the book has been written by the editor, S.H. Lee, who first sets out the basic principles, covering essentially the Fourier transforming properties of lenses and their mathematical implications. His chapter on coherent optical processing then gives an account of filter design and synthesis, including optical feedback, and classifies the various thick and thin filters; a number of more elaborate processor designs are described and clearly illustrated, and the chapter ends with a few words on coherent noise suppression.

The third chapter, by W.T. Rhodes and A.A. Sawchuk, deals with incoherent optical processing, where the advantages of easy input/output, tolerance towards dust and other common imperfections of laboratory equipment and the absence of phase problems is offset by the restriction to real, non-negative signals. This is followed by an extremely important contribution by G.R. Knight on interface devices and memory materials. If the progress described here is maintained, optical processors cannot fail to gain in importance even though an immense amount remains to be done. Some of the problems of purely optical processors can be circumvented by using hybrid systems, as D. Casasent explains in the next chapter. Here, the most powerful features of optical and digital systems are united so that the fast two-dimensional signal handling of the optical unit complements the flexibility of the digital computer. More space might have been given to the achievements of Lohmann's school in Erlangen, which has made many interesting contributions in this field.

The penultimate chapter, by J.W. Goodman, deals with a difficult task on which comparatively little work has been done, linear space-variant optical data processing. Crudely speaking, here we are concerned with integrals that are not in the form of convolutions and hence do not separate conveniently under Fourier transformation. Goodman's clear statement of the problems involved is particularly welcome. The book concludes with a further contribution by the editor, on nonlinear optical processing: "logarithm, exponentiation, intensity level slicing, thresholding, analog-to-digital conversion, logics and bistability", the last four of which are "important toward developing a futuristic digital optical processor".

Applications of these various techniques are only mentioned in passing, as we should expect in a book on "fundamentals", but many are explored in detail in Casasent's earlier volume which contains chapters on optical transforms and systems, enhancement and restoration, synthetic aperture radar (one of the first triumphs of optical processing), photogrammetry, nondestructive testing and metrology, biomedical applications and signal processing. Taken together, the two books give an excellent account of the present state of this field, still young but rapidly maturing. A minor criticism is the under-representation of European work in both works — perhaps this can be rectified in a future volume in the series. Even so, they give the best available account of a mass of new material, written by experts on the various topics. □

Myriapod carnivores

John A. Wallwork

The Biology of Centipedes. By J.G.E. Lewis. Pp.476. ISBN 0-521-23413-1. (Cambridge University Press: 1981.) £33, $69.95.

Few students of the soil fauna can fail to be fascinated by centipedes, although these elusive predators are often overlooked because of their secretive habits. Accounts of their biology have hitherto been widely scattered in the literature, usually in a fragmentary fashion. There has long been a need to gather this information together, stemming from the recognition that these carnivores may regulate the prey populations on which they feed. The prey (mainly Collembola) are principally primary consumers of dead organic material, and predation by centipedes on these "key industry" detritivores may operate to control, indirectly, rates of organic decomposition.

In this book, Dr Lewis does not concern himself with this latter theme to any great extent; indeed, by his own admission, his ecological survey is less than comprehensive. In this, however, he is a victim of circumstances since the integration of centipede ecology with that of the entire soil–litter system is only just beginning. What he has provided is a comprehensive account of centipede biology which soil ecologists will find most useful, and which forms a worthy complement to Eason's earlier taxonomic treatise, *Centipedes of the British Isles* (Warne, 1964). Eason, however, dealt only with British centipedes, and Dr Lewis's experience with temperate and tropical myriapods is reflected in a widely based survey of centipede anatomy, behaviour, physiology, reproduction, life histories, taxonomy and ecology. He devotes as much attention to the mainly tropical Scolopendromorpha as he does to the temperate Lithobiomorpha and the cosmopolitan Geophilomorpha.

As the dust cover of the monograph reminds us, this is primarily a source-book and the way in which Dr Lewis organizes his information — into sections dealing with taxonomic groups — emphasizes the point. Although this device allows the reader easy access to the subject matter, since it is repeated chapter after chapter, the result makes for less than compelling reading; this is a book to inform rather than to be contemplated at leisure. The style is direct, as befits a rather clinical presentation of a catalogue of facts, and the illustrations are numerous but variable in quality, which may reflect the fact that they were taken directly from original sources rather than re-drawn. The reproduction of Manton's (1965) figures are, for example, excellent as might be expected. At the other extreme, the figure of *Lithobius forficatus* eating a fly (Fig. 126) is less than impressive and perhaps unnecessary. Some figures are inadequately labelled (for example, Figs 162a, 203b, 204 and 206). The bibliography is extensive and up to date, and although there is no author index a detailed subject index is provided.

My overall verdict is that the author has succeeded admirably in what he has set out to do. Despite its defects, many of which are unavoidable, the result is a valuable reference book which will be sought by undergraduates and research workers alike. □

John A. Wallwork is Reader in Zoology at Westfield College, University of London.

Everything you wanted to know about protein phosphorylation

P.J. England

Protein Phosphorylation. Cold Spring Harbor Conferences on Cell Proliferation, Vol.8. Edited by Ora M. Rosen and Edwin G. Krebs. Two-volume set, pp.1,421, ISBN 0-87969-140-9. (Cold Spring Harbor Laboratory: 1981.) $140 US, $168 elsewhere.

THE discovery that enzymes could be reversibly phosphorylated, with concomitant changes in activity, was made 25 years ago. For some time after that it appeared that only the enzymes of glycogen metabolism were so regulated, and that protein phosphorylation was a rather special and restricted form of control. However, during the past decade it has become apparent that almost every aspect of eukaryotic cell function is regulated in some way by phosphorylation, and the phenomenon is now known to have implications in many areas of molecular biology. This rapid expansion has made it difficult even for specialists to keep in touch with all aspects of the subject. The publication of these impressive books is thus most welcome; details of almost all of the current research on protein phosphorylation are brought together, so that no one working in this or related areas now has any justification for ignorance.

The books are the result of a five-day conference held in the summer of 1980. It was attended by about 200 people from all the major laboratories working on protein phosphorylation in North America, and a small number from elsewhere. Approximately 100 talks were given, each one of which is represented by a chapter. These individual contributions are grouped into ten sections, the titles of which give a clear idea of the wide range of topics covered in the two volumes — cyclic AMP-dependent protein kinases: structural studies; cyclic nucleotide-dependent and independent protein kinases and protein phosphorylation; glycogen synthetase/phosphoprotein phosphatases; regulation of lipid and carbohydrate metabolism; insulin and growth factor-promoted protein phosphorylation; contractile proteins; protein synthesis; nuclear and cytoskeletal protein phosphorylation; viruses and cell transformation; neural and membrane protein phosphorylation.

Each of the sections contains a wealth of recent results and interpretations from several laboratories. For example, one of the newest areas of interest is that of tyrosine phosphorylation coupled to viral transformation of cells. No less than six chapters are either devoted exclusively to this topic or mention it in detail. There are, overall, some 17 chapters on the role of protein phosphorylation in the control of transcription, translation and cell transformation. However, it should not be thought that some of the more established areas have been neglected; about half of the contents deals with protein kinases, phosphoprotein phosphatases and carbohydrate metabolism. There is now considerable knowledge of the structure and catalytic mechanism of cyclic-AMP-dependent protein kinase, which is discussed at length in several articles. The detailed descriptions of this enzyme at the atomic level contrast strongly with the imperfectly understood role of protein phosphorylation in the imperfectly understood eukaryotic nucleus. The books give the clear impression of a subject with distinct, well-established origins now bursting out in many directions.

Reading either whole sections or individual chapters I found much useful information and many stimulating ideas. Almost all of the chapters give an impression of current work being actively pursued, with little that is dated or incorrect. Excellently produced in the clear, uniform style typical of Cold Spring Harbor publications, the books will be equally useful to those new to protein phosphorylation who wish to discover how it relates to their current research interests, and to those already working in the area who need to be informed of new developments. This is undoubtedly a key reference work which should be in any laboratory working on protein phosphorylation, and in all medical and biological libraries. □

Textbook supplement

Next week's issue of *Nature* will include the Textbook Supplement, comprising reviews of over 100 recently published books for undergraduate students.

What can be inferred from exciton lines?

Dennis Dunn

Excitons: Their Properties and Uses. By Donald C. Reynolds and Thomas C. Collins. Pp.291. ISBN 0-12-586580-5. (Academic: 1981.) $36, £33.80.

THE optical absorption of most insulating crystals exhibits a series of sharp lines at frequencies just below the onset of the continuous absorption spectrum. These are the exciton lines. The non-interacting electron theory presented in most solid state physics texts readily accounts for the general features of the continuous absorption spectrum but fails to predict the existence of the exciton lines. These arise as a consequence of the electron-hole correlation induced by the Coulomb interaction.

The aim of *Excitons* is to provide a self-contained review of the theory and experimental properties of excitons and of the information about electronic structure which can be determined by a study of the exciton lines.

The conventional effective-mass theory is presented in Chapter 2, which includes discussion of the effects of electric and magnetic fields (Stark and Zeeman splitting). The highlights of the book are the chapters on the experimental properties of intrinsic and bound excitons. These, of course, are just the areas where the authors have made significant contributions and their mastery of the subject is clearly demonstrated. Set in between — the chapters seem to be randomly ordered — is a brief review of the recent work on the electron-hole liquid, a condensed phase which occurs only if the optical excitation is intense enough to produce a high exciton density.

There are a few surprising omissions from the text. There is no discussion of the theory or experimental properties of the line-shapes. The mass of research on excitons in alkali halides rates only one paragraph, and the rare-gas solids are not mentioned. This is a great pity because research on these materials, which have "deep" excitons, has demonstrated that the effective-mass theory has a far wider range of applicability than was previously thought.

The low-point of the book is the first chapter which tries to lay down the theoretical foundations of exciton theory. Here the authors have been too ambitious and have attempted to present the whole of many-body theory in one brief account: Green function formalism, Bethe–Saltpeter equations, spectral representations all appear and disappear within the space of ten pages.

Excitons is certain to become one of the standards in solid state literature. Physicists who want to initiate their research students into the mysteries of excitons can safely direct them to this book with just one piece of advice: start with Chapter 2. □

Dennis Dunn is a Lecturer in Theoretical Physics at the University of Reading.

Test-tube babies pilloried again

Physicians' organizations in the United Kingdom are busying themselves with an examination of the ethics of in vitro fertilization and related developments. Why now? And to what end?

The British medical establishment seems bent on making an unpalatable mess of its consideration of the ethical problems occasioned by recent developments in the treatment of human infertility. This week, the ethical committee of the British Medical Association will have held a private but much publicized meeting to brood about the ethical implications of *in vitro* fertilization and the possibility of setting up banks of frozen sperms, oocytes and even embryos. And the Royal College of Obstetricians and Gynaecologists is embarking on a joint exercise with the same objectives. Naturally enough, an army of pundits has joined in the fuss, announcing to an astonished world that a new revolution of technique has suddenly taken place and that a novel set of legal conundrums has been created overnight. Whether or not physicians are enlightened by the work of the committees now hard at work, it is certain that the public will be confused.

The issues provoked by human embryology are by no means novel. For the past fifteen years, Mr Patrick Steptoe and Dr R.G. Edwards have made no secret of their ambitions to use *in vitro* fertilization of oocytes as a means of treating human infertility. The novelty is merely that their techniques are now reproducibly successful, in Britain but also in other places (see R.G. Edwards, *Nature* **293**, 253; 1981). Although first thought of as a technique for treating female infertility, *in vitro* fertilization has also turned out to be a means of arranging for the conception of a live fetus by an oligospermic male partner to a marriage.

Strictly speaking, however, these novel developments occasion no novel ethical or legal problems. So much was made clear in the report in 1974 of a committee of the British Association for the Advancement of Science (see *Our future inheritance: Choice or chance* by Walter Bodmer and Alun Jones, OUP). For it seems generally agreed that conception is preferable to childlessness within a marriage, and that *in vitro* fertilization using a husband's sperm is preferable to fertilization (by artificial insemination) with male gametes from some sperm bank or donor. It may be appropriate (but can hardly be necessary) that physicians should have guidance in advising their patients when one form of treatment or the other may be advisable; they are more likely themselves to be guided by specialists in the field. It is entirely inappropriate that they should be given the false impression that entirely novel issues have been raised.

One particular red herring, wrongly linked with the practice of *in vitro* fertilization because of a recent wave of publicity in Britain, is the fear that there will emerge a new profession of surrogate mothers — people offering uterine hospitality to *in vitro* embryos. The chances of this happening more often now than hitherto are small, while legal precedent suggests that children born in such circumstances would be the children of their host — and that their later disposal would be governed by the law regulating adoption, including the customary strict interdiction against money changing hands.

Superficially at least, sperm banks and frozen embryos are different. That, however, is more illusion than reality. Given that many couples who at present cannot conceive children naturally are driven to AID, what is more natural than that they should seek to make good their disappointment by looking for some genetic authentication of the sperms they eventually use? Such a system would indeed be far preferable to the present amateurish ways of collecting sperms without pedigrees, but it would of course be unacceptable that sperms should be sold at outrageous profit and that the identity of their donors should be advertised or even disclosed. For such reasons, and also because genetic authentication requires supervision, legislation for the licensing of sperm banks is plainly necessary. It goes without saying, however, that sperm banks cannot offer those who use them more than a negative bill of good health; to say that some known genetic defects are absent is not the same as to promise that the particular combination of paternal genes that meiosis had provided in a sperm will be thoroughly welcome.

Similar arguments limit the likely uses of frozen embryos. The bizarre uses of the technique to propagate an endless succession of children from the same parents, often long dead, will run foul of the unwillingness of women to give hospitality to other people's children (and of the long-established unwillingness of physicians to assist them). But the technique might help to avoid maternally transmitted defects, and should for that reason be welcomed in the rare cases in which it is likely to be used. If ethical committees wish to brood about something tangible, they should worry about cloning — still some way off, but no longer out of sight. The trouble is that such a technique may seem to some to offer means of eugenic improvement justifying all kinds of clandestine stratagems — and which are likely, in the end, to be disappointed by the genetic defects well recognized in amphibian cloning. The best safeguard, for the time being at least, is to require that people engaged on such experiments should discuss the implications of their projects with a suitably independent laboratory committee.

Washington Editor, *Nature*

Ms Deborah Shapley has been appointed Washington Editor of *Nature* in succession to Mr David Dickson, who is leaving the journal at the end of March, after four years in the post. Ms Shapley, a graduate of Harvard University, has worked for the MIT alumni journal *Technology Review* (1968–71) and *Science* (1971–79). She is at present Guest Scholar at Resources for the Future Inc. in Washington, DC after three years at the Carnegie Endowment for International Peace; she is completing a book on Antarctica on a project supported by the Carnegie Endowment.

Nature is looking for a second member of staff to join the Washington office, primarily as a reporter and to commission various contributions to the journal. A formal advertisement will appear next week.

Down with airline cartel

The collapse of Laker Airways should provoke an outcry against government interference.

The benefits of a new technology cannot be assessed in the abstract, but only in the marketplace. This is the conventional wisdom. Whatever ingenuity is lavished on, say, the improvement of mousetraps, an innovation can be counted a success only if its performance and price command a sale among those seeking to rid themselves of mice. For mousetraps and similar products, the primacy of the marketplace is well-established. In other fields of technology, however, all governments choose to suspend the rules

0028-0836/82/060445-02$01.00

in their own narrow and political interests. They habitually give national manufacturers preference in much of their own purchasing of technological products, from computers to power stations. The result is that the potential benefits of technological advance, and especially potential reductions of costs to ultimate consumers, are needlessly and often scandalously diluted. And scandal is nowhere more rampant than in the airline business, where the potential benefits of a beneficent aeronautical technology are watered down by the insistence of national governments that the places to which aircraft fly should be decided not by the marketplace but by negotiations among diplomats, and that airline fares should be decided by an international price-fixing cartel organized by the United Nations, the International Air Transport Association (IATA).

The only comfort in the unfortunate financial collapse at the weekend of the independent British airline Laker Airways is that the folly of governments' attempts to regulate the world's airlines may now be more widely recognized. Laker Airways, not a member of IATA, has won its reputation in the past five years by offering cheap fares on various transatlantic routes from the United Kingdom. Its attempts to bust the international cartel on routes between Britain and the rest of Europe were, however, frustrated by the unwillingness of governments other than the British to expose their national airlines to competition. While the airline's collapse is probably as much a consequence of commercial overoptimism as of unrealistic expectations that it would be allowed to continue to expand, the suspicion remains that it would not have run into trouble if the international airline business were, in the commercial sense, a business.

The difficulty lies in the widespread assumption by governments that a soveriegn government without an airline is like a baseball team without a stadium — incomplete and unconvincing. For how would it seem, in the domestic newspapers, if a president or a prime minister were seen alighting in some foreign capital from an aircraft operated by some carrier other than the national airline? Worse still, how could those lined up to receive such a personage be expected to take the visit seriously if he or she were seen to be a mere fare-paying passenger? (The calculation that since many of these journeys are made with the objective of borrowing money, and that ostentatious extravagance might in the circumstances prudently be avoided, is usually overlooked.) One result is that most governments shoulder without too much complaint the direct subsidies their airlines cost (but the United States government provides hidden subsidies instead). Another is that, to ensure that their national airlines have something to do when not transporting dignitaries about the world, governments assume the right to negotiate strictly bilateral agreements with each other to regulate the numbers of flights by national airlines that there should be. Then, to limit the subsidies they must provide, governments agree that their national airlines should rig the prices that they charge.

To be fair, both the British and the United States governments have recently been trying to break free from this pattern. Within the United States, the consequences of substantial deregulation of domestic flights in the past two years have been dramatic, both in providing cheaper fares and in showing which among the competing airlines are the weak and which the strong. In Britain, the government has allowed small and sometimes new independent airlines to operate new routes and has also encouraged independent carriers such as Laker to seek business abroad. Even if, however, a substantial part of the stock in British Airways is eventually sold to the public, the existing apparatus of horsetrading for routes and price-fixing for fares will remain. For, as things are, the restrictive practices now operated by governments and their national airlines serve one practical purpose — they protect governments from themselves and from each other.

So long as most airlines are supported financially by some public and thus supposedly bottomless purse, price-fixing is defensible. Without it, there would be nothing to prevent airlines in collusion with their governments from openly selling airline tickets below the full cost of servicing them, decreasing its own financial loss by making fuller use of its aircraft and, in the process, transferring the loss to some other carrier. The snag, of course, is that those who rig the prices are the national airlines, with no conspicuous interest in competition. Bilateral agreements on which airlines should be allowed to fly which routes should in principle be unnecessary if fares have been fixed correctly, taking full account of the costs of servicing capital as well as of flying aircraft.

Not least from nostalgia for the Laker enterprise (which may yet be rescued), the time has come when this bumbledom should be replaced. Regulations, unfortunately, cannot be entirely set aside, for international air transport is socially and commercially too important to be exposed to the risk of commercial cartelization, potentially as damaging as that now operated by governments. But the present regulation of air transport could and should be replaced by a system consisting of very little more than a set of common rules by which competition is permitted.

The first essential ingredient of such a system is that competition on routes and fares should be freely allowed between airlines provided that they do not enjoy the support of governments, direct or indirect. Common standards of safety would be necessary (as at present), but an airline able to pay its pilots and other people less than its competitors should be entitled to charge lower fares. Arrangements would be necessary to ensure that airlines did not subsidize competitive routes or some categories of passengers at the expense of others, but such tasks are familiar and well within the competence of accountants.

But how, if governments are wedded to the concept of a national airline, can such a state of grace be reached? Fortunately, at least some governments seem now to be disenchanted with the need to hand out subventions every year. Why should they not club together to put the airline business on a rational footing, using the existing apparatus of restriction and pricerigging to regulate their dealings with the airlines of more backward states? Even if only Britain and the United States were able to make a deal along these lines, a telling example would be provided for the others. But the natural place for an agreement is within the European Community, which has been talking about the issue for a decade to no effect.

New budget, no change

Science does well, on paper, in the US budget for 1983. But the promise is paper-thin.

President Ronald Reagan's second budget (or is it his fifth?) is, as predicted, kind to science but, unexpectedly, beastly to the conservative aspirations of the President's supporters. Although there will be many disappointments in the proposals published at the weekend, many of the obvious ways in which economies might have been sought have been avoided. The new (and much delayed) accelerator at Brookhaven is not permanently scrapped but put into suspended animation. The basic research programme supported by the budget of the National Aeronautics and Space Administration survives more robustly than seemed likely only a few months ago, marred only by the folly of the decision that there will be even less support for attempts to make sense of the data existing and new which spacecraft will collect. Similarly, the chief sources of support for research at United States universities — the National Science Foundation and the National Institutes of Health — are to be protected from the consequences of inflation. If only (but see page 449) the Department of Defense can spend some of its extra money in the universities, the research community will be in good shape.

The snags are less easily defined. Cutting back on student support will put more severely to the test than in the past few months the unproven hope that students will, when pushed, work their way through every course of study — and may be disastrous. Even more seriously, the cavalier decision that budgets need not be balanced, with its inflationary and international consequences, may so undermine the economic well-being of the United States that the formal protection of research will count for nothing.

0028-0836/82/060447-01$01.00

DNA panel has second thoughts

Mandatory rules not yet to be abandoned

Washington

Bending to political realities, the Recombinant DNA Advisory Committee (RAC) to the US National Institutes of Health (NIH) has backed away from its support for a proposal that guidelines covering NIH-sponsored research using recombinant DNA techniques should be made voluntary, and that research institutions should no longer be formally required to establish safety committees to ensure that the guidelines are observed.

At its last meeting in September, the members of RAC decided to support the publication for public comment of the proposals for major revisions to the guidelines that would essentially transform them into a voluntary code of conduct.

However, in the light of the comments received — and in particular of warnings that if the guidelines become voluntary states such as California are likely to introduce their own more restrictive regulations — RAC on Monday adopted a compromise formula that would streamline the containment requirements for different types of experiments, but retain their mandatory aspects. Two proposals had been put out for comment. One, a revision of amendments originally proposed by Dr Alan Campbell of Stanford University and Dr David Baltimore of Massachusetts Institute of Technology, would eliminate all the mandatory requirements of the guidelines, including the sanction that noncompliance could lead to a loss of NIH funds.

The alternative proposal, submitted by RAC-member Dr Susan Gottesman of the National Cancer Institute, would retain the guidelines as a required procedure for those receiving NIH grants, including the requirement that certain experiments be reviewed either by RAC or by local Institutional Biosafety Committees (IBCs). The containment classifications, however, would be reorganized, and containment requirements for some classes of experiments would be made less stringent.

The potential consequence of transforming the guidelines into a code of practice for community opinion at local and state levels dominated the discussions.

Most informed scientists who had sent in written comments expressed strong support for making guidelines voluntary, arguing that risks once thought plausible had now been shown to be either remote or non-existent. Dr Paul Berg of Stanford University, for example, one of the three signatories of the original letter suggesting a moratorium on rDNA research, wrote that he believed the guidelines "are now dispensable".

The institutional response, however, has been different. Many local IBCs, those in universities and in private industry, told NIH that they were not experiencing major difficulties in implementing the guidelines as they now stood. Several warned that the absence of mandatory federal guidelines would provide an opportunity for the introduction of a patchwork of individual laws.

The Industrial Biotechnology Association, for example, which represents a number of small biotechnology companies such as Cetus and Genex, wrote that "one significant reason for adherence to a uniform system of federal guidance and overseeing is our belief that such an approach is more compatible with commercial development and the benefits it brings to society than would be a system of varying local requirements".

If there was an unexpected consensus at Monday's meeting that a strong federal presence in regulating rDNA research remains desirable, there was less agreement on whether the potential hazards of such research should be treated differently from related areas of biomedical research.

Some members of the committee, arguing the lack of substantial evidence of additional hazard, suggested that this was a reason for adopting uniform practices by making guidelines voluntary. Others, however, used the same data to urge that the experience of RAC should be used as a basis for encouraging a similar approach to research with other organisms.

After hearing the arguments for both proposed revisions, the members of the committee voted by 17 to 3 to adopt those put forwards by Dr Gottesman as the basis for revising the guidelines, rather than those which had been informally endorsed at the September meeting. It also agreed to set up a small working group to revise the specific recommendations which she had put forward to change the current classifications, and to present its conclusions to the director of the National Institute for Allergic and Infectious Diseases, Dr Richard Krause, who will decide what changes to the guidelines will be introduced.

David Dickson

Budget protection for research

Washington

The United States scientific community has done relatively well out of the budget proposals which President Ronald Reagan submitted to Congress on Monday for the fiscal year 1983, which begins on 1 October.

Overall, the President is requesting an increase of about 10 per cent in expenditure on research and development. With an officially-estimated inflation rate of 6.5 per cent, the Administration is claiming that this would represent a real growth in research and development of about 3.5 per cent. The same pattern of growth is being suggested for the basic research budget, scheduled to increase by 8.8 per cent to a total of $5,821 million.

In both instances, the major contribution to this growth has been increased spending on military research, which rose 25 per cent between 1981 and 1982, and is scheduled for a further growth of 18.9 per cent next year.

Where these increases reflect Mr Reagan's election campaign promises to boost United States military strength, another promise is reflected in moves to reduce substantially federal sponsorship of energy research, on the grounds that this should, where possible, be made the responsibility of the private sector.

The most dramatic reductions are proposed in solar research and other renewable energy sources, such as hydropower and geothermal, scheduled to come

Recommended budget obligations for fiscal year 1983

	Research and development		Basic research	
	Total (million $)	Increase 1982–83(%)	Total (million $)	Increase 1982–83(%)
Department of Defense	24,469	18.9	781	16.0
National Aeronautics and Space Administration	6,513	12.1	682	17.6
Energy Research and Technology Administration*	3,917	-13.3	741	14.5
National Institutes of Health	3,533	3.1	1,897	3.1
National Science Foundation	1,033	7.5	984	7.9
US Department of Agriculture	838	3.8	359	8.1
Environmental Protection Agency	230	- 27.4	10	- 50.0
Other agencies	2,464		367	
Total	42,997	10.7	5,821	8.81

*Previously Department of Energy, intended to become part of the Department of Commerce.

0028-0836/82/060446-02$01.00

down from $248 million in 1982 to $83 million in 1983. Energy conservation research would be reduced even more drastically, from $144 million to $18 million; both proposed cuts are expected to be challenged in Congress.

Another agency which has been the target of criticism from the private sector and which would also see its research budget cut under Mr Reagan's 1983 proposals is the Environmental Protection Agency, down from $317 million to $230 million.

Other research agencies, however, have done quite well, reflecting a broadly-based acceptance within the Administration that strong federal support for research and development is a legitimate claim on the public purse.

The National Science Foundation, for example, is listed for a budget increase of 7.5 per cent, with considerable real growth in areas such as computer research (up 14 per cent) to $29.3 million, earth sciences (up 17.8 per cent) and mechanical engineering (up 13.7 per cent). The Administration has relented slightly in its efforts to cut back support for the social and economic sciences, having initially requested $10 million in the 1982 budget, but now supporting a figure of $17.8 million in 1983, the same level to which the 1982 budget was raised by Congress. However, it is sticking to its previous determination to eliminate virtually all science education activities sponsored by the National Science Foundation, arguing that education at the school level should remain primarily a responsibility of the states and local school boards.

The National Institutes of Health are scheduled for a modest 3.1 per cent increase in its research budget, slightly less than the anticipated rate of inflation. Unlike last year, the Administration is not seeking to eliminate institutional support for research training awards, a move which provoked a major outcry from biomedical research institutions.

Inevitably, budgetary stringencies have caused disappointments. The National Aeronautics and Space Administration, for example, has for the moment abandoned plans to send an orbiting imaging radar to Venus; but the rumoured extinction of the Galileo mission to Jupiter failed to materialize, and space science is scheduled for a healthy increase of almost 20 per cent, including full funding for the gamma-ray observatory, as well as sustained support for the space shuttle.

Dr George (Jay) Keyworth, the President's Science Advisor, said on Monday that he was "delighted" with the budget increase for science. He said that the physical sciences, once in jeopardy, had been spared during the review process to enable increased utilization of existing particle accelerators. "Next year", he said, "there will be more effort to separate the mediocre from the excellent in research."

David Dickson

US budget described in outline

Energy support

Washington

Not unexpectedly, the requested budget for the Energy Research and Technology Agency will contain strong support for the Clinch River liquid metal fast breeder reactor. The design and construction of the fast breeder are described as priorities and will receive $257 million for the initiation of site preparation and continued procurement of parts.

However, work on both the Large Development Plant, started by the Carter Administration as an alternative to Clinch River, and the light water breeder reactor will be phased out, leading to an overall decrease of $108 million from 1982 in spending on breeder reactors.

There will also be reduced support for fusion research, with the focus shifting from the construction of new facilities to what the Office of Management and Budget describes as "resolving key outstanding physics and technology issues". This will delay construction of the tandem mirror test facility at the Lawrence Livermore Laboratory, a decision which has contributed to the resignation of the head of the Department of Energy's fusion programme, Dr Edward Kintner.

Funds for inertial confinement fusion, until recently treated as a major alternative to the magnetic fusion programme, have also been reduced from $209 million in 1982 to $119 million in 1983, again through shifting the focus from the completion of new facilities, such as Lawrence Livermore's Nova device, towards experiments on existing machines.

In contrast to the continued — if slightly reduced — support for research into nuclear fusion and fission, only $315 million is being requested to support research in fossil, solar, biomass and other renewable energy sources, compared with $814 million in 1982.

Unrest on loans

If US universities have been relieved at escaping the prospect of heavy cuts in research spending, there is less consolation in the Reagan Administration's proposals to limit its assistance for students by reducing the support for the Guaranteed Student Loan (GSL) programme.

First introduced in 1965, the programme provides loan guarantees and interest subsidies to states, private lending institutions and eligible students. Under the present plans, federal support would increase from $3,397 million in 1983 to $3,768 by 1987. Tightening up on eligibility requirements and increasing the costs of obtaining a guaranteed loan will result in savings of $912 million in 1983, rising to $2,247 million by 1987.

Loans to about 600,000 graduate students would disappear under plans to reduce by about a third the number of so-called Pell awards. Graduate students would be restricted to raising loans from the less-heavily subsidized GSL auxiliary loan programme, and lending institutions would be required to pay a higher insurance premium to the government.

The Administration claims that the cuts are justified on the grounds that the primary beneficiaries of the guaranteed loans have been "middle and upper income families", which had as a result been able to put their own savings into investment schemes yielding far higher returns. The universities, however, are worried that tightening up the loan conditions could lead to a severe drop in student numbers.

David Dickson

ISABELLE

Construction work on ISABELLE, the 400 × 400 GeV proton–proton accelerator at Brookhaven National Laboratory on Long Island, New York, will be halted under budget plans for the Department of Energy for 1983. However, development work will continue as an accelerator research and development programme on superconducting magnets.

In general, high-energy physics has done well in the budget proposals. Mr Reagan is seeking an increase of 17.5 per cent in funding to $429 million, claiming this will allow increased use of existing research facilities, the completion of both the Energy Saver and the Tevatron I and II at Fermilab, and further research and development at the linear collider being planned by Dr Burton Richter at the Stanford Linear Accelerator Center.

Construction on ISABELLE, which started in 1978 and had been due for completion in 1987, has been held up largely due to difficulties with the magnets. Although these now appear to have been solved, the delays have meant extra expense. Last November, a special panel set up by the Department of Energy's High-Energy Physics Advisory Panel to look at the future of US high-energy physics concluded that ISABELLE was still important, but did not place its completion as a first priority in stringent budget conditions.

According to the Office of Management and Budget, the accelerator research at Brookhaven will be related to a "future high-energy physics accelerator project", and "any decision to proceed with this project will be based on overall scientific potential and budget considerations".

Space science

The Venus Orbiting Imaging Radar (VOIR) has been dropped from the National Aeronautics and Space Administration (NASA)'s list of future planetary exploration missions. However, the agency is discussing with space scientists the possibility of launching a

0028-0836/82/060448-02$01.00

cheaper version of the mission, using real rather than synthetic aperture radar, which could halve the estimated $500 million cost and might still be launched by the end of the decade.

VOIR was initially proposed by the Carter Administration two years ago for a launch from the space shuttle in 1986, with the launch being merely postponed to 1988 by the Reagan Administration last March. It is the major casualty in NASA's space science budget, which otherwise is in a much healthier state than had been widely feared.

Both the Galileo mission to Jupiter and the gamma-ray observatory, which had been threatened by the Office of Management and Budget, have survived. Efforts to cut back substantially on space science seem to have been frustrated by strong pressure from the space science community, and fears that the cuts could have a traumatic effect on NASA's Jet Propulsion Laboratory in Pasadena, California.

NASA will not be providing any money for the development of the Centaur rocket as an upper stage for the space shuttle, previously suggested as an alternative to the delayed Inertial Upper Stage.

One area to be cut will be the analysis of data from other planetary missions, being reduced from $61.8 million in 1981 to a suggested $26.5 million in 1983. NASA officials say that although data will continue to be received and analysed from the Voyager spacecraft, now on their way to the outer planets, it may be necessary to stop tracking or taking data from the Pioneer spacecraft.

Delay for *Explorer*

The National Science Foundation has abandoned plans for a major deep-sea drilling programme aimed at investigating the margins of the continental shelf which was to have been conducted from the converted spy ship, *Glomar Explorer*.

Dr John Slaughter, director of the foundation, announced last Saturday that the Reagan Administration would not be requesting any further funds for the so-called ocean margin drilling programme, which was to have been jointly funded with a number of private oil companies.

According to Dr Slaughter there were two reasons for abandoning the project, first formally proposed by the Carter Administrtion two years ago: a lack of sufficient funding, given general pressures on the federal budget; and the lack of interest by companies in making the type of investment required to convert the *Explorer* and fully equip it.

The proposal has also been a controversial one in the scientific community, since it would have meant curtailing funds for the *Glomar Challenger*. Dr Slaughter said that a decision will be made next summer on whether to refurbish the *Explorer* as a replacement for *Glomar Challenger*. **David Dickson**

US defence research

Signs of doubt

Washington

The Reagan Administration is proposing in its latest budget recommendations to Congress (see p447) that there should be an increase in the amount of university-based research sponsored by the Department of Defense in the fiscal year 1983 beginning on 1 October. But the universities themselves are ambivalent about this promise.

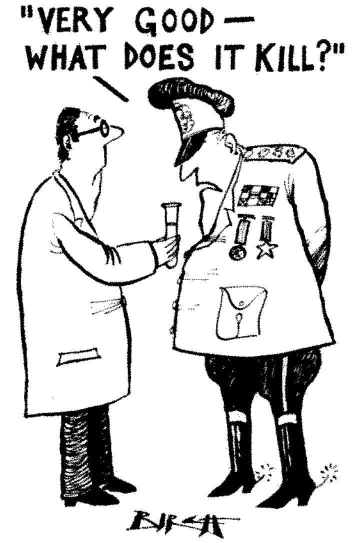
Many universities view Defense Department support as a necessary substitute for other federal funds whose sources are rapidly drying up. However, increased military spending on campuses is beginning to act as a catalyst for protest groups opposed to the Administration's policies.

University administrators seem to have fallen in with recent moves by the Department of Defense to increase support for basic research, while fearing some of the restrictions that this money may bring with it. Although many universities still insist that no classified research is carried out on campus, academic leaders have been quick to reassure Congress that little remains of the anti-military sentiment of the 1960s.

Dr Alan Bromley, for example, professor of physics at Yale University and president of the American Association for the Advancement of Science, told the House of Representatives science and technology subcommittee last week that the time to rebuild bridges between the Pentagon and the university research community was "long overdue".

Yet the enthusiasm for increased military support of university research is far from unanimous and there have already been rumblings of protest:

- 170 people from the University of California were arrested last Monday after demonstrating outside the Lawrence Livermore National Laboratory — run by the university on behalf of the Department of Energy — in protest at the laboratory's research on the design of nuclear weapons.
- At the University of Michigan, the students' union has hired a historian to analyse the Defense Department's support of research in the university and in local companies.
- A demonstration was held last summer at the University of Wisconsin's Madison campus over a visit by army scientists to the university's Mathematics Research Center, sponsored by the Department of Defense, to talk about military needs in mathematics. A group has since been formed to study the university's links with the Department of Defense, and a small organization has been set up to stimulate and coordinate efforts by similar groups elsewhere.
- At the Massachusetts Institute of Technology, about 1,000 people held a demonstration when Vice-President George Bush spoke to the institute's board of trustees. Several study groups have since been holding regular meetings on military topics, and 30 faculty members have just launched a disarmament project for the spring term.
- There have been protests at Rutgers over a statement by its president, Dr Edward J. Bloustein at a congressional hearing last year that he would be prepared to consider lifting the current ban on classified research on the campus.
- Last November, "teach-ins" were held at 148 colleges and universities across the country on the arms race. The meetings were coordinated by the Boston-based Union of Concerned Scientists, which claimed that they had been the largest anti-war demonstrations since the Vietnam era.



"VERY GOOD — WHAT DOES IT KILL?"

Nobody suggests that these isolated protests represent a significant national movement — at least not yet. Several factors have produced a less fertile environment for protest than the 1960s, ranging from the more conservative outlook of most undergraduates to tight research budgets that can lead to a muting of criticism of the sources of research support.

At the same time, some see as significant the fact that each individual incident has taken place on campuses where there were fierce clashes over military research in the 1960s and early 1970s.

University representatives lobbying the Pentagon for more research funds in Washington tend to play down the potential campus disruption. Even the protesters agree that, although anti-military feeling on campuses has grown rapidly over the past two years, it has yet to coalesce into a major source of opposition.

But the military is still treading warily. When the Defense Communications Agency agreed to sponsor a National Science Center for Communications and Electronics — largely sponsored by the private sector — to stimulate science and engineering education, it chose to concentrate its initial efforts on high schools rather than universities.

Building links with the academic

0028-0836/82/060449-02$01.00

community "could be a very delicate issue" the agency's director and the principal sponsor of the centre, Lt Gen. William Hilsman, said in a recent interview, stating that the schools had been chosen because they were less likely than universities to view the military interest in education as a threat to academic freedom.

Meanwhile the universities themselves are hoping to receive some guidance from a report recently completed by the Defense Science Board for the Department of Defense. The report is expected to recommend the development of clear guidelines to separate basic research from that which may be of a more practical nature — and hence require special protection and treatment. **David Dickson**

British university crisis

Cuts with tears

British universities, still in chaos over how to meet cuts in government income over the next three years, were relieved last week to learn that they are to be compensated for payments made to academics who must lose their jobs. A letter from the University Grants Committee set out the terms under which they will be reimbursed for payments made to redundant staff. Essentially, the compensation scheme is that devised by the Committee of Vice-Chancellors and Principals and blessed by the Secretary of State for Education and Science a week earlier.

The approved scheme allows redundant academic staff below 50 years of age to claim one month's pay for each year of service plus one month's pay for every year of service in excess of five years or after their 30th birthday, whichever is the later. Staff over 50 will be entitled to compensation under the universities' scheme for premature retirement introduced a year ago. The grants committee says that it will not meet claims for compensation that are more generous than those now approved, which begs the question of who will pay if the courts decide that higher awards are just.

The universities' relief will also be tempered by other provisos spelled out in the committee's letter. Full reimbursement willl be made only where universities convince the grants committee that redundancies are made in the interests of economy and that resulting vacancies will not be refilled. Redundancies should also be "consistent with academic planning", a vague phrase thought to give the committee some come-back if universities fail to comply with its advice on general policy.

In the meantime, the end of January deadline by which all universities were to have submitted outlines of how they plan to adapt has passed. Most have sent the numbers of staff they plan to lose by the end of the next academic year, on which basis the grants committee will allocate the £70 million already set aside for helping with restructuring. It seems to be accepted that the sum will be inadequate to settle all claims, although the grants committee has not yet totted up those so far submitted. It is hoped, however, that the government will make more money available by the beginning of the following year.

Only about half the universities have managed to submit returns on how they plan to restructure operations. The grants committee will be looking at the returns later this month, when it will decide whether to reallocate money to those universities that have asked to be reconsidered. The committee is unwilling to say whether the returns suggest that the universities are following its advice, except that one or two of them look "a bit odd".

Some universities seem to have managed to get away with fewer compulsory redundancies than was originally expected. The University of Leicester, for example, plans to make none. The Association of University Teachers claims that success in minimizing compulsory redundancies may reflect the efforts of its members in putting forward alternative strategies for coping with the cuts. **Judy Redfearn**

Correction

In the note in News and Views by Dr R.J. Wilson in last week's *Nature* (4 February, page 369), the third paragraph should, except for a misunderstanding in the *Nature* office, have referred to the work of Professor David Weatherall and his colleagues in the Nuffield Department of Clinical Medicine at the University of Oxford; the article describing this work will be published in *Nature* shortly.

Soviet dissidents

Helpers divided

Scientists campagning for academic freedom and civil and human rights for their less fortunate colleagues cannot confine themselves to a single cause or campaign. This was the consensus of opinion at a one-day seminar at University College, Oxford, on 7 February, organized by the Scientific and Medical Committee for Soviet Jewry.

The main guest was Dr Mark Azbel, from the University of Tel Aviv, himself a former refusnik and convenor of the Moscow Sunday Scientific Seminars for Refusniks, Dar Azbel, like most Soviet Jewish activists believes that a clear distinction should be made between the Jewish emigration movement and the dissident movement in the USSR. Any confusion between the Jews, whose only wish is to leave the Soviet Union, and the dissidents who would prefer to stay there and reform the system from within, is, he believes, dangerous to both movements, allowing the Soviet authorities to accuse the Jews of subversion and dissidents of being agents of international Zionism.

The other participants, however, felt obliged to disagree with him. Professor Paul Kessler from the Collège de France, who spoke on "Visiting Refusniks in the Soviet Union", said that he could not in conscience, while on a vist to Moscow, visit refusniks and refuse to visit dissident scientists who had also, though for other reasons, been expelled from their jobs. Dr Louis Cohen, executive secretary of the Institute of Physics, speaking on "Transnational science as an influence on Soviet science policy", talked not only of the work of his own institute which in 1978 had sponsored the parallel trial in defence of Dr Yurii Orlov, but also the valuable work of the American Association for the Advancement of Science, primarily on behalf of victims of oppression in South America and also for other human rights causes, including the refusniks. Dr Gary Low Beer, who is both head of the Scientific and Medical Committee for Soviet Jewry, and a prominent campaigner against the political misuse of psychiatry, put the point bluntly and pragmatically. One cannot expect one's colleagues to campaign for a human rights cause in which one feels a special interest, if one is unwilling to reciprocate for the causes they favour.

In reply, Dr Azbel explained that he did not want to discourage scientists who wished to campaign for dissidents. Everyone, he said, must choose his own cause. But it was better to campaign for only one person at a time, rather than several in parallel.

His support of this line of action seemed inspired not only by practical considerations but by the Yiddish proverb that to save one life is equivalent to saving all humanity. The seminar particpants, however, applauded him warmly, but clearly still favoured a unified stand by the scientific community as a whole, on all abuses of human rights and academic freedom, wherever they occur. **Vera Rich**

Small growth fund

The fund established by the Association for Research into Restricted Growth as a memorial to Mary Lindley, an assistant editor of *Nature* who died in May 1981, has now reached £700. The group intends to use the money to help young people suffering from restricted growth in problems arising during their early education. Further donations should be sent to the Treasurer, Pam Worsfold, 8 Cotswold Avenue, Chelmsford, Essex.

Polish universities

On hold again

Student protest continues in Poland, in spite of the stern controls on university life imposed by General Jaruzelski's Military Council for National Salvation Plans for the opening of undergraduate courses at the University of Warsaw were shelved again last week, following the widespread distribution of an underground leaflet appealing to students elsewhere to support the Poles' right to academic freedom and the restoration of the banned Independent Students' Association (NZS)

NZS, the leaflet pointed out, was legally recognised by the Lodz accords which concluded five weeks of student protest last spring Almost all the students who held office or played an active part in this legal organization are now, the leaflet said, interned

In Gdansk, the already severe restrictions on student life have apparently been tightened after a 3,000-strong demonstration on 30 January was broken up by riot police The local newspaper, which was only allowed to report the event several days later, said that out of the 205 persons detained, 40 were students and 56 were schoolchildren According to the government's press spokesman, Jerzy Urban, stricter controls have also had to be imposed at Wroclaw Technical University following a student protest march

Wroclaw is a sensitive area, last autumn, when a young mathematics lecturer and Solidarity activist, Kornel Morawiecki, was charged with including provocative and anti-state material in internal union publications, the rector and academic council spoke out strongly in his defence Another Wroclaw mathematician, 68-year old Dr Tadeusz Koszecki, is reported to have died of a heart attack while attempting to protect students during a police raid on 23 December

Expulsions of students and the dismissal of academics unwilling to take the oath imposed by the political "verification" process are reported across the country Unconfirmed reports state that the expulsion rate at the Academy of Mining and Metallurgy in Krakow is as high as 35 per cent — which bodes ill for the future of Poland's two major industries, for which the academy is intended to supply experts and research consultants **Vera Rich**

Euratom treaty

Call for change

Brussels

The Euratom treaty, signed by the European Economic Community's six founder members in 1958, is in urgent need of revision, asserted European Commissioner for Industry and Energy, Vicomte Etienne Davignon, at a press conference on 4 February The Euratom treaty is an instrument setting up a common market for nuclear energy It is intended to guarantee common safety standards and safeguards and to ensure that all nuclear energy users obtain a regular supply of nuclear materials Under the treaty, the European Commission has the exclusive right to conclude supply contracts

The economic advantages of nuclear power are once again argued in this provision policy paper The present 16 per cent of EEC's total electricity production created by nuclear power equalled 56 million tonnes of oil equivalent in 1981 With the planned capacity increase of 69 megawatts by 1990, nuclear energy could supply as much electricity as coal and save imports of 150 million tonnes of oil equivalent

The Commission estimates that electricity from nuclear energy is between 30 and 90 per cent cheaper than that from coal, and compared with petrol nuclear power is 100–150 per cent cheaper Although the investment costs are high, nuclear fuel costs are negligible compared with coal and oil And Davignon considers the nuclear option to have other advantages supplying a bonus in jobs and a high level of technology More detailed economic studies are awaited

In order to boost investment, the Commission wants Euratom loans doubled Credit worth 800 million European currency units (approximately $800 million) has so far been taken up out of the ceiling of 1,000 million fixed in 1977 The new ceiling would then be 2,000 million

More common efforts are called for from the member states in the storage and reprocessing of irradiated waste This could involve the establishment of EEC reprocessing companies In addition, Davignon proposes an end to electricity subsidies, which distort competition among power supplies

The essential element in the new strategy relates to the supply of nuclear materials Here judicial changes to the Euratom treaty are envisaged which might mean dismantling the Commission's exclusive trading rights and leaving Brussels with the task of ensuring that there is discrimination towards purchasing countries By this means, Davignon hopes to stimulate competition among suppliers such as the United States, Canada and Australia with which supply contracts already exist The Community would then only guarantee that the fission materials would be used exclusively for peaceful purposes

To reassure public opinion on nuclear safety, the Commission's proposals provide for a more open policy and more information The system of technical controls and safeguards needs to be updated together with a "concentration of powers" Much the same was recommended in a report by the Belgian Member of the European Parliament, Anne-Marie Lizin (see *Nature* 21 January, p 179)

Jasper Becker

Laboratory animals

Culture sought

A multi-laboratory research programme organized by FRAME (Fund for the Replacement of Animals in Medical Experiments) to investigate alternatives to animal toxicity tests is being backed by several established drugs and cosmetics manufacturers Of the £240,000 needed to support the programme, £180,000 has already been guaranteed The programme involves the collaboration of four laboratories the Huntingdon Research Centre and centres at the University of Surrey, the University of Nottingham and St George's Hospital Medical School in London

Although there have been isolated projects on toxicity testing, this is the first in the United Kingdom to link the work of several laboratories The aim is to scrutinize a common list of chemicals, some toxic, using tissue cultures rather than animals

The programme is the product of a two-year study by FRAME's Toxicity Committee who will assess the feasibility of non-animal methods of toxicity testing and report in November 1982

FRAME's board of trustees numbers only four, of whom two are scientists Dr Michael Balls of the University of Nottingham and Dr Peter Hodges, a senior scientist with Pfizer Although still a small organization, FRAME seems to have acquired some influence since its inception in 1969 A group of 40 Members of Parliament, led by Joan Lester, has pledged itself to promote alternatives to animals in experiments Industrial sponsors for FRAME's research programme include Avon Cosmetics, Rimmel International, Bristol-Myers and Pfizer

FRAME's objectives superficially conflict with the interests of the companies, which at present market their products with a degree of confidence in protection from legal proceedings for negligence because of tests using animals Their support for the new research programme seems to have been stimulated by the cost of animal screening tests and the growth in public concern for the welfare of laboratory animals

Thus Avon Cosmetics, which is supporting one of the four research groups says that its interest in alternative methods of toxicity testing is based on ethical considerations Pfizer says that it has incurred "significant expense" in making senior staff available for internal studies of alternatives to animal laboratory tests, and describes FRAME as its chief British channel for this kind of work

The Royal Society was urged at a recent meeting to set up an "ethical committee" Its *ad hoc* Committee on Animal Experiments is likely to decide on the terms of reference and chairmanship of such a working party later this month

CORRESPONDENCE

Original life

Sir — David Dickson has quoted (*Nature* 14 January, p 87) from Judge Overton's ruling against the creationists in Arkansas Among these we find "Although the subject of origins of life is within the province of biology, the scientific community does not consider origins of life a part of evolutionary theory" "The theory of evolution assumes the existence of life and is directed to an explanation of *how* life evolved Evolution does not presuppose the absence of a creator or God " Now, these statements show that much of the creationist attack on the synthetic theory of evolution is irrelevant It would be a pity if that short-term goal contributed towards a long-term predisposition in the minds of the scientific community to continue excluding the origin of life from evolutionary theory That would not be in line with the views of some important evolutionists who contributed to both disciplines Nevertheless, a bias against considering origins exists in the minds of many evolutionary biologists — I discovered for example that my textbook *Evolutionary Biology* (Holt, Rinehart & Winston, New York, 1972) was not favoured by some teachers because it has a prominent chapter on the origin of life

The evolutionary process is represented at the molecular level on the one hand and encompasses cosmogony on the other At some point a theoretical framework covering the entire range of that process will become necessary Presumably the evolution of molecular systems leads to the origin of life just as the evolution of living systems leads to the origin of ecological systems Individuals need not become proficient students of all these subjects, but it is quite another argument for an important legal document to declare that part of this subject matter is not considered proper by important exponents of the study of evolution, when that is only the provincial bias of some Such statements are potentially stultifying and to be regretted by those who otherwise rejoice in Judge Overton's document

Stanley N Salthe

Brooklyn College, New York, USA

All in the Book

Sir — That anyone writing from the evolutionists' standpoint is willing to expose such crass ignorance of the creationists' case as does Jon Marks[1] is almost beyond belief It is much to be hoped that the tone, let alone the substance, from any creationist writing about evolution would not expose such hostility

May I answer only the three biblical points raised? *Leviticus* 11 v 19 is not taxonomic but gastronomic, (and very prudent at that) it does not attempt a classification of mammalia *Luke* 23 v 43 has the comma incorrectly placed, a point of punctuation well understood over the past four hundred years *Genesis*, in respect of the fourth day, as taken up by Origen and later by Voltaire, is explained by Wiseman[2] It is, I regret, open to both sides of this argument to accuse the other of fraud and obscurantism, but nothing useful is served thereby

Frank W Cousins

Westminster, London SW1, UK

Workers' union

Sir — The letter from ten Russian scientists (*Nature* 24/31 December, p 688) is in part an approach to the WFSW The federation is indeed concerned with the difficulties that can afflict scientific workers in any country We have been able, in various circumstances, to resolve or prevent serious problems

We have been aware for several months that certain requests for exit visas from the Soviet Union have remained unanswered On 3 November 1981 I wrote to the president of the "Educational and Scientific Workers' Union of the USSR" in Moscow, in conformance with the policy of the federation first to contact our affiliated organization in the country concerned I asked to be informed of the nature of the difficulties relating to these scientists I feel certain that Mme Yanoushkovskaya is making the necessary investigation and that she will soon be able to furnish an explanation

The list of signatories in the letter published by *Nature* is not identical to that in a letter I had earlier received, two names have been dropped and four added I infer that the situation has evolved since last year

J M Legay

World Federation of Scientific Workers, Lyon, France

Reagan's right

Sir — The editorial "Reagan's mistake on Soviet sanctions" (*Nature* 7 January, p 1) is disturbing Science is not now (as it may have been in Davy's time) merely a pastime for scientists It has powerful consequences for humanity in both peaceful and war-like activities If all humankind were one big happy family, then free interchange of science would be both desirable and inevitable But humanity is divided into groups whose objective is not to have cheery little wars with "sweetness and light" in view down the road, but to destroy each other Therefore, free exchange of science cannot be allowed *Nature*'s reasoning resembles that of "pacifists" in the last two Great Wars who helped the enemy and hindered our own war effort because they hated war We all hate war, and we're all for scientific freedom and exchange But that is no reason to give science that we've worked or paid for — our science — to people who will use it directly (in weapons) or indirectly, by improving their efficiency, to destroy other people Poles, Afghanistanis, or us

R G S Bidwell

Dalhousie University, Halifax, Nova Scotia, Canada

An SOS from a Polish scientist

from a correspondent in Poland

Sir — It was not an eruption of anger as in Hungary, nor was it the movement of a rather narrow group of politically mature intelligentsia as in the Czechoslovakian spring It was a vast popular movement, in which men of the arts, literature and science found their usual role as articulaters of popular demands

This cleansing process began a few years ago In 1978 the group *Doswiadczenie i Przysclośc* (DiP, Experience and Future) was formed This small group of scientists and journalists published a number of important reports, their main message being that the country was on the edge of catastrophe and that the very last opportunity of avoiding it by the introduction of essential social reforms had arrived The authors expected that if their voice was not heard the economy of the country would collapse, leading to social turmoil and possibly bloodshed

The wave of strikes before August 1980 proved the accuracy of these predictions, but the decline was halted — or, as we see it now, postponed — by the "social contract" signed in the Gdansk shipyard

Some of those involved in DiP formed an openly acting *Komitet Porozumiewawczy Stowarzyszen Twórczych i Naukowych* (Coordination Committee of Cultural and Scientific Associations) headed by the philosopher Klemens Szaniawski This committee played a leading role in the cultural life of the country, especially in preparing and promoting the new law concerning publications, the law aimed at moderating the omnipotent power of censors

The most spectacular event organized by the committee was the Congress of Culture chaired by the art historian Jan Bialostocki The congress was planned for three days starting 11 December 1981 Martial law was introduced at midnight December 12 and the last session could not be held

Among many important speeches delivered during this meeting the most prophetic was the opening address by the president of the Association of Polish Writers, Jan Jozef Szczepánski He compared the congress to the orchestra on board the *Titanic* This prophecy was soon verified — several of the participants of the congress met during the night in the corridors of Warsaw prisons, and many are there still

At the end of 1980 the process of revival of all scientific establishments began with a few fundamental demands freedom of scientific inquiry, promotion of scientists according to merit, the right of a university to decide on its curricula and a significant role for scientists in formulating the scientific and educational policies of the country The autonomy of universities and of the academy, including election of their officers, was seen as a necessary institutional guarantee of the promotion of these demands and the improvement of scientific activities Autonomy became the keynote of the whole process of change

Of course none of these demands is very clever But it is also not very innovative for citizens to demand to be able to influence the fate of their own country, or to require history, records and information to be truthful and not selected according to the needs of authorities However, these demands coming after many years of the opposite policy sounded heretical And behind this policy there were people still possessing considerable power and by no means ready to resign from it

Interferon-gamma: success, structure and speculation

from Lois B Epstein

ANOTHER milestone has been reached in the interferon story with the publication in this week's issue of *Nature* of a report by David Goeddel and his colleagues at Genentech and NIH of the first successful identification of an interferon-gamma (IFN-γ) gene and the expression of a cloned cDNA sequence for human IFN-γ in bacterial and monkey cells[1] Since the discovery in 1965 of an 'interferon-like substance' in the supernatants of human leukocyte cultures stimulated with phytohaemagglutinin[2], much progress has been made in defining its cellular origin, range of inducers, physical and chemical properties, actions and methods of purification[3] This substance, originally called type II or immune interferon, is now called IFN-γ to distinguish it from IFN-α and IFN-β which were discovered earlier, and are now known to have different cellular origins, physical properties and antigenic determinants

Lymphocytes produce IFN-γ in response to numerous mitogens, bacterial and viral antigens, allogeneic cells and antisera directed against lymphocyte surface determinants Although the purification of IFN-γ was initially hampered by the relatively low levels induced and considerable loss of activity during the purification procedure, numerous laboratories throughout the world persisted in their efforts To date, preparations having a specific activity of greater than 10^7 units per mg have been attained[4-6], but microsequencing information is not yet available Although at first IFN-γ was thought to be larger than the other interferons with a molecular weight of 35,000-70,000, the most recent report indicates that it can exist in 20,000 and 25,000 molecular weight forms[7]

Initial efforts to define the range of actions of IFN-γ were hampered by the lack of abundant or partially purified material Many investigators were forced to use crude preparations which contained numerous other lymphokines and factors that affected cell function independently of the action of the interferon However, with the development of better methods of purification and the preparation of antisera to IFN-γ[8,9] specific activities could be assigned to IFN-γ in a more rigorous manner It became clear that although IFN-γ differs from IFN-α and IFN-β in its response to low *p*H, antigenic determinants, host range and cellular origin, it still induces the same enzymes[10] and the same peptides[11,12], and shares their ultimate antiviral[11], immunoregulatory[9] and antitumour[13] actions To date no unique function which would distinguish IFN-γ as a separate functional entity from the other interferons has been found

Recently, four laboratories have isolated and translated mRNA for IFN-γ in oocytes[14-17], thus paving the way for future production of IFN-γ by recombinant DNA techniques The latest achievement by Goeddel and his colleagues gives testimony to the tremendous accomplishments now possible with recombinant DNA technology when multiple resources are integrated into an attack on a specific problem If one considers the many methodologies and types of expertise required to accomplish this work it is clear that it could only have been achieved in a large industrial research centre

The cloning of the IFN-γ gene now makes it possible to produce IFN-γ in unlimited quantities and should lead to profound insights into the evolutionary history of IFN-γ, its tertiary structure, the relationship of its primary structure to its function and physical properties, and its genetic control In the report by Goeddel *et al* it is suggested that the gene which codes for IFN-γ contains an intron This is in contrast to the genes which code for IFN-α and IFN-β which contain no introns Conclusive proof of this must await future studies when the genomic sequence of the IFN-γ gene is determined and compared with the present cDNA sequence The results also demonstrate that IFN-γ has a molecular weight of 17,100, consistent with another recent report based on physical measurements[7], and suggest that higher molecular weights observed by other investigators might have been due to multimeric forms of IFN-γ or to the fact that IFN-γ is glycosylated *in vivo*

If the primary amino acid sequences of the various interferons are compared, it is apparent that 80 per cent homology exists within members of the IFN-α family and 30 per cent between IFN-α and IFN-β Goeddel and his colleagues report that their cDNA sequence codes for a polypeptide of 166 amino acids, of which 20 could constitute a signal peptide The authors have looked for sequence homologies between their IFN-γ and IFN-α and IFN-β and indicate that the only homology noted covering more than three consecutive amino acids occurs at amino acids 15-18 in IFN-γ, and these are found in positions 121-124 in two recombinant forms of IFN-α I find it intriguing but strange that although IFN-α, -β and -γ have a common range of biological actions such little apparent homology exists However, in my own comparative examination of the sequence of Goeddel's IFN-γ with that of several recombinant forms of IFN-α I find a definitive pattern of single amino acid homology throughout the entire sequence (see the figure) If one postulates a difference of one amino acid in the length of the IFN-γ sequence between residues 49 and 65 and of the recombinant IFN-α sequence between residues 49 and 66, then 14 positions have identical amino acids and 4 more differ by only the most conservative replacement (Asp for Asn, Leu for Ile, Ile for Leu) Thus there are 12 per cent identical amino acids or most conservative replacements in precise sequence order

Fig 1 Sequence homology of recombinant IFN-γ and IFN-α The information is derived from published amino acid sequences for IFN-γ[1] and IFN-α[22]

Lois B Epstein is a Professor in the Department of Pediatrics and Research Associate in the Cancer Research Institute at the University of California, San Francisco, California 94143

0028-0836/82/060453-02$01 00

Even more intriguing is the fact that if one examines the model for the tertiary structure of IFN-α and IFN-β proposed by Sternberg and Cohen[18] virtually all the conserved areas shown in the accompanying figure are clustered in the exposed β sheets linking the four roughly parallel postulated α-helical segments of the molecule or on the exposed surface of one α-helical region

Although chromosome 21 has been shown to control the response to all the interferons[19], recent evidence suggests that the receptors for IFN-γ and the other interferons may be different[20,21] Without knowing how any interferon interacts with its receptor or what part of the molecule induces its subsequent effects, it is not clear where these conserved amino acids fit into the picture of interferon–receptor binding and interferon function I would expect, however, given the probable existence of different receptors, that the various interferons would differ in regions that bind, and that the conserved regions would be important determinants of effector function, in analogy to regulatory and catalytic sites on allosteric enzymes

There is tremendous interest, enthusiasm and expectation for the future of IFN-γ as an antiviral, antitumour, or immune response modifier The issue that has attracted the greatest attention is its potency relative to that of the other interferons In some cases IFN-γ has been shown to be more potent than the other interferons, but there are an equal number of cases which do not substantiate such a difference Resolution of the question of relative potency of IFN-γ depends on its purification to homogeneity so that it can be compared mole for mole with the other interferons with regard to all their known biological effects At present all units used to describe IFN-γ are peculiar to a given laboratory, and as such are arbitrary It is hoped that an international standard for IFN-γ will be available in the near future, which will permit all the IFN-γ preparations to be compared on a common basis

Not only is IFN-γ of considerable intellectual and scientific interest but also of tremendous commercial interest as well This is demonstrated by the large number of commercial, private, or university-based laboratories now devoted to its production in large quantities by conventional or recombinant DNA techniques The object of many such ventures is to prepare enough IFN-γ for future clinical trials on patients with malignant or infectious diseases or with immunological defects However at present the amount of information available on which these trials would be based is very limited

Thus there is much still to be learned about IFN-γ The primary, secondary and tertiary structures of IFN-γ induced by various inducers must be determined to see whether they are the same or different The chromosome which controls the production of IFN-γ, and the nucleotide sequence of the gene on chromosome 21 which controls the response to IFN-γ, must be determined The biochemistry of the action of IFN-γ and its method of induction at the cellular and genetic levels must be defined Abnormalities in IFN-γ production or action in various diseases must be sought, and the range of viruses susceptible to its antiviral activity determined. Finally, concerted efforts must be made to determine the manner and degree to which the growth of various human tumours is affected by IFN-γ so that its maximum therapeutic potential may be realized ☐

Stem cell regulation in erythropoiesis

from P R Harrison

EVER since it was demonstrated using genetically marked cells that all types of blood cells derive from a common progenitor, the haematopoietic stem cell, interest has been focused on trying to define what controls the differentiation of the stem cell into one type of blood cell rather than another and how the relative numbers of blood cells are regulated

Although it has long been known that the tissue environment has an important influence on the differentiation of a stem cell, the way in which it exerts this influence is highly controversial The various mature functional blood cells are all derived from relatively small numbers of stem cells by way of a series of intermediate precursor cells which become progressively more restricted (or committed) in the types of blood cells they can produce, large numbers of mature blood cells are then produced by proliferation and maturation of the appropriate committed precursor cells (see the figure) One view of stem cell differentiation sees the microenvironment as having an instructive or determinative role in causing a stem cell to become committed to one blood cell lineage rather than another[1,2] through mechanisms such as cell–cell interactions or short-range 'inducers' But critics of this hypothesis have shown that the way in which a stem cell proliferates or becomes committed can be explained in terms of a purely random genetic process[3,4], perhaps involving some form of DNA rearrangement or movement of transposons Other strong evidence against an instructive role of the tissue microenvironment at the commitment stage is the finding that in spleen colonies formed after inoculation of bone marrow cells into irradiated mice the relative numbers of the various types of the earliest granulocyte and erythroid committed precursors (CFU-C, BFU-E) are strongly correlated, irrespective of colony size (or morphology)[5] Thus it is argued that the various haematopoietic tissue environments influence the types of blood cells produced purely by facilitating the proliferation of particular kinds of committed precursor cells

The 'instructive microenvironment' hypothesis now seems to have taken another knock with new experiments reported by Magli, Iscove and Odartchenko in this issue of *Nature* (p 527) They used the classic spleen colony assay for stem cells devised by Till and McCulloch[6], where cells of interest are injected into lethally irradiated mice and the presence of haematopoietic stem cells is quantified by counting the number of macroscopic colonies formed on the surface of the spleen After 7 days the spleen colonies consist mainly of erythroblasts, whereas spleen colonies present after 11 days comprise a variety of haematopoietic cell types, including granulocytes and megakaryocytes as well as erythroblasts It has previously been assumed that, since each colony is derived from a single cell, the changes in the local environment as the colony grows and comes into contact with different parts of the spleen are responsible for changes in the differentiation pattern What Magli and her co-workers have now shown is simply that the mixed colonies present after 11 days are not in the same positions as the early erythroid colonies, and that only the

Simplified ontogeny of blood cells L, lymphocytes, G, granulocytes, M, macrophages, Mg, megakaryocytes/platelets, E, erythroblasts/red blood cells, GF, growth factor, Epo, erythropoietin CFU-C, precursor cell giving rise only to granulocytes and macrophages, BFU-E and CFU-E, early and late erythroid precursors respectively, the CFU-E is responsive to erythropoietin Some scientists believe that the B lymphocytes and the myeloid stem cell are derived from a common precursor whereas the T lymphocytes derive from the haematopoietic stem cell independently Others believe T and B lymphocytes derive from a common lymphoid precursor independently of the myeloid stem cell (see ref 7) There is also evidence for a common precursor of erythroid and megakaryocyte lineages

late colonies contain precursors capable of proliferating in culture to form colonies having mixed differentiation patterns (that is, early precursor cells of some kind, although not necessarily haematopoietic stem cells *per se*) This result rather undermines the argument for an influence of the splenic microenvironment on differentiation pattern during colony growth Furthermore, since stem cell assays have traditionally been based on early colony counts, it also means that certain conclusions about stem cells will need to be reassessed

But the question of how the haematopoietic tissue environment facilitates the proliferation and/or differentiation of particular types of committed precursor cells remains open Much of the progress in this direction has resulted from the development of *in vitro* systems capable of supporting the growth of stem cells on bone marrow feeder layers by Dexter and his colleagues in Manchester and of assays for committed precursor cells of various kinds by Metcalf, Johnson, Iscove, Axelrad and others It seems that, in general, both the earliest precursor cells and the various intermediate committed cell precursors require growth factors to sustain their proliferation and differentiation (see the figure, and ref 7 for a recent review) As such factors are often produced by other haematopoietic cells or stromal cells in the tissue environment, then clearly the regulation of haematopoiesis involves complex interacting cell networks

Does the production of these growth factors explain the effects of the tissue macroenvironment on the differentiation of haematopoietic stem cells? The answer is probably not, according to Dexter[8] It appears, for example, that purified growth factors cannot mimic the local effects of the microenvironment if the stem cells are separated from the stromal cells by a thin layer of agar or if they are cultured in diffusion chambers where direct cell–cell contact is prevented So either cellular contacts are involved as well as the circulating growth factors, or the essential factors produced by the stromal cells are extremely labile and therefore act over only very short distances □

The nature of immune response gene defects

from Ronald H Schwartz

A NUMBER of recent experiments on immune responses *in vitro* have suggested what will seem to some a revolutionary solution to the conundrum of the antigen-specific genetic defects in immunity that are controlled by the immune response (Ir) genes These genes were discovered in the early 1960s, in the course of experiments on inbred guinea pig and mouse strains immunized with simple synthetic polypeptides[1] The experiments showed that some strains (known as nonresponders) are unable to respond to specific antigens, and that this blind spot is due to a single dominant genetic locus in the major histocompatibility complex (MHC) It is now clear[2-5] that the Ir genes code for Ia molecules — polymorphic two-chain polypeptides expressed, like the other major histocompatibility antigens, on the cell surface The first real clue to how the Ia molecules might influence the immune response lies in the phenomenon of MHC restriction[6] T cells can recognize foreign antigens only in association with products of the MHC — the particular product recognized being dependent on the subset of T cells involved in the response The T cell subset that recognizes Ia molecules is the amplifier T cell subset[7], which among other things cooperates with B cells in the production of antibodies These T cells are believed to be activated by foreign antigens presented in the context of an Ia molecule on the surface of a macrophage

Thus it is clear how in principle an Ia molecule could influence an immune response, but it is not obvious how a particular Ia molecule leads to non-responsiveness only to certain antigens Two solutions to this problem have been proposed One, the so-called determinant selection model, is that different Ia molecules possess different abilities to bind antigens, and that non-responsiveness arises from the failure of the macrophage bearing the nonresponder Ia molecule to bind the antigen for presentation to the T cell[8,9] The alternative is that the T cells specific for a particular combination of antigen and Ia molecule are missing in nonresponder strains[10 12] This could be because of the absence of a gene encoding a T cell receptor with the relevant specificity, or it could be secondary to somatic selection of the T cell repertoire Two kinds of selection have been envisaged One is negative selection, in which T cell clones responding to self determinants are deleted during the generation of tolerance The immune deficiency would then arise because a particular combination of Ia molecule and foreign antigen mimicked a self determinant[10] Alternatively, T cells may be positively selected to produce a repertoire in which antigen recognition is restricted to self MHC In this case, the immune defect would be due to a failure to select for those clones recognizing the nonresponder Ia molecule in association with a specific foreign antigen[11,12] It is to this theoretical controversy that the experiments reported by Ishii and his colleagues in this week's *Nature* (p 531) are addressed

Their experiments were designed to eliminate an ambiguity inherent in the results of earlier experiments on the cellular basis of non-response The usual procedure has been to immunize a hybrid (responder x nonresponder) F_1 animal, and then test its T cells for proliferation in response to antigen plus either responder or nonresponder macrophages *in vitro* In such experiments, the F_1 T cells always respond to the antigen in combination with the responder macrophages, but not in combination with the nonresponder

Ronald H Schwartz is in the Laboratory of Immunology, National Institute of Allergy and Infectious Diseases, National Institutes of Health, Bethesda, Maryland 20205

0028-0836/82/060455-02$01 00

macrophages[13] This has been taken to mean that it is the macrophage and not the T cell that is defective But if the defect were in fact due to the absence of certain T cell clones as a result of somatic selection, then one would expect the F_1 to be unable to respond to antigens presented on nonresponder macrophages Thus the only way to test unambiguously whether tne defect is in the macrophage or the T cell repertoire would be by using fully allogeneic nonresponder macrophages to present the antigen

In order to do this, Ishii *et al* had to overcome a technical difficulty normally, T cells would be expected to mount an immune response to the allogeneic macrophages alone, and this would obscure any proliferative response to the combination of allogeneic Ia and antigen They therefore had first to remove any T cells reactive to the macrophage alloantigens This was accomplished by stimulating the T cell population with the macrophages in the absence of antigen and killing the proliferating alloreactive T cells by exposure to bromodeoxyuridine and light The remaining T cell population was then restimulated with the same nonresponder macrophages, but now in the presence of antigen The interesting result which they obtained was that these T cells could respond to the antigen in association with the nonresponder macrophages Even if the T cells were obtained from one nonresponder strain and thus could not see the antigen in association with their own macrophages, they could respond to the same antigen in association with the macrophages from another nonresponder strain These results suggest that a nonresponder T cell population is only blind to the antigen in the context of its own syngeneic macrophages This in turn argues strongly against several of the theoretical models discussed above First, if T cells exist which can recognize the antigen and nonresponder Ia molecules, then genes must exist in the species which encode for these receptors either as direct products or as somatic variants Second, if T cells can respond to the antigen and nonresponder Ia molecules, then the Ia molecules themselves cannot be defective in binding and presenting the antigen Therefore, these experiments can be interpreted as arguing against determinant selection models and by default supporting the somatic T cell selection models for generating Ir gene defects

This is not the first report of nonresponder macrophages presenting antigen to responder T cells In 1973 Kapp *et al* [14] demonstrated that nonresponder macrophages could stimulate a helper T cell-supported antibody response from responder spleen cell populations However, these experiments were criticized because the investigators did not deplete the responding population in alloreactive cells, which might have produced false positive results through complex interactions between lymphocyte subsets and the release of soluble recruitment molecules (so-called positive allogeneic effects)[15] Even in the experiments reported by Ishii *et al* one has to ask whether the authors have sufficiently depleted the T cell population in alloreactive cells to eliminate all such effects They demonstrate that the nonresponder macrophages alone do not induce a proliferative response, suggesting by the criterion of cell division that alloreactivity has been removed However, given the fact that all the strain combinations reported on in the paper produced a response, one has to worry whether residual alloreactivity, such as the release of recruitment factors, still remains The authors state that they have some negative results using strain combinations with only partial histocompatibility differences, but these combinations might also generate reduced allogeneic effects

Nonetheless, the implications of the findings reported in this paper have been supported by recent results from other laboratories Pierce *et al* [16] reported that responder T cell populations contain cells capable of helping B cells from nonresponders to make antibody, whereas (responder x nonresponder) F_1 populations lacked such T cells Even more striking have been the data obtained with cloned T cell populations Clark and Shevach[17] have isolated several clones from a responder strain of guinea pigs that respond to antigen presented on nonresponder macrophages from a different strain, but not to nonresponder macrophages alone, or to the same antigen presented on responder macrophages This last result is analogous to that of the Ishii experiments The beauty of the cloning experiments is that they totally eliminate the possibility of a false positive allogeneic effect since alloreactive T cells have been entirely removed On the other hand, the problem with the cloning results published so far is that they only describe a few examples These could represent rare phenotypes and thus might not be sufficient to explain Ir gene effects, which require the absence or lack of stimulation of whole families of T cells with similar specificities[7] Overall, however, the data from both types of experiments would seem to complement one another, the clones addressing the doubts about alloreactivity and the Ishii experiments addressing the doubts about population size Thus it would appear that these collective experiments represent a strong challenge to determinant selection models It remains to be seen how and if this challenge will be met □

THE MOVEMENTS OF JUPITER'S ATMOSPHERE

Mr Darwin describes the bands on Jupiter as "due to the trades and anti-trades" set in motion by the action of solar radiation on the solid body of the planet as are the trade-winds of the earth Many other eminent astronomers still appear to accept this time-honoured explanation of the phenomena

Have they reflected on the revelations supplied by the low specific gravity of Jupiter? There is no form of matter with which we are acquainted that could exist at a mean density of about one-fourth of that of the earth, while subject to the enormous pressure due to the mass of Jupiter, unless it were sufficiently hot to render the formation of a solid crust on its surface quite impossible In order to attribute terrestrial solidity to either Jupiter, Saturn, or Neptune we must invent a new kind of matter as infusible as platinum, and far lighter than hydrogen, or endow it with absolute incompressibility

These planets, if composed of any of the chemical elements or compounds known to us, can only retain their low density under the enormous pressure of their masses by the agency of proportionately counteracting heat-repulsion At and about their centres this may be so far overcome by the superincumbent pressure as to produce solid nuclei

Assuming the existence of such a central nucleus of Jupiter surrounded by a great fluid envelope, how will it be affected by the gravitating reaction of the satellite, supposing the compression to give it a specific gravity exceeding the mean specific gravity of its envelope?

It will obviously perform an eccentric rotation, or reeling, within the envelope This motion must be very irregular and complex, owing to the different periods and the varying relative positions of the satellites The effect of such internal reeling upon the surrounding gaseous mass explains far more efficiently than any possibility of solar radiation, the disturbances indicated by the ever-changing belts and spots of this planet

Making muonium in vacuum

from C J Batty and G Marshall

MUONIUM is the name given to the simple atomic state consisting of a positively charged muon and an electron For atomic and chemical purposes it is aptly described as a light isotope of hydrogen with only about one-ninth the hydrogen mass However the properties of its 'nucleus' make muonium both interesting and useful in physics and chemistry Two recent papers describe a novel way of forming muonium which will extend its use to measurements in vacuum

The muon, identified in 1936 in cosmic ray studies, was one of the earliest of the elementary particles to be discovered But despite an enormous amount of study and a considerable knowledge of its properties, its existence remains an enigma Like the electron and the positron, negative and positive muons are weakly interacting point-like leptons and are not influenced by the strong interaction felt by hadrons The muon differs from the electron essentially only in its mass, which is 207 times that of the electron

It is relatively simple to produce intense, high-quality muon beams from the decay of pions obtained at some particle accelerators So it has been possible to make a thorough study of the properties of the muon, and then with this knowledge, to use the muon as a tool for measurements in other fields Thus the spin and magnetic moment of the muon, together with the fact that its weak decay (with a mean lifetime of 2 2 μs) into an electron plus two neutrinos is asymmetric or parity violating, have been used to give information on the magnetic fields inside a variety of materials This technique of muon spin rotation, or μSR in analogy with NMR and ESR, is a subject of intense interest at several laboratories throughout the world Another application involves the formation of muonic atoms, in which a negative muon is captured in an atomic orbital, effectively replacing one of the electrons Measurements of the radiation emitted in the subsequent atomic cascade can determine the distribution of charge in the nucleus

The formation of muonium is fundamental to experiments with muons in fields as diverse as quantum electrodynamics, particle physics, solid-state and surface physics, and chemistry For most applications muonium can be formed by arresting a beam of energetic positive muons in a suitable solid, liquid, or gas target, in the same way that hydrogen atoms can be formed by stopping proton beams Near the end of its range, the positive particle loses energy by ionization, and in the low-velocity regime (corresponding to less than about 20 keV for muons) there is a high probability that it will form a neutral muonium atom In general the muon will capture and lose an electron many times before it reaches thermal energies, and if the likelihood for the capture process is large compared with that for electron loss as thermalization becomes complete, muonium will be formed In most chemical and solid-state applications the interaction of muonium with the target material is studied, but this interaction can be a hindrance when studying certain other phenomena It is therefore of interest to develop an alternative method of muonium production so that measurements can be made on the atom in vacuum

A group working at the LAMPF accelerator facility in New Mexico has recently reported the observation of fast ($\sim$10 keV) muonium in vacuum (P R Bolton *et al Phys Rev Lett.* **47**, 1441, 1981) The authors allowed an intense low-energy (4 MeV) muon beam to slow down in a polyethylene degrader before it passed through a thin foil target in vacuum It is predicted, on the basis of proton measurements, that a significant fraction of the muons emerging with energies less than 20 keV will be in the form of muonium

In order to separate the small neutral muonium component from the charged remainder of the beam, a 5 kG magnetic sweeping field is used immediately after the target foil The neutral particles travel 160 cm from the target through the magnetic field to a beam stop The positrons expected from the decay of the muon are detected in an array of scintillation counters and a NaI detector If the e^+ are from the decay of μ^+ then they should have a characteristic energy spectrum with an endpoint energy of 53 MeV

This characteristic energy spectrum, superimposed on a flat background of events due to cosmic rays and dominated at energies below 30 MeV by counts due to the electron contamination in the incident beam, has been observed in the experiment reported The introduction of a few Torr of helium gas into the normally evacuated ($< 5\times10^{-5}$ Torr) apparatus causes the muonium signal to disappear due to the ionizing collisions $\mu^+e^- + \mathrm{He} \rightarrow \mu^+ + e^- + \mathrm{He}$, the μ^+ are then swept away by the magnet, and the background spectrum can be measured The results show that, for the particular muon beam used, the production rate for muonium is about 3×10^{-4} per incident μ^+ regardless of which of several target foils is used The conclusions are consistent with proton beam data and with models of the neutralization process

Estimates of the energies of the muonium atoms indicate that 50 per cent have energies of less than 5 keV and 95 per cent of less than 20 keV

There are two measurements in particular which would benefit from copious quantities of muonium in vacuum One is a sensitive search for the conversion of muonium to antimuonium (μ^-e^+) which can be accommodated in some versions of the electroweak theory The interaction of muonium with matter drastically reduces the expected conversion rate, so that current limits on the process are not particularly restrictive The other is the Lamb shift in muonium, the energy difference between the 2s½ and 2p½ states of the $n = 2$ atomic level Since both the muon and the electron are leptons and thus have no structure, quantum electrodynamics can predict the Lamb shift very accurately, in contrast to the case for atomic hydrogen The fast muonium emerging from the foil in the LAMPF experiment should contain a 2s component of about one-eighth the total muonium intensity

This component was also shown to exist in another recent experiment performed by a group from the TRIUMF meson facility in Vancouver, Canada (C J Oram *et al J Phys* **B14**, L789, 1981) using a similar muon beam and thin foil target Muonium produced in the skin of the foil emerged to pass through two successive sets of parallel plates, used to produce high electric fields at right angles to the direction of motion of the atoms The electric fields will introduce through the Stark effect a 2p component to any 2s state which may be present Decay can then proceed from the 2p to the 1s state by emission of UV light with a lifetime of about 3 ns The light can be detected by a wavelength shifter and photomultiplier system mounted close to the second set of plates A clock is started when a muon is incident on the thin foil and is stopped when an event is recorded by the UV detection system

If voltage is applied only to the second set of plates the time spectrum should show three muon components an exponential decay due to muon-decay positrons incident on the photomultiplier system; a flat background due to uncorrelated events, and a foreground peak, about 150 ns wide, due to muonium in the 2s state decaying in the region of high electric field The foreground peak should largely disappear when an electric field is applied to the first set of plates, as this would cause the 2s state muonium atoms emerging from the foil to decay rapidly to the 1s ground state before they reach the second set of plates and photon detector system

Further experiments are planned to improve the production of muonium in vacuum In this way, the goals of an accurate determination of the Lamb shift and a sensitive search for the conversion of muonium to antimuonium should be achieved □

Is amorphous silicon played out?

from J I B Wilson

IN spite of enthusiasm for amorphous silicon as a means of making cheap photovoltaic diodes, the improvement of the performance of these diodes has recently been slow and difficult. So is amorphous silicon destined to be a false trail in the search for a cheap solar cell? Although some Japanese companies (principally Sanyo Electric Co.) have set up production lines for these solar cells, chiefly for use in consumer products such as calculators, large-scale power conversion requires a better efficiency than the present about 7 per cent. The main barrier to further improvement is the poor photocurrent, caused by the high concentration of imperfections in the material. These trap the free charges produced by light and inhibit their collection by the metal contacts.

Scepticism about the potential of amorphous silicon cells is easily justified. It has always been suspected that an amorphous semiconductor will have unavoidably poor electrical characteristics, even when it is passivated with hydrogen produced by the plasma decomposition of silane gas (SiH_4). So is it possible to improve the electrical conductivity of this hydrogenated amorphous silicon (a-Si:H) only by sacrificing the high optical absorption of the amorphous structure? Although the hydrogen will reduce strain in the structure and reduce the number of unsatisfied silicon bonds, it will not necessarily control the concentration of defects, so that hydrogen content is not in itself a measure of the structural disorder.

Indeed, recent papers[1,2] suggest that in a-Si:H the structural disorder rather than the hydrogen content controls the optical absorption, especially below the 'bandgap', even though the removal of hydrogen by heating leads to both a deterioration in semiconducting behaviour and an increase in optical absorption. This suggests that if the optical absorption is to remain high, then the electrical behaviour of devices made with a-Si:H may always be limited by intrinsic structural disorder even if the structure is modified with hydrogen or fluorine. This conflict is already accepted in efforts to develop solar cells, and more complicated structures than a simple metallurgical junction have been suggested as ways of increasing the photocurrent without abandoning the simplicity of the plasma technique of depositing semiconductors.

In spite of theoretical estimates of the position in the energy level scheme of particular defects, such as unsatisfied silicon 'dangling' bonds and those produced by silicon-hydrogen groups, the inverse process of identifying bandgap energy levels with the physical entities to which they correspond has been unsuccessful, largely because of disagreement about the actual distribution of these energy levels within the bandgap. (Only in a pure crystalline semiconductor is this bandgap completely disallowed.)

Since the bandgap levels are those responsible for photoluminescence and photoconductivity, as well as for the control of electrical conduction, it is surprising that there should still be so many uncertainties. One difficulty in the interpretation of experimentally determined distributions is that the surface of the semiconductor (or its interface with an electrical contact) may contribute a substantial number of additional energy levels, perhaps with an energy distribution different from that in the semiconductor bulk. Another is that some experimental techniques are insensitive to any structure in the distribution. Thus field effect measurements (using a metal oxide-semiconductor transistor) give a mid-bandgap density of energy levels of $\sim 10^{17}$ cm^{-3} eV^{-1}, whereas a transient capacitance technique (deep-level transient spectroscopy), which is said to distinguish between bulk and surface effects, has given a surprisingly low value of $\sim 10^{15}$ cm^{-3} eV^{-1}. There is, however, disagreement about the interpretation of this data[3].

Moreover, there is one intriguing electrical conductance phenomenon for which the simple one-electron model of the energy levels due to defects appears to be inadequate — the 'Staebler–Wronski effect'. This consists of photostructural changes when a-Si:H is illuminated with a high flux of visible wavelength photons[4]: the electrical conductivity gradually decreases by a small factor, but the subsequent dark conductivity decreases by up to 10,000 times. These changes can be reversed by annealing the sample at $\sim$ 150°C for some minutes, but there is no distinct temperature threshold. Although similar effects can be produced by adsorption on the surface, this is definitely a bulk effect and is ascribed to a movement of the Fermi level towards the middle of the bandgap. The phenomenon does not occur in heavily doped p- or n-type samples.

An explanation invoking self-trapped excitons has been proposed by Elliot[5], while a more elaborate model due to Adler[6] successfully explains variations of the effect in lightly doped samples as well as other experimental observations. Adler proposes that two adjacent neutral dangling bonds (T_3^0) in the predominantly tetrahedral lattice (for not all dangling bonds are removed by hydrogen) are dehybridized from their usual sp^3 character to the (trigonal) sp^2-p_z form. The transfer of an electron creates a pair of charged centres, an acceptor (T_3^+) and a donor (T_3^-), but their energy levels within the bandgap are thought to be inverted compared with those of the usual substitutional impurity donors and acceptors.

On Adler's model, interconversion is prevented by a potential energy barrier, for the charge centres have different bond angles within the lattice. On this view, the decrease in photoconductivity and the shift in Fermi level observed in the Staebler–Wronski effect are produced by the asymmetric trapping of free charges at these energy levels, with a consequent conversion of neutral donors to acceptors. The increased concentration of acceptors causes the Fermi level to move downwards, giving a lower dark conductivity. Thermal annealing helps the potential barrier to be overcome, assisting a gradual return to the orginal T_3^0 states. (An inverse effect occurs when the initial position of the Fermi level favours the conversion of neutral acceptors to donors.)

Althougn the Staebler–Wronski effect is of little importance for the operation of solar cells (because the photoconductivity changes are too small to have much effect on the cell resistance), it does demonstrate the complexity of the defects in this disordered solid. These must be better understood before it can be told whether their presence is unavoidable. And even as things are, useful solar cells can be made from plasma-deposited amorphous silicon of existing quality, while other devices are not far behind. Further improvements in the material, either during production or by treatment afterwards, should still be possible. ☐

Corrigendum *from B T Pickering*

In commenting in these columns on the sequence of the common precursor to vasopressin and its neurophysin I stated that it held no surprises (*Nature* **295**, 280, 1982). However I also stated that the signal sequence is separated from that of vasopressin by a pair of basic residues which re-examination of Fig. 4 in the paper by Land *et al.* (*Nature* **295**, 299, 1982) shows to be incorrect. Indeed, had it been so, this would have been a surprise, since the membrane-associated cleavage of prepeptides is not thought to involve basic residues.

TEXTBOOK SUPPLEMENT

What makes a good textbook?

The most warmly welcomed textbooks are new editions of standard works. What lessons should publishers draw?

THAT there is unlikely to be an immediate shortage of new textbooks is well attested by the pages that follow. In spite of the way in which most university systems are at present short of funds, publishers are still prepared to launch new products on student bookshops, while teachers of all kinds appear to have the time to put them together. On the face of things, at least one part of the academic industry is in good shape. Moreover, on the showing of this year's crop of books, there is no reason to suppose that the creationists' complaints about the compilation of textbooks for high schools in the United States, or even the hidden threat engendered by the recent trial in Arkansas, have their counterpart in higher education. Textbooks remain what they have always been — honest attempts to put between two covers (or, sometimes, four) an account of some field of knowledge and, frequently, some means of helping students to be sure that they have come to grips with it. Moreover, some of the fashions of the past few years seem now to be on the decline. The programmed-learning book, for example, seems far less common than a decade ago, partly no doubt because of the high cost usually involved but chiefly because students have apparently voted with their pocket books, and have thus told publishers that they do not like to be so tightly constrained. It is good to have this demonstration that the market functions.

So does it follow that the present offering of textbooks is precisely what the community of students needs? Unfortunately not. Even when it is accepted (as it should be) that students' reading is not confined to the textbooks on their recommended reading lists, even a cursory reading of the reviews that follow will show that the textbooks now available are not uniformly satisfactory, even by the objectives stated by the authors in the introduction. Why should this be? And how does it come about that the three new books on which reviewers have lavished something akin to affection are in their different ways idiosyncratic books? J Z Young's *The Life of Vertebrates* is now a classic, read by people other than students, and has managed to survive more than a decade out of print. Dirac's *The Principles of Quantum Mechanics,* now put into paperback in its fourth edition, has exactly the same status in a very different field and is as much an historical document as a textbook. (Indeed, students should be warned not to trust their conclusions if their arguments are as economical as Dirac's.) Sir Arthur Holmes's *Principles of Physical Geology* (long out of print) was, in its time, in the same mould — it was a robust and almost personal statement of the structure of the Earth which did not, for example, shrink from remarks about the plausibility of continental drift. Textbook writers (and their publishers) should prudently consider why these three volumes, and others like them, have been such great successes, intellectual and no doubt commercial.

The common properties of such volumes are easily listed. First, their authors were practising and enthusiastic teachers. (Though when Dirac's book first appeared, more than half a century ago, he was by no means an experienced teacher.) Second, the enthusiasm has been transferred from the classroom to the page. Third, perhaps as a consequence, the selection of topics and the distribution of emphasis is not what would be recommended by a solemn academic committee brooding about the exact balance of some students' course. Fourth, the sweep of all these books is grand, the reader is left in no doubt that the essence of the field concerned has been fully described, even if a great many details have been omitted, which is most probably why they have all appeared in one edition after another. Finally, the language in which the text is written has an interest of its own. These three books are more than merely literate. Each also has a distinctive and even memorable style that somehow impresses on the reader's mind a sense that he is acquiring not merely information but an imaginative assessment of it.

For publishers, these reflections are no doubt discouraging. If textbooks of distinction require of their authors such a blend of uncommon qualities, the chances of outstanding success must be very small. Fortunately, the prospects are not so gloomy. Often, a group of people may be found collectively to show the qualities of a single talented author. One interesting example among this year's textbooks is *The Principles of Neural Science,* edited by E R Kandel and J L Schwartz but in reality an apparently accurate reflection of the interests and enthusiasms of the strong research group at Columbia University. As the reviewer remarks, readers may learn less about the chemistry of the central nervous system than (at this level) they need to know — and they may also learn more about the motor system than they want to know. But the book, bulky though it is, makes good reading and has a character of its own.

The consequences, for the textbook trade, are straightforward. The principles that apply elsewhere in book publishing are still applicable. The first test that should be satisfied by a textbook proposal is that it should be organized around a clear intellectual objective — and not too much encumbered by extraneous chapters whose function is chiefly to satisfy course requirements in this or that department. Self-conscious attempts to define the content of textbooks by means of curriculum development, which have been valuable and successful in the schools, have not so far been of great value in higher education. The chief but obvious difficulty is that even undergraduate courses are these days bound to be evolving rapidly, while the committees that superintend curriculum projects are bound to dilute the vision of their most imaginative members. By the same test, there are also limits to what can be done, in advance of publication, to ensure that textbooks for use in higher education can be tested by representative groups of the intended users. For the outstanding textbooks are those which, by being available, influence the pattern of what is taught. As elsewhere in the book trade, publishers cannot hope to know in advance whether they have published an outstanding book or a mere potboiler.

Thus the charitable view of the continuing spate of textbooks is that it represents the efforts of publishers and their authors to produce books that will endure, influencing the pattern of teaching in the process. There is, unfortunately, more to be said. The numbers of apparently similar titles, especially in fields in which the scale of teaching is quickly growing, are too great to be explained simply by people's earnest wish to put a potentially worthwhile book to the test of time and the student market. Too often, new textbooks uncannily resemble well-established works. Too often, they reflect the narrow idiosyncracies of individual teachers or departments. And, too often, they leave their student users with the false impression that science is, after all, a dull business.

In Dirac's shadow

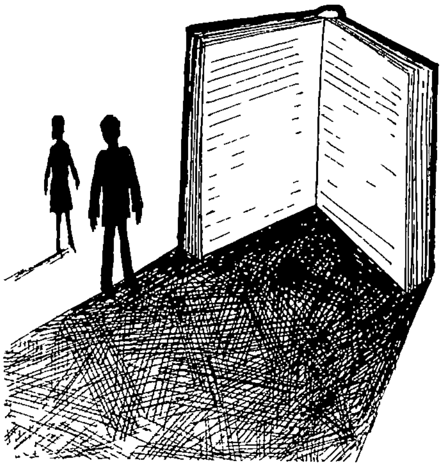
R.B. Jones

The Principles of Quantum Mechanics, 4th Edn By P A M Dirac Pp 314 Pbk ISBN 0-19-852011-5 (Oxford University Press 1981) £7 95, $29 50 *Basic Quantum Mechanics* By J L Martin Pp 241 Hbk ISBN 0-19-851815-3, pbk ISBN 0-19-851816-1 (Oxford University Press 1981) Hbk £17 50, $39 50, pbk £7 95, $17 95 *Quantum Mechanics* By Hendrik E Hameka Pp 387 ISBN 0-471-09223-1 (Wiley 1981) £24, $43 25 *Quantum Mechanics For Applied Physics and Engineering* By Albert Thomas Fromhold, Jr Pp 430 ISBN 0-12-26915-4 (Academic 1981) £22 60, $34

It is a malicious fate that sends a new book on quantum mechanics to be reviewed beside that of Dirac It places an inhuman burden of restraint on the reviewer, whose first thoughts of Decline and Fall seem to require the pen of Gibbon or perhaps rather Evelyn Waugh Dirac's classic textbook, *The Principles of Quantum Mechanics,* first appeared in 1930 but it remains incomparably the best book on the fundamentals of quantum theory Here it is freshly reprinted as a paperback from its hardbound fourth edition, incorporating the revisions of 1967 on quantum field theory

For those not yet familiar with it, let me say briefly that starting from the clearest of all accounts of the linear structure of quantum mechanics it proceeds to cover all the standard non-relativistic aspects of quantum mechanics other than variational techniques In addition, the relativistic single electron and the quantum field theory of photons, electrons and positrons are described with masterly clarity and economy Only the section on field theory may be regarded as provisional or seriously incomplete, since there is no hint of the rich development of quantum field theories since 1967 for the description of leptons and hadrons All serious students should read this book but it demands unflagging intellectual courage Moreover, it seems to get better and to yield more insights with increasing experience on the part of the reader For these reasons almost no lecturer dares to use it as a standard textbook

It is doubtless for similar reasons that we have, year after year, yet another crop of new books on quantum mechanics for irascible reviewers to condemn John Martin's *Basic Quantum Mechanics* is meant as an introductory book for physicists His approach is modern and non-historical, and from the beginning he banishes classical thinking in favour of the calculus of probability amplitudes This approach is shown to good effect in his use of the Stern–Gerlach experiment to set up the two-component description of electron spin He treats the standard solvable problems and then covers time-independent and time-dependent perturbation theory through the golden rule and the resonance approximation There is a short account of dipole radiation and finally an introduction to the variational principle Many familiar topics, however, are missing There is very little discussion of the uncertainty principle and no mention of the geometrical shape of wave functions or of the link between nodes and quantum numbers There is no commutation rule treatment of orbital angular momentum eigenvalues, no three-dimensional scattering, no exclusion principle In spite of many such omissions, this is a good, well-written introductory book with a distinctive point of view to justify its existence



Quantum Mechanics by Hendrik F Hameka is a book written for chemists His approach is historical and primarily wave mechanical, he has made the book self-contained in its mathematical techniques to a degree not necessary for physics students but perhaps helpful to chemists In this respect he over-emphasizes the role of special functions at the expense of matrix mechanics aspects of the subject His treatment of the standard solvable examples is undistinctive and for me the book only came to life with the treatment of approximation methods There is a nice combination of time-independent perturbation theory with variational techniques to include perturbations about approximate eigenfunctions Time-dependent perturbation theory includes an introduction to line widths and lifetimes There is both a semi-classical and a second quantized treatment of atomic radiation Spin and the exclusion principles are discussed, with a clear introduction to Slater determinants and Slater orbitals in the Hartree–Fock treatment of many-electron atoms There is very little on angular momentum addition and no three-dimensional scattering theory This is a reasonable textbook for a course biased towards atomic structure but, while perhaps an attractive book for chemistry students, it will not be a text of first choice for physicists

Albert Thomas Fromhold, Jr, calls his book *Quantum Mechanics for Applied Physics and Engineering* and intends it as a two-year course for technologists working with solid state devices such as tunnel diodes or Josephson junctions It is, in fact, three books in one for he covers elementary quantum mechanics, statistical mechanics of ideal quantum gases and solid state physics — an ambitious venture which does not succeed to my mind because these three subjects appear in unbalanced and piecemeal form Thus in the section on quantum mecnanics the simple harmonic oscillator and the hydrogen atom are omitted, apart from quoting their energy levels, while endless pages are devoted to one-dimensional tunnelling probabilities for square and trapezoidal barriers in WKB approximation One learns about the almost free electron model of metals but nothing serious about phonons or magnetic properties of solids The book is well produced and copiously supplied with problems and illustrations, but I do not think this approach will produce a broadly based or coherent understanding It would not take so much longer to learn these subjects as a physicist would by using the excellent textbooks already available and, incidentally, obtaining a much broader understanding

One last stone remains to be hurled at each of the three books just considered The authors treat mathematics as a subject which will terrify or confound their readers It is in fact the natural language of quantum mechanics, and should be used without comment rather than segregated into separate sections marked "Dangerous" □

Variations on cosmology and astrophysics

Joseph Silk

The Physics–Astronomy Frontier By Fred Hoyle and Jayant Narlikar Pp 483 ISBN 0-7167-1160-5 (W H Freeman 1981) £16 60, $23 95 *Relativistic Cosmology An Introduction* By Jean Heidmann Pp 168 ISBN 0-387-10138-1 (Springer-Verlag 1980) DM48, $28 30 *Cosmology*, 2nd Edn By Michael Rowan-Robinson Pp 152 Hbk ISBN 0-19-851857-9, pbk ISBN 0-19-851858-9 (Oxford University Press/Clarendon 1981) Hbk £12 50, $44 50, pbk £5 95, $17 95

IN ANY rapidly developing area of science, the textbook writer should do more than prepare a guide, no matter how thorough, to past accomplishments in his field He must capture some of the excitement of developments in research, of new and tentative discoveries, of competing claims and counterclaims An up-to-date treatment is especially crucial in the field of astrophysics, where the student is confronted in the daily press with a barrage of half-digested reports of new advances

The texts by Jean Heidmann and by Fred Hoyle and Jayant Narlikar are failures by this measure This defect is unfortunate since both books possess refreshingly novel features Heidmann's text is a translation from French, originally published in 1973 Few revisions were made for the English edition, affecting only about five per cent of the text The field of cosmology has developed enormously in the past decade, little of this is reflected in *Relativistic Cosmology* However an unusual feature is the attempt, on the whole successful, to make esoteric topics in differential geometry accessible to the non-specialist

The book begins with a discussion of topics in extragalactic astronomy that are of interest to the aspiring cosmologist, including clustering of galaxies, the expansion of the Universe, and intergalactic matter The text, though, suffers from a lack of modern results Although the intent is for the reader to fill in details by reference to the bibliographies, this will be difficult, since the references, almost without exception, stop at 1978 The section on the differential geometry of curved spaces is lucid and interesting My only quibble is that it is almost irrelevant to the rest of the book The remaining sections consist of a discussion of the Friedmann–Lemaitre cosmological models and of rudimentary observational cosmology While the level of this book is appropriate for a first-year course for an undergraduate with a mathematics and physics background, it is difficult to imagine any course being based on this text without an enormous amount of supplementary material

By way of contrast, *The Physics–Astronomy Frontier* does provide a self-contained account of astrophysics Its aim is to describe astronomy from the perspective of a physicist Consequently, each section begins with a discussion of one of the fundamental forces of nature (electromagnetic, nuclear weak and strong, and gravitational) before moving on to the astronomical phenomena This book is especially interesting on historical developments and anecdotes — such as when Hoyle reminisces about how Walter Baade almost discovered the pulsar in the Crab nebula — and the early years of radio and X-ray astronomy are well covered However, the authors do not mention any observational discoveries of the past five years Consequently, the explosive growth in radio and X-ray astronomy and other fields is ignored This is especially unfortunate in a book that purports to be probing the frontiers of astronomy and physics One notable omission is any discussion of particle physics in the very early stages of the big bang Instead, the reader is offered an exotic cosmological theory, developed, and possibly only taken seriously, by the authors themselves

The Physics–Astronomy Frontier is written for students who possess a strong secondary school science background The text is mostly non-mathematical Does it succeed, as the authors hope, by focusing on the fundamental forces of nature in enabling the reader to actually acquire a physical understanding of astronomical phenomena? Certainly it is far superior in this regard to other astronomy texts at a comparable level However, the astronomical contents are deficient and dated, at best, one might use the Hoyle–Narlikar book to complement a more conventional astronomy text assigned for an undergraduate course for non-specialists

Michael Rowan-Robinson's second edition of *Cosmology* is an updated version of a text originally published in 1975 for first-year mathematics and physics undergraduates It provides a self-contained description of the visible Universe, including both galactic and extragalactic phenomena of interest to the observational cosmologist There are minor omissions, such as any discussion of chemical evolution, but a reasonably thorough basis is established for cosmological theory The meat of the book lies in its discussion of the big bang models and of their observational implications This is a well-written summary of cosmology, which aspires (not without good reason) to be a successor to Hermann Bondi's text of the same title that had such a profound influence on undergraduates two or three decades ago □

Life of cosmic rays

G.T. Bath

High Energy Astrophysics By M S Longair Pp 412 Hbk ISBN 0-521-23513-8, pbk ISBN 0-521-28013-3 (Cambridge University Press 1982) Hbk £24, $49 95, pbk £8 95, $19 95

IT IS a considerable task of synthesis to show the connections between the main fields of astronomy which have flourished in recent years and at the same time convey the drama of research at the frontiers It must range from the solar wind to clusters of galaxies, from radiation processes in the presence of strong magnetic fields to the space–time structure of black holes This is the ambitious aim of this introductory textbook — to show how astronomers work, how they think and how the subject has developed — by introducing the reader to many of the discoveries of the past 20 years, and by explaining some of the theoretical interpretation that has survived the rigours of criticism and discussion

But this book is not simply an exposition of modern astrophysics The author adopts a quite original approach Taking as his central theme the subject of cosmic rays, their detection and the physics of their interaction with the environment, the presentation derives the necessary basic physics to trace the cosmic ray propagation path through the atmosphere, the magnetosphere, the solar wind, and the interstellar and intergalactic medium, back to the production of high energy particles in galactic and extra-galactic objects The high energy astrophysics of the title refers to these ultimate sources of cosmic rays in the Universe, which are introduced as their peregrinations through the hazards of space are traced back to their birth

The author makes no apology for presenting the material, and referring to it, as a lecture course Indeed his personality and enthusiasm shine through the informal and stimulating style of the writing The depth of discussion varies from subject to subject In a book which introduces cosmic ray physics and detectors, basic astronomy at all wavelengths, stellar evolution and stellar death, the properties of galaxies and clusters of galaxies, and high energy astrophysics, this is not surprising As a stimulating undergraduate introduction to particle propagation at high energies, and the astrophysical environment in which it all takes place, this book gives a broad background without losing contact with the dynamism that created the subject

Blinded with theory

J.S.A. Green

An Introduction to Atmospheric Physics, 2nd Edn By Robert G Fleagle and Joost A Businger Pp 432 ISBN 0-12-260355-9 (Academic 1980) $29 50, £19 60 *An Introduction to Atmospheric Radiation* By Kuo-Nan Liou Pp 392 ISBN 0-12-451450-2 (Academic 1980) $34 50, £22 80

We live in a world where physics students seem to believe that if a process can be visualized, it must be trivial Thus the really important things to study are theoretical physics, quantum mechanics and nuclear physics A subject such as biophysics becomes more respectable if the object of study is first reduced to a molecular soup, less so if an actual tangible biological entity is involved Meteorology comes somewhere in the middle because, though we have our share of specialized incommunicable topics, the essential feature of the subject is the bringing together of many branches of physics in a way that can lead to understanding the very tangible phenomena presented by the weather

Fleagle and Businger cover aspects of cloud microphysics, scattering and absorption of electromagnetic radiation, fluid dynamics and photochemistry at a level acceptable to a graduate student of physics or mathematics The text is clear, but as in any such collection of work from different specializations notation is a problem and the authors' suffix notation gets out of hand at times Worked problems are used to extend the students' appreciation, though it takes a lot of will power not to cheat and look at the solution straight away Definite improvements to the 1963 edition are the addition of a useful chapter on dynamics and more modern theory of turbulence, with the rather isolated chapter on geomagnetic effects now being omitted

Liou deals with the transfer and detection of solar and terrestrial radiation, aimed perhaps at the student anxious to study data provided by the earth-satellite programme Recommendation is difficult because the book is so carelessly written The text is distinctly oriental at times — cgs and calories are dominant units, rainbows are a consequence of scattering and 1cm = 30 GHz A more conventional explanation of the rainbow is given later and the chapters on Mie theory and multiple scattering are extensive

Something, however, is missing from both books and finally I concluded that it was that there isn't actually any meteorology in them Never do the authors dig you in the ribs and mutter conspiratorially "there — you have seen that phenomenon before, and never realized the beauty of the physics behind it" Thus both books suffer because they do not make use of the students' (or the authors') prior knowledge of what the atmosphere is like For judgement, context and excitement the student would too often have to refer to the original texts, and so, he might as well study quantum mechanics

Most telling to me is that the authors do not use their eyes Liou's three-dimensional diagrams (pp 130 and 222, for example) look as though they were drawn by Escher for purposes other than conveying information about physics Fleagle and Businger's are not much better ☐

John Green is Reader in Physical Climatology at Imperial College, University of London, and runs a course in atmospheric physics

Mixed diet for students of climatology

J.P. Palutikof & T.M.L. Wigley

An Introduction to Climate, 5th Edn By Glenn T Trewartha and Lyle H Horn Pp 416 ISBN 0-07-065152-3 (McGraw-Hill 1980) £18 25, $32 95 *Climatology· Selected Applications* By John E Oliver Pp.260 ISBN 0-7131-6303-8 (Edward Arnold/Halsted 1981) £14 95, $34 95 *Mountain Weather and Climate* By Roger G Barry Pp 313 ISBN 0-416-73730-7 (Methuen 1981) £17 50, $33 25

If climatology were breakfast, these three books would be eggs Benedict (Barry), Spanish omelette (Oliver) and rather old porridge (Trewartha and Horn) Barry's book is imaginative and nourishing, but perhaps a little esoteric for everyday tastes, Oliver's, original in concept although not totally successful in execution, is nevertheless full of good things As for Trewartha and Horn, while the book still has some nutritional value, the average breakfast eater would probably choose to eat out

An Introduction to Climate is the fifth edition of a book which was first published in 1937 The style is still reminiscent of the pre-War approach to climatology, although in this edition some effort has been made to give the book a "more modern cast" Unfortunately it needs a completely new script as well as a new cast Much of the book is devoted to the Köppen classification of climates, and little attention is paid to modern developments in climatology One hopes that few lecturers or teachers today would structure an introductory course on climate with this sort of emphasis As an illustration of the old-fashioned approach, the data given in the form of maps, diagrams and tables rarely have any indication of the period represented, the reliability or the source This denies two key issues in modern climatology — the facts that climate *does* change, on all time-scales, and that our knowledge of *global* climate is very meagre The book is at best misleading, at worst wrong; it provides a salutary lesson that a time must come when updating (even if it is done well, which it is not here) is no longer a useful exercise

The stated aim of *Climatology Selected Applications* is to "supply appropriate real-world applications" for basic university courses in climatology The author takes in turn each of the themes which form the content of such courses, summarizes it, and then proceeds to provide case studies of the incidence and impact of the climatological features involved To take one example, Chapter 7 begins with a general description of global circulation patterns, then examines in detail the synoptic patterns of the severe winter of 1976–1977 in the United States and finally considers the impact of this unusual climatic event This is followed by a complementary analysis of the contrasting summers of 1975 (wet) and 1976 (dry) in the US midwest The approach is a new and valuable one, which for many teachers will supply a long-felt need For others, awareness of this text may well provide a new dimension to teaching

The book is likely, therefore, to be widely read and have considerable influence As a first attempt, it must be praised Criticism may be levelled at it for being somewhat shallow, although this can be rectified in subsequent editions when the concept is better established British readers will perhaps think that the concentration on examples from the United States is disappointing, others will find the system of blocking the data analysis sections into separate boxes disrupting to the flow of the text Perhaps the greatest compliment one can give any textbook is that it makes learning interesting and dare we say it, fun In this, Oliver's book certainly succeeds

Barry's *Mountain Weather and Climate* is a unique volume on a special subject He discusses all aspects of the weather and climates of mountainous regions The coverage is global and the framework very general, but the material presented is invariably most detailed and specific As an example of a specialist work it is excellent

ideal as the basis for an upper-level undergraduate or graduate course, and sufficiently detailed and authoritative that it can act as a comprehensive and up-to-date reference work. Since no other publication covers this field, and because the author perceives well the far-reaching implications of the subject matter, it succeeds also as a basic source book for botanists, foresters, glaciologists and hydrologists. The bibliography is most impressive, but unfortunately there is no author index. This is a mere token criticism, however. Although a specialist work, this book should be on the shelf of all climatologists and all those interested in the mountain environment.

Comparing three such different books is an invidious task, one which we shall not attempt. The fact that, in a "small" discipline like climatology, such diversity is possible illustrates the mushrooming growth of the subject in recent years. The different approaches of Trewartha and Horn on the one hand and Oliver on the other are an indication of the extent to which the subject has developed. Both Oliver's and Barry's books show how much climatology impinges on many other disciplines, and are harbingers of future developments. □

J. P. Palutikof and T. M. L. Wigley are in the Climatic Research Unit at the University of East Anglia.

Earthly delights . . .

Keith Bell

Essentials of Earth History: An Introduction to Historical Geology, 4th Edn. By W. Lee Stokes. Pp. 577. ISBN 0-13-285890-8. (Prentice-Hall: 1982.) $25.95, £19.45. *Evolution of the Earth,* 3rd Edn. By Robert H. Dott and Roger L. Batten. Pp. 573. ISBN 0-07-017625-6. (McGraw-Hill: 1981.) $31.50, £17.50.

To write a well-balanced, comprehensive textbook at the introductory level about the history of the Earth, palatable to both arts and science students alike, offers something of a challenge, particularly at the present time. Results of space exploration, as well as new findings in plate tectonics and evolution (dare I mention the word?) must be fitted into one compact volume along with at least some of the basic principles of stratigraphy.

Exciting introductory textbooks are rare. My own favourite used to be the second edition of Arthur Holmes's *Principles of Physical Geology* (Ronald Press, 1965), a book written in a bold, masterly style, brimful of ideas and still retaining a freshness some 20 years later. But what of present-day texts?

Under review are new editions of two books that have been popular in North American universities for some years. Both are well-written, profusely illustrated, accurate and surprisingly similar both in scope and in content. Diverse topics such as the evolution of the Solar System, the origin of life and palaeomagnetism are included, along with a generous serving of historical geology. Both books retain layouts similar to the earlier editions. Stokes's text, however, has been extensively rewritten and many new illustrations either supplement or replace those of the previous work.

Stokes's approach is the more cautious and circumspect of the two. Although *Essentials of Earth History* tends to be written in a dry, somewhat formal style, the book is by no means dull. The well-illustrated volume contains a number of excellent photographs, including some from the recent Pioneer and Viking missions. Most chapters are self-contained (Chapter 7, "Cosmic Beginnings", was particularly enjoyable). And, under the heading "Search for an Ethic" in the final chapter, it was interesting to see at least a token attempt to reconcile present evolutionary theory with religious beliefs. Stokes, throughout most of the book, seems to have the knack of anticipating students' questions and needs, rather than evading contentious issues, the author confronts most of them head on.

The book by Dott and Batten is generally more direct and the reader is led at a fairly brisk pace from start to finish. The diagrams are superb and are among the clearest that can be seen in any introductory textbook. Topics such as geochronology, plate tectonics and the early evolution of the Earth are handled with a minimum of jargon and in a straightforward, concise style. However, I suspect that those chapters dealing with historical geology, mainly of North America, may overwhelm most students, each of them contains too much detail and too many disjointed topics. Although the introduction of many concepts within each chapter was probably meant to challenge, the overall effect may be to daunt all but the most enthusiastic students. Chapter 14, for example, includes discussions about sedimentary cycles, the red-bed problem, the Appalachian Orogeny, the significance of thrust-faulting and Palaeozoic land floras!

Nevertheless, either book would make a good introductory text, though less stratigraphy and a little more about igneous and metamorphic rocks (mentioned but briefly) would certainly extend the scope of both of them. An interesting feature of each book is a glossary of geological terms — to any student just coming into the earth sciences this is particularly useful. □

Keith Bell is Professor of Geology at Carleton University, Ottawa.

. . . heavenly bodies

L. Wilson

Earthlike Planets: Surfaces of Mercury, Venus, Earth, Moon, Mars. By Bruce Murray *et al.* Pp. 387. Hbk ISBN 0-7167-1148-6, pbk ISBN 0-7167-1149-4. (W. H. Freeman: 1981.) Hbk $27.50, £20.40; pbk $15.95, £10.95.

The constant development of the planetary sciences presents problems for the writers of textbooks, since such works are in real danger of being significantly out of date, at least in parts, by the time they are published. This problem is avoided by the authors of *Earthlike Planets* by omitting all mention of the gas giants, Jupiter and Saturn, and their satellites (targets of the most recent planetary probe missions), and confining attention to the more truly Earth-like inner planets — Mercury, Venus, the Moon and Mars. Many aspects of the major stages of evolution of these bodies are now well understood and it is becoming possible to make useful comparisons between these planets and the Earth, both in terms of the histories of their interiors and of the geological, physical and chemical processes which have moulded their surfaces.

Indeed, this book is explicitly committed to the concept of comparative planetology and the first four chapters deal with various aspects of the study of all the inner planets taken as a group: a summary of changing ideas on the ways in which these bodies were formed, a global description of the surfaces and atmospheres, a review of processes modifying planetary surfaces (impact by meteoroids and asteroids, mass movement under gravity and, where appropriate, wind erosion and fluvial action), and a survey of the volcanic and tectonic processes which renew planetary crusts. The next three chapters are explicit attempts to synthesize the planetary history for each of the Moon, Mercury and Mars. Finally, emphasis returns again to comparisons, with a review of those processes which appear to have influenced all of the inner planets to varying degrees — impact modification of the earliest-forming crust, magmatic and tectonic evolution of the interior and, on the planets with atmospheres, climatic change.

Each chapter ends with a well-chosen list of books and papers for further reading, and an excellent guide to sources of planetary photography is included as an appendix before the index. *Earthlike Planets* is probably the best general introduction to planetology available at the moment and will find a place in undergraduate courses at all levels. It is equally suitable as a starting point for a postgraduate student entering the planetary science field. □

L. Wilson is a Lecturer in the Environmental Sciences Department at Lancaster University.

Tectonics as theory, tectonics as history

B.C. Burchfiel

Geology of the Continental Margins By G Boillot Pp 115 ISBN 0-582-30036-3 (Longman 1981) £4 95, $11 95 *Geotectonics* By V V Beloussov Pp 330 ISBN 0-387-09173-4 (Springer-Verlag 1980) DM48, $28 40 *Tectonics and Landforms* By Cliff Ollier Pp 324 Hbk ISBN 0-582-30032-0, pbk ISBN 0-582-30033-9 (Longman 1981) Hbk £20, $55, pbk £9 95, $24

WITH our rapidly increasing understanding of global tectonics, books published on the subject are commonly outdated within a few years of publication Two of the books reviewed here (*Geology of Continental Margins* and *Geotectonics*) are translations of previously published works, which originally appeared several years ago and contain material which is already somewhat out of date *Tectonics and Landforms*, in contrast, promises an interesting approach and in some instances makes excellent use of recent tectonic concepts and their relationship to geomorphology However, books on such broad topics often cannot adequately cover each subject within their scope, and this one is no exception

Geology of Continental Margins is a translation of a book first published in French in 1978 No subject in the earth sciences has evolved more rapidly in the past five years, which renders the book introductory at best and outdated at worst While some of the material presented is still generally valid, recently developed details of continental margin evolution, particularly passive margin evolution, are obviously missing

Instead of focusing on the great wealth of information which now exists about the geology of the continental margins of the world, the book concentrates on plate tectonic models of continental margins and presents little real data, if readers are looking for factual information on particular continental margins, they won't find it in this book I was also surprised to find lengthy discussions of subduction, the deep seismic structure of subduction zones, paired metamorphic belts, geosynclines and collisional tectonics

Although advertisements for the book suggest that some updating has been done for the English edition, it seems to have been minor Some articles published in 1979 have been added to the "further reading" section, but little new data appears in the written part of the text In my view this is a model-orientated, highly simplified presentation of continental margins The emphasis is on the plate tectonic development of continental margins, rather than on what they are really like

Geotectonics is a slightly-updated translation of a book published in Russian in 1976 Some of the data presented were published as recently as 1978 Even so, the book presents a view of the geotectonics of the Earth in the well-known and unique conceptual framework developed by Beloussov himself In the preface it is suggested that the reader should be familiar with the principles of tectonophysics developed in Beloussov's *Structural Geology* (published in 1978, in French) I think this would be advisable, as much of the terminology and some of the conceptual ideas in this work need such a background

Most of the geological examples and figures presented are either from older works — 1960s or earlier — or are Beloussov's reinterpretations of work by other scientists The examples cited, as well as those not presented for the same area, were apparently selected to develop the author's particular view of geotectonics Vertical movement of material in the crust, mantle and core remain the dominant principle of Beloussov's view of the evolution of the Earth, horizontal movements of rocks are considered to be of limited importance Basification of continental crust leads to the formation of ocean crust These and other concepts developed by the author are generally not acceptable to many of us, but deserve publication If we cannot explain more adequately the geotectonic evolution of the Earth, and do not continue to test all reasonable hypotheses, earth science will stagnate

Except for a five-page discussion of plate tectonics near the end of the book and another seven pages of critique, the book is all Beloussovian tectonics and will be of interest to only avid scientists interested in the subject

The purpose of *Tectonics and Landforms* is to relate tectonics and structure to landforms on a scale which ranges from continents and oceans to local surficial features This is truly an admirable purpose and potentially very exciting and interesting With such a broad purpose but abbreviated length, the presentation has some successes, but inevitably some subjects are treated superficially Much of Ollier's presentation focuses on large-scale tectonics, developing the concepts of plate tectonics and its resultant geomorphic features From this basis, a great variety of subjects, such as flow of ice and rock, planation surfaces and drainage patterns are covered in very short sections Not only are modern concepts developed in the book, but reviews of older, historical, and in many cases obsolete, theories are also presented

I was particularly pleased to see that many of the pioneering ideas on tectonics by S W Carey are discussed, but I doubt whether a chapter on the expanding Earth was necessary, particularly when most of the book is devoted to the development of plate tectonics In several places the author gives plate tectonic explanations for various features followed by a disclaimer that other explanations which are incompatible with plate tectonics, such as interpretations based on expanding Earth models, should not be discounted

Tectonics and Landforms is well written, well organized and well illustrated Although the author claims to aim at senior undergraduates, in my opinion the book is too superficial for students at that level Rather, it would be better suited to an introductory audience, but even then offers a rather uneven overview of a great variety of earth science subjects ☐

Crystal growth

R.A. Howie

Crystallography An Introduction for Earth Science (and Other Solid State) Students By E J W Whittaker Pp 254 Hbk ISBN 0-08-023805-X, pbk ISBN 0-08-023804-1 (Pergamon 1981) Hbk £13 50, $32 50, pbk £8 35, $19 95 *Mineralogy for Students*, 2nd Edn By M H Battey Pp 355 ISBN 0-582-44005-X (Longman 1981) £8 95, $19 95

Crystallography is presented in two evenly-divided parts the first deals with morphological crystallography, symmetry and systems, stereographic projections, and derivation of symmetry and forms in all 32 crystal classes, while Part II covers the fundamental features of X-ray crystallography, the 14 Bravais lattices, the interpretation of powder photographs, X-ray diffraction by single crystals and symmetry in repeating patterns Part I thus somewhat overlaps in coverage with *An Introduction to Crystallography* (4th Edn, Longman, 1971) by F C Phillips and A C Bishop's *An Outline of Crystal Morphology* (Hutchinson, 1967) though, like the former, it aims to be of use not only to geologists and mineralogists but to other students of the solid state

Although both of these older texts (and *Mineralogy for Students*) give relatively brief treatment to X-ray crystallography, Part II of Whittaker's book covers this expanding field in considerable detail and develops a number of novel features in response to the difficulties and attitudes of students who are unlikely to have a primary interest in morphological crystallography There are brief but useful chapters on electron diffraction, the determination of crystal structures and on irregularities in crystals (though here twinning is touched on rather too briefly whether or not we understand why and how twins form they are frequently to be seen under the microscope and may be of considerable relevance) The book concludes with a brief essay on the relationship between morphology and crystal structure Altogether this elegant text should be a worthy successor to that of F C Phillips As Whittaker states in his introduction, mineralogy is merely the first branch of solid state science to be developed, and structural crystallography is equally relevant to all students of the solid state

The format and most of the text of the new edition of *Mineralogy for Students* are identical with that of the first The only fresh feature is the inclusion of a new series of optical orientation diagrams for most of the common rock-forming minerals, but whether this justifies the whole work being labelled as a second edition is, in my opinion, doubtful Nevertheless this was a useful, well-written text when it first appeared in 1972 and is improved by the additional diagrams — though it is a pity that these are not presented at the appropriate places in the section on descriptive mineralogy

The book has some things in common with *Crystallography* in that it deals with the principles of crystal structure, crystal morphology and X-ray diffraction in some 85 pages, a reasonable proportion for an elementary mineralogy course It has the advantage for students of including both the principles and methods in Part I (comprising just under half of the book) and descriptions of minerals in Part II, compared, for example, with the rather more detailed descriptive mineralogy (but without any descriptions of techniques) provided by Deer, Howie and Zussman's *An Introduction to the Rock-Forming Minerals* (Longman, 1966) Dr Battey's text is well illustrated and presented, though surely the formula of chloritoid could be given in a rather simpler fashion than one involving four consecutive brackets, the book will nevertheless continue to be deservedly popular with students ☐

R A Howie is Professor of Mineralogy at King's College, University of London, and Principal Editor of Mineralogical Abstracts

Mixed sediments

R.C. Selley

Sedimentary Petrology An Introduction By M E Tucker Pp 252 ISBN 0-632-00074-0 (Blackwell Scientific/Halsted 1981) £8 50, $24 95 *Sedimentology of Shale Study Guide and Reference Source* By Paul E Potter, J Barry Maynard and Wayne A Pryor Pp 303 ISBN 0-387-90430-1 (Springer-Verlag 1980) DM59 90, $32 80 *Depositional Sedimentary Environments With Reference to Terrigenous Clastics,* 2nd Edn By H -E Reineck and I B Singh Pp 549 ISBN 0-387-10189-6 (Springer-Verlag 1981) DM59, $34 90

THE three books considered in this review all deal with the study of sedimentary rocks but differ widely in subject area, level of assumed knowledge and approach

Tucker's *Sedimentary Petrology* is an excellent textbook for second-year geology students An introduction is followed by chapters dealing with sandstones, shales, carbonates, evaporites, ironstones, phosphates, coal, chert and volcaniclastic sediments, each concluding with a selective reading list There are many clear line drawings and photographs, though some of the latter have suffered from over-reduction

The chapter on sandstones (conglomerates and breccias) also briefly describes sedimentary structures and processes, the textural properties of grains and sediments, and the concept of facies That on limestones (including dolomites) deals adequately with the complex genesis of the various carbonate grains and presents a synthesis of the horrors of carbonate diagenesis

These two chapters make up nearly half of the volume and it is by them that the work as a whole will be largely judged Basically they are excellent introductions which lay the foundation for later, more advanced study Even the concept of porosity is introduced, and there are short sections on the porosity of sandstones and carbonates

The book as a whole is most nearly comparable with Greensmith's *Petrology of the Sedimentary Rocks* (Thomas Murby, 1975) Both deal with sedimentary rocks largely from the microscopic as opposed to the megascopic aspects Tucker's book, however, lacks a chapter on weathering so students may not be too clear on where on Earth all this sediment actually comes from

Sedimentology of Shale is a very different book Until recent years, shale had long played Cinderella to the ugly sisters of sandstone and limestone The advent of modern analytical techniques, however, coupled with the quest for oil shales and oil source rocks, has stimulated interest in the mud rocks The book is subtitled *Study Guide and Reference*

New Text Books from

HEYDEN

An Introduction to Atomic Absorption Spectrometry: A Self-Teaching Approach
L. Ebdon, Plymouth Polytechnic, UK.

Based on the author's well-validated teaching programme, this self-study text will equip the newcomer with a thorough theoretical and practical understanding of the technique Self-assessment questions and revision exercises are provided, keywords are highlighted throughout, and numerous instructional diagrams illustrate the theory
ISBN 0 85501 714 7 138pp 1982
Softcover £9 00 $19 50 DM43 00

The Structure and Properties of Solids: An Introduction to Materials Science
Bruce Chalmers, Harvard University, USA

A clear introduction, using non-mathematical terms, to the fundamental themes of materials science The book describes the characteristic structures of the four major classes of man-made materials - ceramics, metals, polymers, and semiconductors - in terms of the role played by electrons in bonding atoms together to form solids

Circle No 26 on Reader Enquiry Card

Source This must be noted for the work is unconventional in format It contains but three chapters "Overview", "Question Set" (*sic*) and "Annotated and Illustrated Bibliography" Chapter 1 covers the mineralogy and chemistry of clays, but ranges widely from Bouma sequences to ichnofacies The second deals with methods for analysing shales, ranging from descriptions of the measurement of a section to the reflectance of phytoclasts Fifteen colour photomicrographs illustrate various shale microfacies

It is the third chapter that is unconventional This takes up over half of the book and consists of an annotated and illustrated reference list It is divided into sections with headings ranging from "Books, Classics and Classification" to "Shales as Hosts for Metallic Minerals" and "Environmental and Engineering Geology" Within each section the authors have arranged alphabetically references which they deem to be significant

A sentence or, at the most, a paragraph explains the relevance of each reference, and key illustrations are reproduced from the original papers This is a novel and painless way of "writing" a book There may be some customer resistance to buying a volume which is largely an annotated bibliography — many geologists may prefer to use *GeoAbstracts* or a computer-based literature retrieval system For those who do not, *Sedimentology of Shale* will prove to be an essential source book, pity, though, that with three authors "desiccation" is misspelt throughout

Of Reineck and Singh's *Depositional Sedimentary Environments* there is far less to say The first edition appeared in 1973 and rapidly became established as the definitive work on recent terrigenous sedimentary processes, structures and environments The standard of the second edition ensures that it will maintain this position A major re-write has not been attempted, but the book has been updated throughout and sections have been added to each chapter on ancient environments Nonetheless, the main emphasis of the book remains on recent terrigenous sediments ☐

From the abyss to the lecture theatre

Peter J. Smith

Marine Geology By James P Kennett Pp 813 ISBN 0-13-556936-2 (Prentice-Hall 1982) $34 95, £26 20

No disrespect to Professor Kennett, but in one sense this huge volume is alarming For only three decades ago hardly any of it could have been written Only during the past 20 years or so has the vaguely peripheral topic of marine geology moved to centre stage as Marine Geology — and with such vengeance that it is now possible for Kennett to write a textbook of an astonishing 813 pages at the comparatively lowly undergraduate–early-graduate level

What made the rise of marine geology possible was the development of the appropriate exploration techniques, but what has made it matter is the discovery of the oceanic lithosphere's central role in the plate tectonics story and the consequent realization that the ocean floor's evolution is altogether more complex and interesting than that of a passive sedimentary dumping ground of great antiquity Holism is the keyword here, and despite the need to become expert in a bewildering variety of subdisciplines, Kennett is wise enough not to allow his presentation to disintegrate into its constituent elements

Of course, the parts are important, and in a teaching text it is essential that they be dealt with in some detail Thus well over half of the volume is devoted to the basics of ocean morphology, marine stratigraphy and correlation, the current plate tectonic framework, crustal structure, sea-level changes, ocean margin processes, sediments and their microfossil loads, and so on The extended climax of the book, however, is a long three-chapter section on palaeoceanography — a splendid synthesis of almost everything we know, or think we know, about how the ocean system has evolved

This is the first major textbook on marine geology to appear since the plate tectonics revolution, although others are in progress in what could turn out to be a small publishing growth area during the 1980s Because so much of the material is new and far from all of it has become part of the consensus, the book is necessarily referenced to an extent that undergraduates will find unusual, and perhaps even distracting, but graduates will find helpful On the whole, Kennett has achieved a reasonable compromise between the need to attribute and the desire to find a lucid instructional style The book is clearly intended chiefly for advanced undergraduates in the marine geology courses now springing up in the more forward-looking universities and colleges, but in view of the subject's crucial importance to all geology, it will prove indispensable to earth scientists at much higher levels and of all persuasions Potential competitors will be hard pressed to improve on it ☐

Peter J Smith is Reader in the Department of Earth Sciences at the Open University, Milton Keynes, and editor of Open Earth

Soils: their genesis and physics

David Rimmer & Michael Adey

The Soil Resource Origin and Behavior By Hans Jenny Pp 377 ISBN 0-387-90453-X (Springer-Verlag 1981) DM57, $33 70 *Fundamentals of Soil Physics* By Daniel Hillel Pp 430 ISBN 0-12-348560-6 (Academic 1980) $40, £26 40 *Applications of Soil Physics* By Daniel Hillel Pp.385 ISBN 0-12-348580-0 (Academic 1980) $40, £26 40

It is now 40 years since the publication of Hans Jenny's classic monograph *Factors of Soil Formation* (McGraw-Hill, 1941), a book which provided the framework for much subsequent work in soil genesis Now in his eighties, Jenny has written what amounts to a sequel to that earlier work In it he develops his ideas into a broader, ecological view, describing how, by analysis of the "state factors", either whole ecosystems or their separate components — vegetation, animals and soil — evolve with time and vary from place to place This treatment occupies the second half of the book and is preceded by a consideration of the processes of soil genesis (water balance, ion exchange, clay formation, for example)

Jenny draws many of his examples from his own work and that of his students and colleagues His use of the English language is unconventional, for example, he talks of "swarms" of ions around particles, "particle bondage with humus" and words like "porositors" and "depauperizes" appear In addition the editors have purposely retained many of the original drawings which he made for the diagrams and figures, in order "to carry through the artistic touch" So what one gets overall is a very personal, even idiosyncratic, view of the soil resource Although written in a textbook style, and in part intended for students, one would not recommend this as an undergraduate text However the second part of the book particularly will be of interest to the many soil scientists who have been influenced, directly or indirectly, by the ideas of Hans Jenny

In recent years a number of texts on soil physics have been published, rectifying the absence of much choice which had existed for some time *Fundamentals of Soil Physics* together with its companion volume *Applications of Soil Physics* further extends the range of material in a most comprehensive way Whilst each is a separate, self-contained volume, the latter does draw on the former and assumes an appreciation of the basic principles of soil physics Together they cover the broad range of soil physics, providing a welcome integration of basic principles and practical applications

Fundamentals treats the basic static and dynamic properties of the solid, liquid and gaseous phases in turn After an introduction to the general physical characteristics of soils and basic properties of water, the solid phase of soil is studied through a consideration of particle size distributions and specific surface areas, the properties of clays, and structure and aggregation The concept of soil water potential is carefully developed and used in a consideration of both saturated and unsaturated hydraulic conductivity and the movement of solutes The roles of diffusion and respiratory activity in determining the composition of the soil atmosphere are considered and this leads naturally to a chapter on heat flow and temperature Finally, soil strength, consistency and compaction are discussed

The author introduces essential physics where appropriate and is thorough without being overly mathematical Thus care has been taken to use both one- and three-dimensional forms of flow equations Developments of theoretical aspects describing basic processes are complemented by discussion of both laboratory and field methods of measuring important parameters Except, perhaps, for the lack of any coverage of the soil–plant–atmosphere continuum and erosion, this text alone should cover most undergraduate courses

Applications continues the discussion, paying particular attention to the management of the soil environment and the field-water cycle Thus infiltration, drainage, irrigation, evaporation and soil moisture uptake by plants are considered, drawing on the basic principles introduced in the companion volume These themes are elaborated in a second section consisting of five chapters by invited authors who cover further aspects of the field-water cycle and the problems of studying soil heterogeneity These contributions dovetail well with the earlier section and give a useful insight into some of the more advanced realms of soil physics

These two books provide a modern, clear and concise introduction to soil physics They are international in style and content, drawing examples from a wide range of situations Unfortunately the cgs system of units is used, though the metric equivalents are often given (however, the Pascal is not introduced when considering soil water potential) Whilst the texts do introduce an appreciable amount of mathematics, they should not prove too difficult for the careful student and understanding is aided by the excellent sample problems at the end of each chapter Over 400 references (up to 1980) are given at the end of each volume, and provide a good starting point for further work

Together, the two volumes represent an admirable textbook for undergraduates They should certainly be in every library covering soil science ☐

David Rimmer and Michael Adey are Lecturers in the Department of Soil Science at the University of Newcastle upon Tyne

Dirty work at the crossroads?

M.J. Kirkby

Soils and Landforms An Integration of Geomorphology and Pedology By A J Gerrard Pp 219 Hbk ISBN 0-04-551048-2, pbk ISBN 0-04-551049-0 (George Allen & Unwin 1981) Hbk £15, $35, pbk £7 95, $16 95

Soil science and geomorphology have borrowed from one another throughout their joint histories and, as with other disciplines, the relationship has been very fruitful Areas of mutual interaction have, however, largely relied on the static properties of soil or sediment, while understanding of process dynamics has followed rather divergent paths in the two disciplines Pedologists have tended to concentrate on the chemistry, physics and biology of the soil, mainly at a micro-scale, while geomorphologists have attempted to understand sediment and solute transfers, generally at a macroscopic to world-wide scale

One very important area of common ground has, I think, been surprisingly neglected At its simplest, it springs from the obvious fact that contemporary soils are the very materials which are moved downhill by current landform processes It follows that the physical and chemical processes by which landforms and soils evolve are substantially identical To develop this theme — and there are signs that it is being increasingly developed — there is an urgent need to collate existing concepts and data, to translate concepts between the two disciplines, and to re-think many of our approaches in a new idiom

John Gerrard's book makes a worthwhile contribution to the first of these three aims, by bringing together work on soil formation, on soil movement and removal, on hillside hydrology and on the catena concept which must be central to any integrative work In reviewing this material there is however little evidence of fresh insights or of the author's own syntheses, so that little headway is made in translating concepts or adding to them

About half of the book then proceeds to consider soils on the basis of the landforms on which they are formed, including soils on erosion surfaces, flood and coastal plains, and glacial deposits In this section, there is the focus on landforms which might be expected from the title, but not enough emphasis on the links with solution and other geomorphological processes The final chapter, "A Pedogeomorphic Synthesis", is very brief and summarizes the general timidity in approaching any conceptual development With other recent books, such as R V Ruhe's *Geomorphology* (Houghton Mifflin, 1975) and P W Birkeland's *Pedology, Weathering and Geomorphological Research* (Oxford University Press, 1974), it will nonetheless be of help to those wishing to begin work on a topic which is, and should be, ripe for considerable development ☐

M J Kirkby is Professor of Physical Geography at The University of Leeds

Back to the land

D.L. Dineley

The Stratigraphy of the British Isles, 2nd Edn By Dorothy H Rayner Pp 460 Hbk ISBN 0-521-23452-2, pbk ISBN 0-521-29961-6 (Cambridge University Press 1981) Hbk £32 50, $59 50, pbk £12 50
The Structure of the British Isles, 2nd Edn By J G C Anderson and T R Owen Pp 251 Hbk ISBN 0-08-023998-6, pbk ISBN 0-08-023997-8 (Pergamon 1980) Hbk £13 75, $32, pbk £5 95, $14 50
Methods in Field Geology By Frank Moseley Pp 211 Hbk ISBN 0-7167-1293-8, pbk ISBN 0-7167-1294-6 (W H Freeman 1981) Hbk $29 95, £12 95, pbk £6 95, $14 95

Good "standard" geological texts abound, trying to revise them to keep abreast of new facts and ideas is a daunting task for any author In this trio, the stratigraphy and structure of the British Isles are described in two second editions, while the third text shows how basic field studies may be carried out Whilst the influence of new hypotheses upon the Rayner and the Anderson and Owen books is rather small, Moseley's book is another matter altogether, new ideas have their place there, and in style and content it is very welcome

Since the first edition of Rayner appeared in 1967, the impact of plate tectonic theory upon stratigraphy has prompted intriguing new scenarios explaining the geological evolution of the British Isles and western Europe Dynamic stratigraphy has replaced the classical "static" listing of strata, attention has swung to the relationships between sedimentation, igneous activity and tectonism The first edition was a clear account of the strata found in these islands The second is equally elegant and there is reference to plate tectonic influence upon palaeogeography and the stratigraphic record Such references are, however, so restrained as to seem reluctant Perhaps because we now have so many working hypotheses in this area, Dr Rayner has deliberately avoided them and has confined herself to making few changes to her previous account The individual stratigraphic trees have not lost their identity in the collective crustal evolutionary wood The diagrams are clear and good — many more of the same standard would have been welcome

The teaching of stratigraphy now involves emphasis upon correlation and interrelationships of many different kinds of phenomena, essential in all of this is the use of fossils Without palaeontology stratigraphy will fail, and the reference to biostratigraphy in this text remains far too meagre Lists of strata commonly are as short of meaning as are lists of fossils to most students, but it ought not to be so — here is a missed opportunity to remedy the one substantial criticism that I had of the original edition All in all, however, the book is adequate for the undergraduate "who may have only a general acquaintance with the broad principles of geology"

Structural geology has made some significant strides since the first edition of Anderson and Owen's book was published in 1968, and not only in the field of plate tectonics Ideas about the formation of sedimentary basins and about both shallow and deep geological structures in Britain are changing and debate is lively This text has not gone as far as might have been expected in presenting new ideas and integrating them with previous knowledge It remains an orthodox description of structural units, one by one, grouped as Precambrian, Caledonian, Hercynian and Alpine terrains, Tertiary igneous terrain and with a chapter on "The Seas around Britain" (an unfortunate and inaccurate title) that contains material that should have been integrated into the preceding chapters The geographical distinction between structures on land and those on the submerged continental shelf is, to an increasing extent, untenable

Chapters 2 and 3 deal with the tectonic evolution of the British Isles A simpler outline of palaeogeographical changes might have served better at this stage, with a fuller, more decidedly plate-tectonic-orientated discussion at the end of the book The style of this volume is very dry, the illustrations are generally poor and many are very poor indeed The authors advise that the book should be read with the aid of the appropriate geological maps published by the Institute of Geological Sciences, but there are very few pointers in the text as to which maps should be consulted regarding specific features or terrain The list of references is extensive, but the standard bibliographical abbreviations are not used and several entries are inaccurate The printing, direct from authors' typescript, the errata and the poor diagrams give the book the air of having been compiled in a great hurry One would have expected better

A book to turn students' attention and interest towards how (a local) stratigraphy or structure is discovered, examined and recorded seems doubly welcome in the context of what has been said above Hail, then, Moseley's students' manual of field geology! Principles of geological mapping are nicely stated and readable case histories are provided to illustrate them The latter cover diverse terrains, from Greenland's icy mountains to the seared wastes of Oman, with Cumbria, Andalusia and even a Quaternary torment in between Igneous, metamorphic, sedimentary and surficial geological examples are treated with just about the right level of technicality and with commendable care. The book shows how aerial photographs, field survey and data logging of many kinds are pressed into map-making Abundant and generally excellent illustrations complement the text very well

This is an attractive book and something of a bargain, especially since it seems to capture the essence and spirit of geological exploration Congratulations to author and publisher for a brave new book ☐

D L Dineley is Chaning Wills Professor of Geology and Head of the Department of Geology in the University of Bristol

Geological classics

K.G. Cox

Basalts and Phase Diagrams An Introduction to the Quantitative Use of Phase Diagrams in Igneous Petrology By S A Morse Pp 493 ISBN 0-387-90477-8 (Springer-Verlag 1981) DM62, $36 60

In the teaching of igneous petrology the study of phase diagrams for compositionally-simple synthetic systems occupies an honourable niche similar to that of Latin in the arts subjects It is thought to be good for the soul, though the precise benefits are sometimes difficult to define

Professor Morse's book is probably the most comprehensive survey available for all those systems which are relevant to the study of natural igneous rocks, particularly though not exclusively, basalts It is written with clarity, humour and a loving attention to detail The diligent reader, undergraduate or postgraduate, will acquire a good feel for the way igneous processes work, by absorbing the many, but inevitably rather diffuse, parallels between synthetic and natural systems Our old friends such as Ab–An–Di, Fo–Di–SiO_2, the ternary feldspars and many more, are dealt with in detail, and there are good sections on the effects of volatiles and the interpretation of layered intrusions On the level of simple, every-day problems of how magmas crystallize, fractionate or originate by partial melting, this is an excellent book

I am less happy when the author becomes involved with more major issues of basalt genesis The decision to restrict discussion to synthetic systems means that problems arising from work on natural materials (basalts and peridotites), and no less from geochemistry and field studies, cannot be adequately dealt with In itself this might be acceptable — any author has to decide what to leave out — were it not for the misleading nature of some of the comments which do appear I doubt, for example, if many petrologists really would agree that "the heart of the basalt problem lies in the eruption, often from the same vent, of tholeiitic basalts at one time and alkali basalts at another time" (p 2), though they might have in the mid-1960s. Other examples, which are consistent with this rather dated viewpoint are numerous, and constitute something of a hazard to the incautious reader Nevertheless, as a book on phase diagrams this is first rate — it is only the basalts which should be taken with a pinch of salt ☐

K G Cox is a Lecturer in Petrology at the University of Oxford

Plants of the past...

Keith Allen

Paleobotany. An Introduction to Fossil Plant Biology By Thomas N Taylor Pp 589 ISBN 0-07-062954-4 (McGraw-Hill 1981) $41 25, £22 95

I have awaited this publication with much interest, because it is the first general palaeobotany textbook to be written in the English language for almost 20 years During that time, new discoveries, new interpretations and a much wider use of both stereoscan and transmission electron microscopes have greatly increased knowledge of fossil plant morphology and anatomy Interest in the origins of plant life, the earliest land plants, the evolution of flowering plants, fossil fuels and the palynological correlation of strata has sparked an awareness of palaeobotany which now reaches far beyond university botany departments

In writing a palaeobotany textbook, one must choose either to make it very botanical, giving comprehensive taxonomic coverage throughout the plant kingdom, or to aim for a wider audience, especially amongst geologists, by reducing the morphological information and including details of floras, palaeogeography, palaeoclimatology, fossil fuels and palynology Like most earlier authors, Taylor has chosen the former course

This is a scholarly, well-researched textbook, bringing the reader right up to date on plant groups, from bacteria and fungi through to angiosperms There are also chapters on methods of preservation and techniques for studying fossil plants, on Precambrian biology and a particularly good one on origins and evolution of the seed habit Taylor's own research interests are reflected in a fuller treatment of the Pteridosperms, though all groups are adequately covered In the angiosperm chapter, he has wisely forsaken the taxonomic approach and dealt more broadly with selected topics, including the possibility of pre-Cretaceous angiosperms The bibliography, usefully listed by chapter, contains over 1,000 references

Taylor's research papers are always accompanied by excellent illustrations, and he must be aggrieved at the poor production of many of the photographs in the book, some of which are so ghostly that they fail to show clearly the details intended Also, the positioning of many illustrations leaves unnecessary blank areas which could usefully have been filled with photographs at larger magnification The photographs of "extinct" palaeobotanists add a nice touch, though I would have liked to see Professor Lang in the Hall of Fame, having contributed so much to Devonian floras and in particular to that from the Rhynie Chert

To whom do I recommend this book? Clearly all palaeobotanists will find it valuable in bringing them up to date on groups outside their main fields of interest, for this, I find it excellent Third-year botany students, though perhaps being slightly overwhelmed by the number of genera included, will find it a most useful and readable source of information I cannot, however, recommend it with too much enthusiasm to geologists, who will find the comprehensive morphological approach very hard going However, this informative textbook replaces many of the earlier palaeobotanical books, and should be available in all biological libraries □

Keith Allen is Senior Lecturer in Botany at the University of Bristol

. . . and the present

Peter D. Moore

100 Families of Flowering Plants By Michael Hickey and Clive King Pp 567 Hbk ISBN 0-521-23283-X, pbk ISBN 0-521-29891-1 (Cambridge University Press 1981) Hbk £27 50, $66, pbk £9 95, $19 95 *The Study of Plant Structure Principles and Selected Methods* By T P O'Brien and M E McCully Hbk ISBN 0-632-00926-8, pbk ISBN 0-632-00927-6 (Blackwell Scientific 1981) Hbk £20, pbk £12

ATTEMPTS are being made to shed the Victorian image of botany in many universities, sometimes even resulting in radical, but rarely fruitful, alterations in departmental titles in order to attract more students (Plant Science or Plant Biology, for example) Courses offered to plant-orientated students are also changing rapidly, often in the direction of subcellular studies or, at the whole-organism level, towards physiology and ecology Subjects which once occupied a substantial part of the undergraduate curriculum are now becoming neglected, amongst which are classical (structural) taxonomy and anatomy

An unfortunate consequence of this is that we are spawning a generation of ecologists which is incapable of defining the criteria upon which plants are identified in the field, and of physiologists which is often sadly deficient in a knowledge of the anatomical structure of the plants with which they deal In the long term this problem can only be dealt with by a reassertion of balance in undergraduate training, and the two books under review here are designed to encourage the development of such courses

Hickey and King's book, as its title implies, covers 100 plant families, devoting about four pages to each (up to eight pages for more complex families such as Compositae and Gramineae) For each family one is given general information such as distribution (but no maps), general characteristics (most of which are available from a good flora), economic or decorative uses, and taxonomic subdivision Thus far the book is comparable to V H Heywood's *Flowering Plants of the World* (Oxford University Press, 1978), but is more detailed in its coverage of family characteristics and rather less so in dealing with uses

A typical member species of the family (or sometimes more than one for families with a wide spread of structural variation, as in the Rosaceae), chosen for ease of availability for student classes (alternatives are suggested), is then fully described and the descriptions are accompanied by detailed line drawings These will provide valuable aids to students as they dissect the flower and fruit Extensive annotation is provided on the pages opposite these

Optima for Animals
R. McNeill Alexander
Optimization theory is the branch of mathematics concerned with finding those structures and behaviours that are in some sense the best possible, and is therefore a very appropriate tool for trying to discover why animals have evolved in particular ways
£5 approx paper 160 pages
Probable publication April

Plant Growth Curves
A Functional Approach to Plant Growth Analysis
Roderick Hunt
A review of the theory, practice and applications of the use of fitted mathematical functions in plant growth analysis The approach taken is very broad and includes an extended coverage of the philosophical and scientific links between this topic and related fields of activity in plant science
£8 50 approx paper 240 pages
Probable publication April

A Biologist's Guide to Principles and Techniques of Practical Biochemistry
Second Edition
Edited by Bryan L. Williams and Keith Wilson
Contemporary Biology Series
This book aims to make biology students aware of the principles and methodology of those analytical techniques which are fundamental to the development of our understanding of cellular and subcellular processes The second edition has been revised to include new techniques, in particular a new chapter on immunochemical techniques
£8 50 paper 336 pages

drawings, but a more helpful approach would have been achieved by adding labels to the diagrams In the seeds of the Violaceae, for example, one can talk of elaiosomes and their function in dispersal, but it would help to have a detailed drawing with an appropriate label The diagrams are, however, generally well chosen and informative, they lack the striking, aesthetic appeal and full vegetative detail of those in Heywood's book, but they make up for this in precision and clarity

This book will become a vital and valued tool to those botanists, both amateur and professional, who wish to look more closely at the structure of easily available flowers

O'Brien and McCully's book is also concerned with observational techniques, but is evidently intended both for teaching and research It is essentially a laboratory manual of microscopic, anatomical and morphological methods, giving both theoretical background and practical instruction It begins from first principles of microscopy and has a "cook-book" approach with some very helpful and informal marginal comments, such as, "If you cannot budge something with finger and thumb before exerting your strength, ASK!" Very clearly aimed at the undergraduate! This chatty style, accompanied by lucid explanations of principle and practice should prove very helpful, especially in such areas as phase contrast and interference contrast microscopy The language used avoids unnecessary jargon and has many hints for trouble-shooting and image improvement Chapters on specimen preparation and microphotography for both light and electron microscopy are included However, the format and sub-heading numbering demand serious criticism, what is otherwise an agreeably usable book is given an unduly forbidding appearance by a complex cross-referencing system and an ugly off-set litho production

Both of these books seek to reach a small, and still shrinking market They will serve this market well, but whether they will succeed in reversing its slow demise is questionable ☐

Panglossian botany

J.L. Harper

Physiological Plant Ecology, 2nd Edn By W Larcher Pp 303 ISBN 0-387-09795-3 (Springer-Verlag 1980) DM59, $34 90 *Environmental Physiology of Plants* By A H Fitter and R K M Hay Pp 355 Hbk ISBN 0-12-257760-4, pbk ISBN 0-12-257762-0 (Academic 1981) Hbk £19 60, $47 50, pbk £7 95, $19 50

"PLANT ecophysiology, a discipline within plant ecology, is concerned fundamentally with the physiology of plants as it is modified by fluctuating external influences" (Larcher) "How do the intricate physiological mechanisms which have been elucidated over the last 100 years by plant physiologists really operate under natural conditions?" (Fitter and Hay) These sentences define the scope of these two books and at the same time relegate the rest of plant physiology (that which is not "eco-") to the study of plants in constant and perhaps irrelevant conditions

It is easy to recognize a text in environmental or eco-physiology by the high frequency of the words "adaptation" and "stress" Counting their occurrences and guessing their meanings in different contexts is a fascinating exercise I suspect that to most ecophysiologists adaptation is that feature of an organism that may be explained away as "a good thing" It is, then, a comfort that the word carries the guesstimate that such properties are the result of all-powerful natural selection which has sought out the optimal solutions to the problems set by nature It then remains the task of the ecophysiologist to demonstrate just how everything about his organisms is for the best in the best of all possible worlds

Stress is, of course, a "bad thing". Sometimes it is a nasty stimulus, sometimes an uncomfortable response Fitter and Hay don't like the word because it lacks the precision given to it in mechanics — yet, use it 22 times on one page (Stress is not in the index, though strain is) To Fitter stress appears to be a stimulus, a force imposed by the environment, but to his co-author the word appears to mean response — a state induced in the organism "Plant cells at a turgor pressure lower than the maximum value are said to be suffering from Water Stress" To Larcher "stress is the exposure to extraordinarily unfavourable conditions" — clearly to him it is a stimulus, not a response and must be extreme I also puzzled about Fitter and Hay's phrase "low light stress" but suppose it is a synonym for "shade stress"!

These two books cover very similar ground — the responses of plants to light, water, nutrients, temperature (and for Fitter and Hay the effect of animals and some microorganisms) Fitter and Hay are more interested in cellular and biochemical processes than Larcher, who is more concerned with the whole plant and its contribution to community processes Fitter and Hay include a section on allelopathy in which they accept uncritically some very dubious evidence

Both books carry an extensive bibliography and between them cite more than 1,500 references, of which only about 50 are quoted in both Together they give a splendid introduction to the literature Fitter and Hay's is a very Anglo-American text (less than 5% of the references are in alien tongues) Larcher's bibliography is international, as befits an author who advises "Despite the difficulties it is worth taking the trouble to read original works in that language in which the author can express himself most precisely" Is this a warning to those who are reading his own book in its excellent translation?

Students could be expected to read and enjoy chapters in Larcher and not become too badly infected with teleology and Panglossian optimism However, as regards Fitter and Hay, I admit to a bias I cannot stomach phrases such as " respiration has a purpose ", " the various mechanisms that have been adopted to fit the species [*sic*] to their environment"; "plants appear to use it [phytochrome] to detect shading", "species [*sic*] may need to maximise plastic responses to permit offspring to colonise a wide range of habitats " I must stint my praise for a book that seems to present biology as a study of purposeful and soothsaying species like football managers planning their future goals ☐

Renewed growth of plants

James F. Sutcliffe

Growth and Differentiation in Plants, 3rd Edn By P F Wareing and I D J Phillips Pp 343 Hbk ISBN 0-08-026351-8, pbk ISBN 0-08-026350-X (Pergamon 1981) Hbk £20, $40, pbk £9, $20

THIS popular textbook, which was published first in 1970 and reprinted several times before the second edition appeared in 1978, has now had another face-lift Apart from a shortening of the title — which does not indicate any change in approach — there is a new format with double-column printing on a larger folio size Even the flowering shoot of *Plumbago indica* which continues to decorate the front cover appears to have had a new lease of life The plant has turned green again and several new leaves have appeared

The increase in the size of page has made it possible to achieve a more pleasing layout, and despite the use of a larger typeface and slight expansion of the text, there is a reduction in the number of pages Unfortunately the improved appearance of the book is not enhanced by the photographic reproductions, the quality of some of which (for example Figs 1 10, 3 4 and 6 1) seems to have deteriorated progressively in succeeding editions

The sequence of topics follows closely that of the second edition but the chapters have now been arranged in four sections Structural and morphological aspects of development (Chapters 1 and 2), internal controls in plant development (Chapters 3–6), environmental control of development (Chapters 7–12), and, molecular and general aspects of differentiation (Chapter 13) Each section is prefaced by a short introduction and these serve to link the book together The reading lists at the end of each chapter have been expanded considerably by the inclusion of some recent reviews and research publications

However, much of the text remains unaltered and the claim of the publisher that the book has been "extensively re-written" is hardly justified New material has been added here and there, particularly in the chapter dealing with the biochemistry of growth-regulating substances Despite continuing research we are still a long way from understanding the mechanism of their action In fact, as the authors recognize, the picture instead of becoming clarified seems to be getting more confused — a cause of some embarrassment to those of us who attempt to teach this subject to biologists

Librarians who stocked up recently with copies of the second edition of this book will be relieved to learn that there is no great need to replace them with the new edition Undergraduates who have little choice may begrudge the extra cost, but we will go on recommending the book to our students as the best overall introduction to the physiology of plant growth that is available at present ☐

James F Sutcliffe is Professor of Plant Physiology at the University of Sussex

Introducing whom to natural products?

T.W. Goodwin

Secondary Plant Metabolism By Brian Vickery and Margaret L Vickery Pp 335 Hbk ISBN 0-333-27017-7, pbk ISBN 0-333-27018-5 (Macmillan Press, London/University Park Press 1981) Hbk £25, $49 50, £12

It is important not to criticize a book for not being what it was never intended to be This is made difficult in the present instance because neither the authors nor the publishers give any hint of the type of reader the book is aimed at What the book clearly is, is a full and up-to-date descriptive account at a rather simple level of the formation and metabolism of secondary plant products On a slightly lower level, the function, uses, ecological interactions and chemosystematic properties are also discussed

After an introductory chapter, which considers such topics as the differences between secondary and primary metabolites and how biosynthetic pathways are elucidated, the bulk of the book is devoted to essays on families of compounds which arise from basic precursors these are sugars and sugar derivatives arising from the primary product of photosynthesis, considered to be glucose 6-phosphate, the various fatty acids produced from the acetate–malonate pathway and their incorporation into plant lipids and glycerides, polyketides from acetate which are mainly fungal rather than higher plant products, terpenoids derived from mevalonate, shikimic acid derivatives, compounds synthesized from two different fundamental units as exemplified by the flavonoids, porphyrins, purines and pyrimidines, compounds, including alkaloids, which are derived from various amino acids A great deal of ground is covered and one's way about the concentrated information in the book is facilitated by three good indexes

One can make a reasonable guess that this book is aimed at organic chemistry students studying a natural products course in their second year It would be a satisfactory basis for such a course but probably lecturers would nowadays concentrate more on reaction types and reaction mechanisms rather than simply on biogenetic schemes Certainly, stereochemical aspects would be given more prominence than they are afforded in the present text The book would be useful to biochemists for basic information but not as a working text because, as the authors state, enzymology — the ultimate key to the explanation of all biosynthetic activity — is not included In the same way it would be useful as a source book for botanists, agriculturalists and pharmacists

This, then, is a good introductory book on natural products, although there is difficulty in visualizing exactly which academic slot it is intended to fill ☐

Botany for beginners

Ralph S. Quatrano

Biology of Plants, 3rd Edn By Peter H Raven, Ray F Evert and Helena Curtis Pp 686 ISBN 0-87901-132-7 (Worth 1981) $19 95, £10 50

One of the most widely adopted textbooks for introducing students to the plant sciences over the past several years has been *Biology of Plants* by Raven, Evert and Curtis The new and much improved third edition of this popular text must still be considered as one of the best overall books of general botany

Previous editions were clearly aimed at beginning courses for majors Such courses would form the basis upon which more advanced courses, such as morphology, physiology and ecology, would build The new edition is no exception The depth and breadth are still sufficient for majors and it will be a good source book for any student of the biological sciences However, the detail is not overwhelming and with the continual mention of applied and practical aspects of plant biology, as well as good chapter summaries, appendices for chemistry and classification, and a complete glossary, makes it a possible choice for non-major courses Much of the condensing and rewriting in this edition have also helped to make it an attractive choice for a less rigorous introduction to botany The length of the text, however, may be excessive for such courses, especially in view of the availability of other shorter, good "non-major" texts (see *Nature* **284**, 91, 1980)

Although the sequence of topics presented in the text may not be followed, most botany instructors will find no problem in choosing specific chapters to fit their schedule Several changes for the better in the organization of the third edition include moving the chapter on the chemistry of heredity to the section on genetics and evolution, more emphasis on the Cyanobacteria, and the treatment of the fungi as a group separate from the water and slime moulds (Protista) Several sections have been condensed (for example "Ecology", "Genetics and Evolution") without deleting important concepts, while others have been extensively updated and revised (for example "Growth Regulators", "Uptake and Transport")

The illustrations and diagrams are clear and the inclusion of colour plates for angiosperm anatomy in this edition will be helpful to students in the laboratory The book will undoubtedly maintain its high ranking and competitiveness with other new editions of excellent, popular texts such as the sixth edition of *Botany* by Weier *et al* (Wiley, 1982) ☐

Ralph S Quatrano is Professor of Botany and Instructor in General Botany and Biology Courses at Oregon State University, Corvallis, Oregon

Legacy of tradition in plant geography

Honor C. Prentice

Historical Plant Geography An Introduction By Philip Stott Pp 151 Hbk ISBN 0-04-580010-3, pbk ISBN 0-04-580011-1 (George Allen & Unwin 1981) Hbk £12, $30, pbk £5 95, $14 95

THIS book is an elementary introduction to the traditional subject matter of "plant geography" — species distributions and their interpretation It is concise, very readable, well produced and accessibly priced Care has been taken to make it comprehensible to students with different backgrounds in biology, geography or environmental science There are chapters on taxonomy, maps, distribution patterns, disjunctions, endemism, and geological and historical evidence

I am sceptical, however, about the value of a textbook on plant geography that carefully avoids modern ecological *and* evolutionary concepts Some plaintive remarks on the state of biogeography (Chapter 1) are revealing — if the "ecological tradition" has "flourished and grown out of all proportion" it is surely because of advances in ecological theory!

Classical phytogeography has not made comparable progress, and indeed the same paradoxes and ambiguities that run through the classical literature reappear, unresolved, in Stott's book ("Isoflors are used to locate centres of origin and migratory patterns " — but how?) Pollen analysis is introduced, but its most relevant results — reconstructions of complex Late-Quaternary migrational histories — are not There is no discussion of how taxonomic information may lead to reconstructions of phyletic patterns, cluster analysis and the like are dealt with, but cladistics is not mentioned, despite the impact of cladistic and vicariance concepts on modern evolutionary biogeography For many reasons, then, I find this a disappointing book however well it succeeds in its stated aims ☐

Honor C Prentice is a Visiting Research Fellow in the Department of Biology at the University of Southampton

Ethology: the classic and the *avant-garde*

Peter Marler

An Introduction to Behavioural Ecology By J R Krebs and N B Davies Pp 292 Hbk ISBN 0-632-00666-8, pbk ISBN 0-632-00668-4 (Blackwell Scientific/ Sinauer 1981) Hbk £18, $39 50, pbk £7 50, $16 50 *Modern Ethology The Science of Animal Behaviour* By S A Barnett Pp 705 ISBN 0-19-502780-9 (Oxford University Press 1981) £12 95, $23 95

ETHOLOGY helped the study of animal behaviour off to a good start with a number of simplifying assumptions, one of which was crucial in convincing sceptics that natural behaviour is even studiable Given the right kind of description, it was asserted, behaviour would turn out to be as stereotyped and species-specific as morphology This worked well for a time, but in the 1960s it became obvious that, just as morphology exhibits adaptive variations, so patterns of behaviour vary widely within a species Even small differences in the behaviour of groups of individuals may be so amplified by processes of social interaction that different patterns of social organization are created The theorizing of Lorenz and Tinbergen, primarily reductionistic in its orientation, was ill-suited to guide investigations of the quantitative impact of behavioural variations on animal–environment interactions Counsel was sought from other disciplines such as ecology, population genetics and economics

In the past ten years several subdivisions of ethology have developed to deal with such problems one of which, behavioural ecology, is admirably reviewed in the introductory text by Krebs and Davies The approach is that of the evolutionary biologist, concerned with functional explanations of behaviour at the level of individual and kin selection The book is a pleasure to read Its style is lucid and entertaining, and the illustrations are clear and instructive There are well-balanced reviews of the evolution of alternative social systems and evolutionarily stable strategies, feeding strategies and optimality modelling, fighting and manipulation, altruism and cooperation The pride of place assigned by Kropotkin and Allee to cooperation, however, is now superseded by an emphasis on conflicts of interest, effectively translating the motivational drive conflicts of Tinbergen into the functional domain Instead of collaboration, we have selfishness, spite and calculated exploitation

While arguing their case forcefully, Krebs and Davies are cautious about over-extending their theorizing, much of which, they admit, serves more as description than as predictive theory In that sense, the book also serves well to point the more ambitious student towards new problems awaiting solution In particular, genetic issues raised, such as uncertainties about paternity and how "kin" are actually distributed in natural vertebrate populations, deserve to be tackled by direct observation and experiment as well as at the abstract, theoretical level

Behavioural ecology forms only a part of Barnett's much larger endeavour *Modern Ethology* is more of a "mechanisms" book than that by Krebs and Davies, analysing critically the concepts of classical ethology in the light of recent research, and reviewing an extensive literature in the process It is both a textbook and a serious, scholarly work that grapples with conceptually difficult and controversial issues such as intention, conscious awareness and the role of reductionism in behavioural science Accounts of social behaviour are interwoven with such topics as behavioural endocrinology and learning theory One of the major index entries, habituation, does not appear in the index of Krebs and Davies, though clearly relevant to their subject matter In this sense, the two books complement one another well

Especially salutary are Barnett's discussions of concepts of heritability and aggression Aggression is interpreted with care, especially in the section on human ethology A quotation from W D Hamilton, a founder of sociobiology and behavioural ecology, stating that "vicious and war-like tendencies are natural in man'' sounds a cautionary note Misunderstandings about such issues are bound to arise until we understand the epigenetics of such traits as aggressive behaviour and the points in development at which they are accessible to environmental modification As Barnett indicates, the interaction of nature and nurture is a central problem in biology and those trained in the ethological tradition are especially well placed to deal with it An historic opportunity will be missed if current enthusiasm for behavioural ecology diverts all young ethologists from what has to be the most challenging and momentous issue ethology has yet faced Only when we understand how genes impose adaptive limits on behavioural plasticity will we fully appreciate the pervasiveness of genetic influences on the development of behaviour, whether animal or human ☐

Peter Marler is Professor at the Rockefeller University, New York, and a member of the Rockefeller University Center for Field Research in Ecology and Ethology

Sixty years on?

Michael B. Usher

Elementary Mathematical Ecology By John Vandermeer Pp 294 ISBN 0-471-08131-0 (Wiley 1981) £24 05, $43 25 *Population Systems A General Introduction* By Alan A Berryman Pp 222 ISBN 0-306-40589-X (Plenum 1981) $16 95, £10 71 *Population Ecology A Unified Study of Animals and Plants* By Michael Begon and Martin Mortimer Pp 200 Hbk ISBN 0-632-00812-1, pbk ISBN 0-632-00667-6 (Blackwell Scientific/Sinauer 1981) Hbk £15, $33, pbk £7 90, $16 95

MANY origins of the subject of population dynamics can be traced to the 1920s, when A J Lotka, R Pearl, P F Verhulst, V Volterra and others were publishing relatively simple mathematical models of population growth and interaction During the following half-decade the subject grew slowly, but in the 1970s there was an explosion of research interest It is inevitable that this would eventually manifest itself in teaching and writing textbooks to fill the students' need Three recent examples are considered here

John Vandermeer teaches population dynamics with a programmed text of ten lessons, each of which is designed to take 5 ± 2 hours The explanatory sections of *Elementary Mathematical Ecology* are kept short, and the exercises, for which relatively sketchy but adequate answers are given, are both numerous and essential for understanding the lesson I am reasonably certain that most undergraduates would take considerably longer than the designed time, and in the exercises I found the lack of consistency of rounding intermediate results most confusing (for example, in the first chapter one has $\ln (2\ 25)=0\ 81093$ and $\exp (0\ 83)=2\ 3$)

In *Population Systems,* Alan Berryman has written a more traditional textbook, setting the subject out in only six chapters which contain few exercises and only brief solutions The text itself does not make reference to the ecological literature a series of notes, listed in rather small type at the end of each chapter, provides reviews of a few references and also gives some of the more technical material I found the shuffling between text and notes a rather frustrating aspect of the book's subject presentation

A slight departure from the usual progression from single-species to two-species interactions to communities is a characteristic of Michael Begon and Martin Mortimer's *Population Ecology* Although the first five chapters follow the first two steps in this sequence, the authors conclude the book with three chapters — on life-history strategies, population regulation and community structure — in a section called "Synthesis" Although this makes for interesting, if unexpected, reading, since one is asked to think about migration, costs of reproduction, r- and K-selection, and so on, after reading about interspecific competition and predator–prey relationships, the attempt at synthesis really fails

It is interesting to compare the subject matter of these books All of them include introductions to population growth, interspecific competition, predator–prey relationships, spatial patterns (rather briefly dealt with in *Population Ecology*) and community structure (only sketchily introduced at the end of *Elementary Mathematical Ecology*) A consideration of life tables is the most surprising omission from *Population Systems,* which also lacks an account of matrix models of age-structured populations These, then, are the core topics, but what are the specialities? *Elementary Mathematical Ecology* contains data on island biogeography and species-area relationships, but I wish that the author had not used the ambiguous term "species number" (implying ranking) for the unambiguous "number of species" *Population Systems* takes a systems analysis approach, introduces much of the jargon such as "feedback", which then leads to an extensive consideration of density-dependent effects *Population Ecology* includes chapters dealing with life-history phenomena, key factors and harvesting None of the books contains detailed discussions of genetical aspects of population regulation

The theoretical foundation of 60 years ago is still strongly evident *Population Systems* perhaps diverges most in taking a systems theory point of view But, for teaching, I would certainly recommend the excellent blend of example and theory in *Population Ecology,* and possibly support some areas by the greater theoretical and practical development coming from the 291 exercises in *Elementary Mathematical Ecology* ☐

Michael B Usher is Senior Lecturer in Biology at the University of York

Search for a science

Graham Hoyle

Neuroethology An Introduction to the Neurophysiological Fundamentals of Behavior By Jorg-Peter Ewert Pp 342 ISBN 0-387-09790-2 (Springer-Verlag 1981) DM 49, $29 *Neuroethology An Introduction* By D M Guthrie Pp 221 Pbk ISBN UK 0-632-00303-0, ISBN US 0-471-26993-6 (Blackwell Scientific/Halsted 1981) £8 75, $27 95

THESE two introductory texts, appearing independently at about the same time, offer an insight into viewpoint as well as subject matter Ewert does his research on a backboned animal, the toad, Guthrie on invertebrates Each goes out of his way to offer a fair balance, with extensive examples from the other's group Many of the same studies are reported by both authors, showing that they agree as to what constitutes neuroethology It is remarkable to find such concurrence, since others who consider themselves to be neuroethologists have quite different notions as to what should be included Guthrie has chapters on evolutionary trends and human neuroethology, with illustrations taken directly from textbooks on neuroanatomy, psychology and animal behaviour Ewert avoids such a nebulous search for principles, sticking to observations and hypotheses — although he does manage to squeeze in a section termed "Stress in Human Society"

The Nobel prize-worthy finding of Lorenz and Tinbergen in the name of ethology was a simple generalization complex behavioural acts of animals as different as insects, birds and human beings are handled genetically — and therefore evolutionarily — as wholes This applies especially to acts of territoriality, home-building, prey-capture and courtship They introduced key concepts and clear descriptive terms, notably "fixed action pattern", "releaser", "drive" and "consummatory act" Each of these offers a major challenge to neurobiologists, because each implies a specific kind of underlying neural circuitry and properties Working them out offers a splendid and significant intellectual/laboratory pursuit, but there have been only a very few successes in this new field so far Ewert and Guthrie both cover them, but all too briefly To create a larger body of knowledge, each has padded the relevant data with selected bits of physiology, psychology, sociology and ethology Thus students will be able to learn from either of these books, but only if they also receive lectures and extensive reading assignments, and if they already have a good background in basic neurophysiology Both books are lavishly and attractively illustrated, Ewert's, in particular, is well-endowed with clear diagrams, many of which are original, in two colours Each represents good value for money

Unfortunately, the uninitiated reader is very likely to suffer from a severe attack of mental indigestion because of the highly condensed treatments of diverse sets of data The budding researcher will still have to make a critical choice within some traditional discipline before being able to practise neuroethology, and will be forced to face the difficult decision as to whether to go with backbones, or a "squishy" or "crunchy" invertebrate In effect, this is a choice between going for cellular detail now, or for the prestige and significance automatically associated with vertebrate animals, but which at present show few signs of yielding the information needed for understanding at the level of nerve cells and circuits □

Graham Hoyle is a Professor in the Department of Biology at tne University of Oregon, Eugene

Strong-minded neuroscience

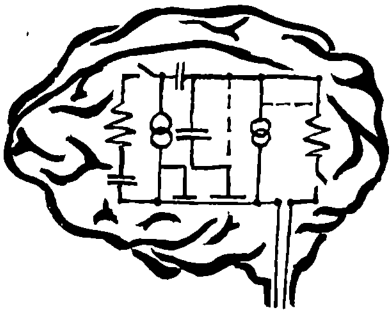
Maria Fitzgerald

Principles of Neural Science Edited by Eric R Kandel and James H Schwartz Pp 731 Hbk ISBN 0-7131-4405-X, pbk ISBN 0-7131-4406-8 (Elsevier/North-Holland/Edward Arnold 1981) Hbk £45, $60, pbk £25 50, $32 50

NEUROSCIENCE is one of the most rapidly expanding branches of biology today, the task of putting together a comprehensive textbook on the subject is therefore becoming increasingly difficult Such a book should inform clearly and accurately of the basic scientific facts while giving a balanced account of newer, less substantiated work Ideally it should also convey the excitement of new ideas and the importance of future research *Principles of Neural Science* fulfills all of these requirements It is an excellent book, fun to read yet informative and accurate — a combination rare in scientific literature

The editors believe that it is implicit in most neuroscientists' thinking that "all behaviour is an expression of neural activity" The task, therefore, of the neuroscientist is to explain how the brain and its cells function and so to understand behaviour This view is the underlying theme of the whole book and it contributes greatly to its strength It results in a great emphasis on behaviour, from simple spinal reflexes to the neural basis of emotions It also results in a strong emphasis on disease and mental illness After all, if behaviour is a reflection of brain function, then disorders of affective and cognitive functions must result from disturbances of the brain, and much can be learnt from them Some may disagree with this philosophy and thus with the framework of the book, nevertheless they will still find the contents useful and stimulating

All of the expected chapters are there, from cellular membranes to motor control, plus good, up-to-date sections on topics such as sleep, ageing and CNS development In each section, the relevant regional anatomy is surveyed, which is especially useful in discussions of the brainstem and the limbic system At the end of the book there are several excellent appendices on brain fluids, neuro-ophthalmology and electrical circuit theory with set questions to work through



Of course there are shortcomings Neurochemistry, one of the most challenging branches of neuroscience, is inadequately covered The basic, classical information is there but neuropeptides, for example, get only cursory attention The autonomic nervous system is mentioned now and again but should certainly have had its own chapter The index is so short as to be practically useless, although in compensation the chapters are clearly divided by straightforward subheadings These are in the American style of a statement of fact, some are refreshing in this cautious age, some irritating My particular favourite, arbitrarily used in the chapter on diseases of neuromuscular transmission, is "Unsolved problems remain" □

Childish thoughts

Albert Yonas

Foundations of Developmental Psychology By R C LaBarba Pp 545 ISBN 0-12-432350-2 (Academic Press 1981) $20 75, £13 20 *Developmental Psychology*, 3rd Edn By R M Liebert and R Wicks-Nelson ISBN 0-13-208256-X Pp 665 (Prentice-Hall· 1981) $21 95, £16 45

I DO NOT know how many students enroll in introductory courses in child psychology each year, but the number must be vast Apparently, every publisher of textbooks feels that it is worthwhile to produce a new book, or at least a new edition of an old one, every two or three years in an attempt to attract part of this huge market Something like 80 to 100 introductory child psychology textbooks are currently available This competition has resulted in some specialization of books, as well as a great deal of homogeneity in the content and organization within each type of book

Ten years ago, many leading texts tried to do everything They were organized by age, beginning with prenatal development and infancy, and describing the child up to adolescence In addition, within each age section, topics such as perceptual and social development were discussed The writing style of many of these books has always reminded me of a sequence of 3" × 5" note cards

In recent years, specialization has led to the creation of a great many texts that do little to introduce students to the scientific discipline of child psychology, rather, their goal is to give the prospective parent or teacher a picture of what the average child is like at each stage of development and to provide information of practical use At the opposite end of the continuum, we have LaBarba's *Foundations of Developmental Psychology* This book is a scholarly and historical introduction to the theoretical issues that have guided developmental researchers It presents empirical studies primarily to illustrate issues and concepts, and makes little attempt to give the reader a picture of what behaviour to expect from a newborn child or to describe the average two-year-old

The book is organized topically, with a heavy emphasis on biological areas such as genetics and human behavioural embryology The behaviour of the neonate apparently is not of sufficient interest to the author to merit inclusion Very little space is given to the development of sensory and perceptual processes, there is no mention, for example, of any sensory modality other than vision

Unlike most introductory books, LaBarba's presents theoretical and empirical work not as fact but as the focus of argument with the opposing point of view This may confuse and depress students, although it does convey the state of the art

The basic problem with this text may be its assumption that a unified discipline of developmental psychology exists with its own explanatory concepts and body of facts that can be presented in an introductory text in the same manner as would a physics text In reality, developmental psychology is an interdisciplinary field, strongly concerned with practical applications It focuses on the description of the course of development, and is still groping towards theoretical concepts which will make explanation possible

Developmental Psychology, by Liebert and Wicks-Nelson, is the third edition of a comprehensive and successful text that should be even more successful in this new version The authors view developmental psychology as a branch of science that is both basic and applied, they believe that students can best understand practical applications in the light of the theory and research on which they are based.

The authors and publisher have responded to competition by producing a book with every pedagogical aid imaginable, from an outline at the beginning and a summary at the end of each chapter, to coloured and italicized marking of important concepts and terms The figures are especially effective

The quality of the writing is probably the book's most outstanding trait It has fewer details, and is more readable, than a similar, widely used book by Hetherington and Parke Students are introduced to basic research with as little pain as possible, interest is gained by discussion of practical topics (for instance, various childbirth methods) The sense of controversy and uncertainty in developmental psychology is almost entirely missing from this book, but this may well be pedagogically necessary

While many teachers may find LaBarba's book full of fascinating information useful in the preparation of lectures, they are more likely to assign Liebert and Wicks-Nelson's book to their students ☐

Albert Yonas is a Professor of Developmental Psychology at the Institute of Child Development, University of Minnesota

Merit in a minefield

B. Burnet

Behavior Genetics and Evolution By Lee Ehrman and Peter A Parsons Pp 450 ISBN 0-07-019276-6 (McGraw-Hill 1981) $31 50, £17 50

As A focus of intellectual excitement, the genetics of behaviour is rivalled only by pursuit of an understanding of the genetics of differentiation and development Since it requires an interdisciplinary approach in integrating biology and genetics with social sciences, it is also a minefield for misunderstanding, and requires a nice balance of scholarship and careful judgement in any who would venture a good textbook for teaching Here is just such a text *Behavior Genetics and Evolution* is a revised and updated edition of *The Genetics of Behavior* published a few years ago by the same authors It gives a comprehensive account of the principles and methods used to study the genetics of behaviour and stresses the point that greater understanding of the genetic architecture of complex behavioural traits necessitates subdividing them into discrete components prior to genetic analysis Separate chapters are devoted to reviewing the genetics of behaviour of human beings, small mammals and fruit flies, together with a range of other organisms including some less familiar invertebrates and domesticated species

The authors give a balanced account of the genetics of human behaviour and, rightly in my opinion, emphasize the need for concentration less on the current obsession with IQ differences than on the genetic analysis of more accessible human sensory, perceptual and motor skills — although, in view of the difficulties inherent in interpreting EEG wave patterns, speculation about their possible significance with regard to deviant or criminal behaviour should be treated with caution Particularly valuable is the discussion of the complications caused by cultural transmission in relation to the inheritance of human behavioural characteristics In the later chapters the special merits of the book emerge in a synthesis discussing the genetic architecture of behaviours in relation to niche breadth of species, habitat selection, population structure and mechanisms of evolution Relatively little attention is given to kin selection and the evolution of altruistic behaviour, which is surprising in view of the widespread current interest in this topic

The book is directed towards undergraduate and postgraduate students in biology and psychology, and should also be valuable to those professionally involved in the social sciences, agriculture or medicine who require a comprehensive treatment of the subject ☐

B Burnet is Reader in Animal Genetics at the University of Sheffield

Two views of evolutionary genetics

J.S. Jones

Basic Population Genetics By Bruce Wallace Pp 688 ISBN 0-231-05042-9 (Columbia University Press· 1981) $26, £12 95 *Introduction to Quantitative Genetics*, 2nd Edn By D S Falconer Pp 340 ISBN 0-582-44195-1. (Longman 1981) £9 95, $23

The old controversies about Darwinism have made their periodic return to the public stage In modern terms, evolution is nothing more than a change in gene frequencies Here are two books dealing with genes in populations, one, that of Wallace, is concerned largely with natural populations, the other mainly with genetic responses of populations in the laboratory or on the farm

Wallace's substantial work surveys many aspects of population genetics After a chapter on the usefulness of models (which are used throughout the book, but always at a level which should be accessible to undergraduates), he considers attempts to measure genetic variation, the effects of migration and assortative mating on population structure, the influence of inbreeding and mutation, and modes of selection in field and laboratory An account of genetic load (a term which has lost much of its earlier prominence) leads into a treatment of heterozygote advantage, which is considered in the context of "hard" natural selection (which depends on the rigid application of environmental challenges) versus "soft" selection (in which fitness depends as much on the frequency of competing genotypes as on the rigours of the environment) The book concludes with a discussion of coadaptation and population differentiation Wallace's treatment is biased towards the familiar laboratory species of *Drosophila* — organisms which are unique in the extent of our knowledge of their genetics and our ignorance of their ecology There is little mention of the classics of ecological genetics such as industrial melanism, mimicry or heavy metal tolerance in plants

In later chapters Wallace enters into speculation and polemic which, although always entertaining, means that in some ways the book belies its title, this text is much more than an account of the basics of evolutionary genetics

Falconer has produced a new edition of a book which has for 20 years been the basis for almost all introductory courses in quantitative genetics His second edition looks as durable as the first It gives a clear and complete account of the inheritance of continuous characters, many of which are of considerable practical importance Falconer does not hesitate to discuss the relevance of research on laboratory populations to cattle milk yield or corn production, so that his book will have a wide audience Two-thirds of the references cited have appeared since the first edition, and the inclusion of so much new work inevitably means that the book has lost some of its earlier clarity and directness, quantitative genetics has, in common with all other aspects of genetics, gained nothing in simplicity as our knowledge has increased. Nevertheless, this new text is unrivalled as an introduction to the subject.

As Wallace points out, there are parallels between the theories of population genetics and those of economics. In both fields there exist impressive and complex models of the process of change, a huge literature, of increasing mathematical sophistication, deals with their most obscure workings, and at the furthest reaches of these great machines small bands of workers labour to improve still further our understanding of the details of the evolutionary or economic universe. Economics and evolution share another remarkable feature, in each there exist two quite different sets of models which, although largely complete within themselves, provide mutually incompatible explanations of the same phenomena.

The present dominance of one economic model means that academics must now assess textbooks as much by price as by content. In population genetics there is an equivalent controversy between the view that most evolution results from the differential action of natural selection on genetic polymorphisms, and the more radical thesis that much evolutionary change — including even changes in the fossil record — arises from the accidents of sampling. Wallace, in particular, is an evolutionary Keynesian, throughout *Basic Population Genetics* he emphasizes the directing influence of gradual natural selection in controlling the course of evolution. Although Falconer does devote a higher proportion of his space to the influence of random events, he too does not give this view the prominence which it now has in much of the population genetics literature. Evolution by random change still awaits its student text. ☐

Mendel meets DNA: the story continued

D.J. Cove

An Introduction to Genetic Analysis, 2nd Edn. By David T. Suzuki, Anthony J. F. Griffiths and Richard C. Lewontin. Pp.911. Hbk ISBN 0-7167-1263-6, pbk ISBN 0-7167-1307-1. (W. H. Freeman: 1981.) Hbk $24.95, £18.50; pbk £11.95.

Genetics: A Molecular Approach. By Laura Livingston Mays. Pp.693. ISBN 0-02-378320-6. (Collier Macmillan/Macmillan, New York: 1981.) £15.95, $23.95.

Genetics: Its Concepts and Implications. By Anna C. Pai and Helen Marcus-Roberts. Pp.711. ISBN 0-13-351007-7. (Prentice-Hall: 1981.) $24.95, £18.70.

LAST year, I reviewed here (*Nature* **289**, 702–704) seven textbooks of genetics, published in 1980, which were primarily intended for use by undergraduates taking introductory genetics courses. In 1981, three more general genetics texts have appeared and so we have moved in the space of only two years from a state of relative famine to what might be judged to be a glut.

In my previous review, I was allowed to devote space to my own views of how genetics should be taught at this level. These have not changed so I will not repeat them here at length, but I believe that the teaching of genetics is not made easier by a rigid adoption of a historical approach nor by the compartmentation of classical and molecular genetics. However, as with almost all of the 1980 textbooks, last year's were again slaves of history. All, for example, introduce Mendelian genetics by considering the pattern of segregation observed when, in a diploid tissue, a character difference is due to a pair of alleles, one dominant to the other. In fact, in all three textbooks, the first segregations described are in the garden pea. Once again, the student is expected to cope with diploidy and dominance at the same time as understanding the principles of segregation. All three texts also adopt a "Mendel before molecules" approach, but Mays manages to deal with meiosis, Mendelism, DNA and even the regulation of gene expression, all in her first chapter. She returns to most of these topics later, where her treatment is, of course, more detailed. There is certainly something to be said for this approach, but in Mays's case its adoption has been accompanied by the sacrifice of rigour.

My review has so far implied that the three textbooks are rather similar and it is therefore time that I should redress the considerable injustice that this impression would cause to Suzuki, Griffiths and Lewontin. Although I was disappointed to find that these authors should have adopted such a conventional approach to the teaching of genetics — and that even they should imply that every gene has only two alleles, one dominant to the other, for about 70 pages of their text — of its kind, this textbook is excellent. It is clearly written, well illustrated and, in particular, as its title implies, puts considerable emphasis on the analytical aspects of genetics. Although it adopts a historical approach, it is up-to-date but, perhaps surprisingly, it is better in this respect on molecular than evolutionary topics. It contains, for example, a clear account of how DNA base sequence can be determined but does not deal with the punctuated equilibria debate. Lewontin's chapters on quantitative, population and evolutionary genetics, although as usual tacked on behind, are just as good as would be expected from a geneticist of his stature. However, most students will find the book's first chapter, which explores the difference between genotype and phenotype, and which was also contributed by Lewontin, difficult and only understandable when they return to it later having acquired some knowledge of the physiology of gene expression.

The book is not without faults, its treatment of the regulation of gene expression in the context of metabolism is weak in so far as it implies that there is much more uniformity of mechanisms than now seems justified and in particular that the operon is universal among prokaryotes and fundamental to gene regulation.

Mays's book, subtitled "A Molecular Approach", attempts to integrate molecular with classical genetics much more than Suzuki, Griffiths and Lewontin. It adopts a descriptive style which therefore neglects the logical rigour which is central to both molecular and Mendelian genetics. It is up-to-date and deals, perhaps in too much detail, with topics such as DNA sequencing. Population, ecological and evolutionary genetics are covered in two chapters, but although one of these is not at the end of the book, there is no greater integration of these topics with the rest of genetics than in most other texts.

Pai and Marcus-Roberts is unfortunately the runt of this litter. Its approach is conventional, very descriptive and where it attempts to explain classical genetical phenomena in physiological or molecular terms, the explanation is often misleading or even wrong. The book is in fact full of errors, some trivial, others more important. *Hemophilus influenza* (*sic*) is said to be a virus, a heterokaryon "a cell with a diploid nucleus", an *E coli* strain developed for safe genetic engineering to have no sites in its DNA "which can be acted on by restriction endonucleases".

All three books contain set problems. Mays contains no answers while Suzuki, Griffiths and Lewontin in their book give answers only to selected problems, although answers to all problems are available in a separate booklet. The answers are as usual rather brief, no doubt publishers will say that space is at a premium but I still believe that very full answers, perhaps to fewer questions, are essential.

Finally, I must compare this year's books with last year's. Suzuki, Griffiths and Lewontin goes straight into my "best buy" category. It is inevitably a little more up-to-date than my last year's choice, Ayala and Kiger's *Modern Genetics* (Benjamin/Cummings, 1980) but I do not think that it is obviously better I prefer Ayala and Kiger's somewhat less historical approach and their greater integration of molecular and Mendelian genetics, although I believe both should be taken much further I still think there is much to be said in favour of Fristrom and Spieth's *Principles of Genetics* (Chiron/Blackwell Scientific, 1980), last year's second choice, which adopts a much less conventional approach to the subject, and so my own list of recommended texts now includes all these three Mays's book is neither good enough nor bad enough to warrant special mention but I am afraid I will have to warn my students off Pai and Marcus-Roberts

D J Cove is Professor in the Department of Genetics at the University of Leeds

Not quite Wilson

Michael Ashburner

Cytogenetics The Chromosome in Division, Inheritance and Evolution, 2nd Edn By Carl P Swanson, Timothy Merz and William J Young Pp 557 ISBN 0-13-196618-9 (Prentice-Hall 1981) $25 95, £19 45 *Cytogenetics· Plants, Animals, Humans* By Jurgen Schulz-Schaeffer Pp 446 ISBN 3-540-90467-0 (Springer-Verlag 1981) DM69, $40 60

A DISTINGUISHED cytologist of my acquaintance never ventures abroad without his copy of the third edition of E B Wilson's *The Cell in Heredity and Development* (Macmillan, 1925) under his arm, carefully preserved from the elements by a wrapping of plain brown paper I fear that neither of the two textbooks of cytogenetics reviewed here will command such devotion 60 years hence Both Swanson, Merz and Young (SMY) and Schulz-Schaeffer have written texts aimed, by and large, at an advanced undergraduate audience, though both hope that their volumes may be of use to more "advanced" researchers

The books are not only similar in purpose, they are similar in the general extent of their coverage, treating such broad topics as the structure and function of chromosomes, the behaviour of chromosomes at mitosis and meiosis, chromosome aberrations and chromosomes in evolution in a reasonably conventional way There is, it is true, a considerable difference in emphasis between SMY and Schulz-Schaeffer, the latter gives the cytogenetics of plants (especially cereals) particularly strong attention, whilst the former devotes more space to a consideration of evolutionary issues It is, perhaps, for this reason that I am more naturally drawn to SMY and approached Schulz-Schaeffer more from the desire to know what new I could glean from it

I began this review with an implicit comparison of these two books with E B Wilson's masterpiece Part of the reason for Wilson's greatness (I speak of both book and man) was the regard and understanding he had of genetics The signal failure of Schulz-Schaeffer stems, in my opinion, from the absence of any true integration of the "cyto-" and the "genetics" This book suffers too from a lack of balance in the presentation of the material and from the author's inability to distinguish between the trivial and the lasting Perhaps I should illustrate these harsh criticisms A very common class of chromosome aberration, both in natural and experimental populations, is the inversion Inversions have the property that, when heterozygous, they suppress genetic recombination The precise mechanisms by which this suppression of recombination is achieved were elucidated by Sturtevant and Beadle in 1936, and their paper (*Genetics* **21**, 554–604) is one of the most elegant in genetics Not only does Schulz-Schaeffer fail to give a summary of this work (let alone reference it) but he wastes his reader's time with such trivia as the "fact" that "twenty seven different autosomal inversions have been reported from three different localities in Bulgaria in the mosquito species *Anopheles messeae*"

A second example of the lack of balance in this book may not be amiss A paragraph (p 294) discussing somatic crossing over includes the statement that "soybean seems to be an ideal object for the study of somatic crossing over" This may well be so, but it is rather an eccentric statement to make when the detailed and sophisticated studies of mitotic crossing over (as it should be called) in both yeast and *Drosophila* have virtually been ignored

The lack of balance that I see in this textbook is serious not only will it mislead the student but it will also undermine the confidence of other readers who might otherwise seek from it new information There is, not surprisingly, much in Schulz-Schaeffer that is new to me, yet I am reluctant to take anything at face value from an author who awards Francis Crick a knighthood (trivial in itself, perhaps, but a minor irritation) and who has, at least on occasion, clearly not consulted his original references His account of parthenogenesis in aphids is but a poor paraphrase of White's review in the third edition of *Animal Cytology and Evolution*, and I see no signs of any attempt to look at the original data or take into account subsequent studies

The second textbook, that by SMY, is far better Although the second edition of a text first published in 1967, it is really the successor of Swanson's *Cytology and Cytogenetics* published by Macmillan ten years before that Not only have SMY made a reasonably successful job of integrating the cytology and genetics (though even here I think Swanson did better in 1957) but they have also stamped upon the whole volume an evolutionary perspective that generates an impression of intellectual coherence There is, however, one area of weakness in this book that is in the various discussions of molecular cytogenetics Not only is this subject treated, to my mind, in a rather oversimplified manner but the authors are too naive, accepting at face value some of the more speculative of models whose very authors, I am sure, would shudder to see exhumed in student text □

Michael Ashburner is a Reader in the Department of Genetics, University of Cambridge

Citron pressé?

P.A. Lawrence

The Genetic Basis of Development By Alistair D Stewart and David M Hunt Pp 221 Hbk ISBN 0-216-91161-3, pbk ISBN 0-216-91160-5 (Blackie/Wiley 1982) Hbk £18 95, $27 95, pbk £8 95

THE genetic approach to developmental biology can be fun and ought to be popular But embryology is traditionally a soft subject that has often been closer to theology than science, while genetics has always been hard and numerological Which may explain why, in the past, practitioners of the two disciplines have understood each other little and have rarely collaborated to solve biological problems This makes no sense at all as genes are there to provide materials and information to construct and maintain animals Genes and their products ought therefore to be at the heart of embryology — which is just where Stewart and Hunt perceive them to be

Their aim was to write a brief embryological text from the geneticist's view point, and the result is a usefully analytical account It is also up to date and breaks with the common practice (especially in embryology) of beating a new textbook out of older ones In short, the authors have used the primary literature as their source This may explain why the book is often tricky — especially for the "advanced undergraduate" for whom it is written And also why it is too much of a review, being strong on lists of experiments and results and weak on explanation A good example is the description of the bithorax complex of *Drosophila* This locus is an illuminating link between genetics and development, as it appears that the elements of the locus are specifically deployed in developing segments

Lewis (*Nature* **276**, 565-570, 1978) has shown that without this gene complex most of the segments develop identically and the result is more like a worm than an insect Unfortunately the account of bithorax by Stewart and Hunt is so replete with facts that this advanced undergraduate found it almost incomprehensible Nevertheless, the original approach of the book makes it refreshing and, as with a cold drink, one can always leave the ice in the glass ☐

Peter Lawrence is at the MRC Laboratory of Molecular Biology, Cambridge

Genetics: bottom . . .

Neville Symonds

Bacterial and Bacteriophage Genetics An Introduction By Edward A Birge Pp 359 ISBN 0-387-90504-9 (Springer-Verlag 1981) DM54, $25 70

EDWARD Birge's brief was to produce a book of reasonable size which would serve as a contemporary text for introductory courses in bacterial and phage genetics This has involved starting with a brief treatment of DNA replication and the nature of mutation, proceeding through chapters on phage genetics and the mechanisms underlying transduction, transformation and conjugation, and then bringing the story up to date with further chapters on plasmids, gene regulation, the molecular basis of recombination and gene manipulation

The "historical" chapters on the development of the basic prokaryote genetic systems using the phages T4 and λ and the bacterium K12 as examples are of necessity only sketches of what took place and do not give a balanced idea of the nature of the discoveries involved or the problems which had to be overcome More successful is the chapter on the properties of the less well-known phages which outlines clearly the amazing variation in the strategies which have been adopted in various situations, and there are two well-researched chapters on plasmids which bring together a lot of useful ideas and practical material Transposition and its consequences are treated rather briefly, but there is a clear exposition at the end of the book of how modern techniques in gene manipulation are performed and of the new frontiers which are being opened up by these techniques

Overall the book succeeds in what it sets out to do It is clearly written, the diagrams and format are of a high standard, and it is as up to date as can be expected in such a rapidly expanding field There is no doubt it will be a useful adjunct in teaching introductory courses in molecular genetics ☐

Neville Symonds is Professor of Microbial Genetics at the University of Sussex

. . . to top

Dorothy A. Miller

Genetics Human Aspects By Arthur P Mange and Elaine Johansen Mange Pp 675 ISBN 0-03-056751-3 (Holt, Rinehart & Winston 1980) $25 95, £14 95
Human Chromosomes Structure, Behavior, Effects By Eeva Therman Pp 235 ISBN 0-387-90509-X (Springer-Verlag 1981) DM37, $21 80

THE tone of *Genetics Human Aspects* is set by the cover, which has a picture of Adam pondering as he sits alone on the stump of a primitive tree Perhaps he is thinking about the fact that all human beings will arise from him and hence be similar, but never identical, to him This is not to imply that this is a creationist text, but rather one which builds on the assumption that the study of human genetics should be of interest to a student just because he is a human being

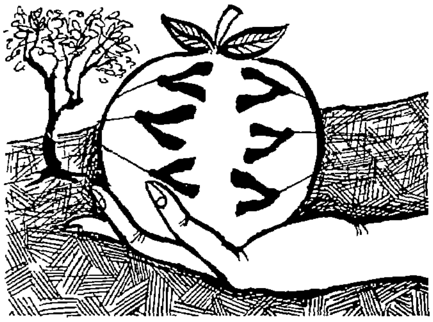
Mange and Mange have written a very readable book, indeed It is aimed at those with only a moderate scientific background, not including a general genetics course Hence the authors try to give a comprehensive presentation of genetics in which, whenever possible, concepts are illustrated by human rather than plant or animal examples Simple statistics and chemistry are dealt with in appendices

In addition to the easily understood, not to say sprightly, text, the book has much to recommend it The material is up-to-date and relatively free of errors The line drawings are particularly well conceived and are very effective in simplifying concepts as they are presented in the text The references are well chosen and include some original articles so that the student can appreciate the step by step nature of research The authors refer to numerous areas that still require research, leaving some room for student imagination There are adequate questions at the end of each chapter and the answers are accompanied by explanations

Will the book be suitable for a course? The fast pace that makes the book so enjoyable also means that most areas are not dealt with in depth Hence, the text would be more suitable for undergraduate or adult education courses than for graduate or medical school courses As in any text, the balance of material selected is a matter of personal preference which teachers must assess for themselves They would be well advised to at least examine this text

The material in *Human Chromosomes* by Eeva Therman overlaps about one-fourth of that in *Genetics Human Aspects* because chromosomes play such an important role in human genetics The text covers areas of human cytogenetics that have been studied using the light microscope chromosome structure, mitosis, meiosis, banding, structural and numerical abnormalities, changes in cancer cells and human gene mapping Examples are drawn primarily from human material, but use has been made of plant or animal studies when these provide the best material available The book does not deal with molecular approaches to cytogenetics and includes almost nothing about findings of biophysical, biochemical or electron microscopic studies (for example, nucleosomes are not mentioned)

Therman's writing is clear and her style didactic She includes many definitions and presents the facts that have been established Although she has carried out extensive research on the human X chromosome, her presentation is not research orientated She does not, for example, discuss the way the facts were obtained, nor does she try to entice students into cytogenetics by emphasizing questions that remain to be answered She prefers to cite reviews rather than original articles so that "the reader is encouraged to delve deeper into any question of interest", whether this will have the desired effect is not clear For me it produced a rather static image of an active field



Cytogenetics is a visual science, unfortunately the illustrations of human chromosomes given in the book do not provide a very complete background for the student Full human karyotypes are shown for unbanded Giemsa (two), G- and Q-banded cells, but not for C- or R-banded cells, which are represented by a partial karyotype of C-banded E group chromosomes and a single R-banded number 1 Reciprocal translocation is poorly illustrated by the karyotype of an unbanded endoreduplicated cell, even though the figure legend states the identity of the translocated chromosomes was confirmed with Q This selection of illustrations must have been a matter of choice, rather than space limitation, because a full page is devoted to C-banding of plant chromosomes and another to a G-banded karyotype of the rat

Human Chromosomes is an introductory text suitable for undergraduate or graduate students Since the subject matter is not dealt with in great detail, it should be compared to presentations of the same material in general human genetics texts

Dorothy A Miller is a Senior Research Associate in the Department of Human Genetics and Development at Columbia University

Science or scholarship for students of developmental biology?

D.R. Newth

Patten's Foundations of Embryology, 4th Edn By Bruce Carlson Pp 672 ISBN 0-07-009875-1 (McGraw-Hill 1981) $30 25, £16 25 *Development,* 2nd Edn By Gerald Karp and N J Berrill Pp 692 ISBN 0-07-033340-8 (McGraw-Hill 1981) $32 95, £18 25 *Developmental Biology* By Leon W Browder Pp 602 ISBN 0-03-056748-3 (Holt, Rinehart & Winston 1980) $28 95, £13 95 *Introduction to Embryonic Development* By Steven B Oppenheimer Pp 404 Hbk ISBN 0-205-06899-5, pbk ISBN 0-205-07348-4 (Allyn & Bacon 1981) Hbk $23 95, £16 50, pbk £8 95

THE student of developmental biology, or of its senior component animal embryology, does not lack for possible textbooks However, perhaps paradoxically, only the most elementary can afford to be comprehensive, the more advanced being tempted to specialize in one of two ways They may be restricted systematically, dealing for example, only with animals, only with vertebrates or only with *Xenopus* Or they may be mechanism based and call widely upon prokaryote, unicellular, and plant and animal multicellular systems for illustrations of their themes In either case one senses a certain discomfort in the authors and fears a lack of satisfaction in the student reader

Of the four books now considered, one — Carlson's revision of Patten — is unashamedly selective both systematically and thematically It derives from an earlier book which celebrated the developmental anatomy of chick, pig and man but had little use for other material Dr Carlson has now remodelled the work with the object of narrowing the gap between accounts of formal changes in developing animals and their experimental analysis His main changes have been to stress the morphogenesis of organs that have been important in analytical work, to give an account of limb development that is a genuine integration of the formal and the analytical, and to introduce experimental findings at points where they help to solve anatomical problems

The material is presented clearly and the book is abundantly and effectively illustrated The student will gain from the self-imposed limitation of the treatment in that at the end he or she will feel confident of, and in, what has been accomplished Dr Carlson provides an introduction to laboratory studies on early chick development as a long appendix

Karp and Berrill have produced a very much revised and improved second edition of a fairly ambitious text They cover so much and their treatment is so good in so many ways, that it seems churlish to question the coherence of the picture of development that emerges And yet, after the early chapters in which a developmental story unfolding can be discerned, the book inevitably fragments into sections whose sequence seems arbitrary This, I must emphasize, is not meant as a criticism only as an acknowledgement of the impossibility at the present time of ordering our presentation of developmental problems consistently

Plants apart — and few texts successfully integrate them with animal material — the systematic coverage is catholic, and the emphasis biological That is to say that the biochemical and molecular biological approaches do not predominate, although usefully presented at many points

Karp and Berrill, in my view, offer one of the half-dozen best general texts of developmental biology now available in English They will run to a third edition no doubt, and may then take the opportunity to improve the proof reading, most especially in correcting the spelling of proper names

Browder's *Developmental Biology* is also a large and ambitiously conceived work, but leaning more heavily upon molecular biology, and being somewhat kinder to plants It has the virtue of clarity and is well illustrated, but it too shows that selection of material has been a serious problem It would not be simply an act of piety to include discussion of, say, the development of the immune system and of the origin of antibody diversity in a textbook of developmental biology, especially in one which concentrates on biochemical and cellular matters Yet Browder skates over these and a number of other fields which might have been expected to attract him, amphibian metamorphosis, for example, is given cavalier treatment

Yet his discussions of the matters that he deals with are well balanced and should incite students to explore the original literature Especially in the area of gene control of development, his accounts are among the best available at this level

Oppenheimer's book is the shortest and claims only to be an introduction It is eclectic in coverage, but not very kind to plants It is written with enthusiasm, is sometimes a little careless, but deals with most of its topics in a stimulating way However, as with so many elementary introductions, it does not avoid the danger of unquestioning acceptance of matters which are not quite as certain as all that In a section quaintly headed "Gastulation in Amphibian" *(sic)* is given a not very good account of the process in question, but with no suggestion that it may still have uncertainties or that it may vary from one amphibian species to another Yet it does Nor is bird gastrulation so simple, or so well understood, as the student reading Oppenheimer might believe

These are, of course, complaints of a kind that most elementary texts invite To avoid them is difficult, but the attempt must be made if the reader is to be helped into science rather than into scholarship

The authors of all these books have clearly gone to some trouble with their illustrations Many, especially the scanning electron micrographs, are excellent But publishers will have to take greater pains to ensure that their production methods are equal to the challenge □

Biology: broad brush for a large canvas

E.C. Cox & R.M May

A View of Life By Salvador E Luria Stephen J Gould and Sam Singer Pp 806 ISBN 0-8053-6648-2 (Benjamin/Cummings 1981) $26 95, £10 95

THIS introductory biology text aims to concentrate on "the great themes and arguments of biology", rather than to offer the encyclopaedic catalogue that characterizes many of its competitors The result is an interesting and unusual text which in places has a minimalist air to it; this is particularly true in the earlier sections, where a lot of the material is simply set forth without critical examination of the historical or contemporary experiments that compel belief

The broad pattern of organization is the conventional one beginning with the basic chemistry of living things, we progress through genetics, developmental biology and the functioning of organisms to evolutionary biology and ecology The presentation is uniformly lucid, easy to read and backed by first-rate line drawings and other illustrations (along with "boxes" developing special points)

Among the early chapters are some strikingly elegant and careful discussions the structure of water, allosteric effectors (where the models and figures are superb), introductory genetics and gene regulation in bacteria The molecular biology is not as contemporary as one might wish, virtually passing over much of the exciting new work on the gene structure of higher eukaryotes (such as gene inserts, the splicing together of variable and constant regions of the globulin chains, the molecular changes associated with the regulation of mating type in yeast and so on) In short, the early sections are strong on the classic things, but appear a bit dated

The chapters on the functioning of organisms do a good job of covering the major problems faced and solved by higher organisms nutrition and gas exchange, transport, hormone functioning and the like The emphasis is strongly on human biology (again with excellent illustrations), with occasional genuflection toward comparative and evolutionary analyses

The concluding chapters focus on the broad themes of evolutionary thinking the history of the subject, micro- and macroevolution, biogeography and the fossil record No other introductory text treats this material so thoroughly or so well These chapters expound the essential philosophical character of Darwin's theory, and discuss problems associated with it, both past (blending inheritance, Mivart's doubts about the evolution of the incipient stages of useful structures, as instanced by the two reptilian jaw bones that are ear bones in contemporary mammals) and present ("neutral evolution", mechanisms that can maintain heterozygosity in populations, cladist, phenetic and classical evolutionary schools of taxonomy) Given the current misrepresentation of evolutionary thinking by the so-called "scientific" creationists, these chapters are especially valuable They are marred only by an occasional tendency to intrusive editorial comment, and by the misrepresentation of Darwin as holding thât evolution proceeds at a consistently gradual rate, in contrast with contemporary notions about "punctuated equilibrium" As observed by Andrew Huxley in his Presidential Address to the Royal Society last year, Darwin's statement that "each form remains for long periods unaltered, and then again undergoes modification" and

> the periods during which species have been undergoing modification, though very long as measured by years, have probably been short in comparison with the periods during which these same species remained without undergoing any change

effectively makes him a punctuated equilibrist

The treatment of population genetics is brief and not well organized, and that of population biology and ecology is perfunctory

In short, this is a distinctive introductory biology text that all teachers of such courses will profit from reading But we feel it is a bit too thin and quirky to displace the canonical Curtis or Keeton, unless supplemented by extensive additional readings □

Edward C Cox is Chairman of, and Robert M May Professor in, the Biology Department at Princeton University, where they jointly teach an introductory biology course

The multifarious questions of evolution

Bentley Glass

Understanding Evolution By Earl D Hanson Pp 556 ISBN 0-19-502784-1 (Oxford University Press 1981) £14 95, $23 95

THE recent flurry of attacks on school textbooks and the teachers of biology who deal with evolution should focus attention on the college textbooks of evolution and the way in which the subject is taught The questions to be asked are multifarious Is organic evolution itself, as distinct from the mechanism of natural selection, a theory or a fact? Is adequate attention given to the gradual change of ideas about a theory, starting in the case of evolution with the first glimmerings of the concept among the Greek philosophers and the ancient and mediaeval belief in spontaneous generation? What of the long debate over the inheritance of acquired characteristics, continuing even today? Just what was Darwin's contribution to the theory of evolution? How does the evolutionary synthesis of today differ from Darwin's own ideas? There are many more

In most respects, the teacher — if not the student — will welcome Hanson's book It is comprehensive and clearly written As might be expected from his earlier books, Hanson emphasizes animal and plant diversity, homologies and relationships But there is a substantial section devoted to Mendelian and modern genetics as the basis of understanding what Darwin always affirmed was the crux of the matter the nature and origin of hereditary variations There is also a detailed treatment of the evidence for relationships that comes from biochemical comparisons of amino acid sequences in proteins and nucleotide sequences in DNA For a course intended to run only for one semester of a college year, there may be far more technical detail here than a student can master, yet better too much than too skimpy a treatment

As for noticeable deficiencies in the book, it seems to me that not enough attention is given to the history of the idea of evolution, to the pre-Darwinian as well as post-Darwinian gropings for an explanation of origins, to the marvellous combination of evidence from every sub-field of biology. I notice also a tendency to deal rather briefly with the evolution of plants, although their speciation by polyploidy, especially allopolyploidy, affords some of the best evidence for the origin of species in recent times The coverage of plant and animal geography in relation to evolution is also somewhat meagre Nevertheless, the classical evolutionary synthesis is well expounded

Finally, in respect to human evolution, in my opinion a fuller development of primate and hominid evolution would be enjoyed by teacher and students alike It is difficult, in this area of knowledge, to keep pace with discovery and choose between conflicting interpretations Hanson has relied heavily on the work of the Leakeys He omits entirely any reference to the breathtaking discovery of "Lucy", the three-million-year-old, erect-walking australopithecine whose complete skeleton is the most magnificent and astounding of all palaeoanthropological discoveries This section of Hanson's book already cries out for revision

The last 200 pages of *Understanding Evolution* are devoted to a phylogenetic survey of plant and animal groups That is clearly the author's own bent Other teachers may wish that those pages had been used for a fuller treatment of some of the matters I have mentioned that have received little attention In particular, there would be a solid advantage in allotting space to an explicit exposé of the assumptions and subterfuges of the "scientific" creationists □

Natural history of vertebrates

Barry Cox

Patterns of Vertebrate Biology By E W Jameson, Jr Pp 477 ISBN 0-387-90520-0 (Springer-Verlag 1981) DM 63, $33 20

THE preface to Jameson's book states that it is concerned with the natural history of vertebrates, and he comments that "the laboratory, however essential and productive, is a departure from the animal's real world" Much of the book is therefore primarily descriptive, made up of a collection of discussions of different aspects of the field biology of vertebrates

However, Jameson commences with chapters concerned with "An Overview of Vertebrate Phylogeny", "Mechanics of Evolution" and "Zoogeography" It is always difficult to know where to draw the line between relevant topics and those which are merely general background, but I thought that none of these contributed significantly to Jameson's main thesis, while the first also revealed an uncertain knowledge and understanding of this topic

The remainder of the book is divided into three parts "Individual Environmental Responses" (with chapters on breathing, food and feeding, thermoregulation and water balance, activity and seasonal dormancy), "Communication" (sensory receptors and perception, signals), and "Population Phenomena" (reproduction, growth, community and population density) Here again, there are sections that have little to do with natural history For example, the details of the structure and ventilation of the bird's lung and airsac system are merely functional anatomy, and only become natural history if comparative data are given on variations in the structure or relative size of the system in different birds, such as penguins, ostriches, humming birds and so on The book is also not without errors for example, hagfish do not have only a single pair of gills (p 104), and the spiracle is not the vestigial *last* gill (p 106)

Nevertheless, those wishing to flesh out structural anatomy with interesting examples of natural history will find many useful examples in this book, and there is an extensive bibliography of well over 1,000 entries ☐

Barry Cox is a Professor of Zoology at King's College, University of London

The welcome return of J.Z. Young

L. Beverly Halstead

The Life of Vertebrates, 3rd Edn By J Z Young Pp 645 Hbk ISBN 0-19-857172-0, pbk ISBN 0-19-857173-9 (Oxford University Press 1981) Hbk £25, $26 95, pbk £14 *The Chordates*, 2nd Edn By R McNeill Alexander Pp 510 Hbk ISBN 0-521-23658-4, pbk ISBN 0-521-28141-5 (Cambridge University Press 1981) Hbk £35, $69 50, pbk £12 50, $24 95 *Lecture Notes on Vertebrate Zoology* By R Pearson and J N Ball Pp 180 Pbk ISBN 0-632-00729-X (Blackwell Scientific/ Halsted 1981) £7 50, $21 95 *Anatomy of the Chordates*, 4th Edn By C K Weichert Pp 814 ISBN 0-07-069007-3 (McGraw-Hill 1981) $37 75, £20 95

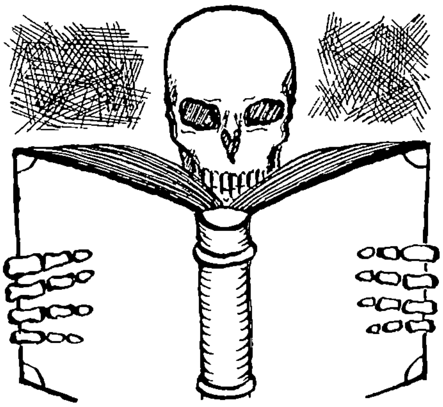
IN 1950 J Z Young published *The Life of Vertebrates*, which rapidly came to dominate the teaching of vertebrate zoology at a time when the vertebrates occupied an entire academic year in most zoology degree courses In 1962 the second edition appeared, but by the end of the 1960s and throughout the 1970s there was no J Z and teachers were obliged to look elsewhere Not only that, but vertebrate zoology had to relinquish much of its territory as newer aspects of biology rose to the fore Vertebrate courses became a catalogue of anatomy, with long names to be studied and learnt for no other apparent reason than that it was supposed to do students good The vertebrates tended to be relegated to a smaller and smaller part of the curriculum As this process was underway, by some curious irony advanced texts, monographs and symposium volumes on the group seemed to be constantly pouring out of publishing houses, yet there was nothing remotely suitable in the way of a general textbook

In 1975 there appeared McNeill Alexander's *The Chordates*, a general textbook of vertebrate zoology written by a leading expert in biomechanics, which in many ways fitted the bill Here, the structures of the vertebrates were discussed from the standpoint of their mechanics This approach lent itself especially to practical demonstration of the basic principles involved and was a truly excellent contribution to teaching, though the mathematical aspects tended to intimidate both the students and the less numerate teachers However, this textbook signalled a refreshing new approach that deserved encouragement The publication of a second edition, which has been updated and includes several new topics such as a useful discussion of dinosaur biomechanics, augurs well for the future of vertebrate zoology and the biomechanical approach being promoted by Alexander

The appearance of Pearson and Ball's *Lecture Notes on Vertebrate Zoology* clearly fills a need in the teaching scheme of things It is sad that it should be so This book as far as one can judge sets out to record all the boring bits of the subject, with its emphasis on pure anatomy The authors' aim "to release the teacher from the drudgery of simply reproducing anatomy and to create a platform for profitable expansion on innumerable other topics" Well, here is the drudgery all right but I fear that having created this platform, far from inspiring a prospective student into "profitable expansion" it would convince him that the subject is one of stupefying boredom to be avoided at all cost The illustrations are notable for their variable quality the crude sketch of the structure of a reptile scale (p 93) conveys nothing to me, and I suspect the authors would not have included it had they ever looked at a microscopic section of, say, lizard skin Worse, some of the information is so out of date that it would appear that the authors have cobbled together their material from a selection of older textbooks I suppose a teacher could use the book to instruct students in some basic information but they would be failing in their duty to allow students a glimpse of it This book can only do harm in that it is guaranteed to snuff out any spark of enthusiasm

Last year also saw the appearance of the fourth edition of Weichert's *Anatomy of the Chordates*, a system by system comparison of the chordates — a worthy, albeit rather fusty book, again dating from a time (1951) when the vertebrates formed a larger proportion of the syllabus than today This book, however, can be recommended for all teachers of vertebrate zoology in that it is relatively easy to pick out how, for instance, the vascular system varies from one major structural grade of vertebrate to another This is the kind of book to have to hand as a reference for teaching

For teachers and students of vertebrate zoology the publishing event of 1981 was, however, the long awaited return of J Z Young, with the third edition of *The Life of Vertebrates* It all comes back now, why J Z had such a profound effect on both teachers and students, here he speaks directly to the reader about really fascinating topics It is always possible to complain that the choice of topics is rather too personal but this is surely what gives the book its vitality The notable thing about *The Life of Vertebrates* is that a mass of information is communicated in such a light and easy manner, but, more important, the enthusiasm of youth pervades this book There are odd bits where one cannot help but be irritated because it is either grossly out of date or plain wrong, such as the hopelessly inaccurate diagram of the visceral arches and jaws in early vertebrates One of the greatest surprises is that the current controversies on methods of classification and the arguments over the process of evolution and the fossil record are alluded to and the clear voice of common-sense always characterizes J Z 's overview, not only of current fashions but of the place of zoology in its wider perspective



The pre-eminent position of J Z Young as the teacher and enthusiast of the study of the vertebrates is richly deserved This is the best textbook around The occasional lapses can be forgiven, it is the inspiration that he provides that will encourage a new generation to come into vertebrate zoology ☐

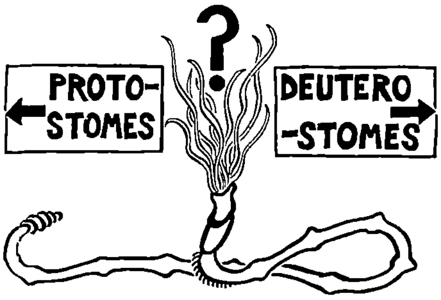
A.E. Brafield

Invertebrate Zoology, 4th Edn By R D Barnes Pp 1,089 Hbk ISBN 0-03-056-747-5, pbk ISBN 4-8337-001-8 (Holt-Saunders 1980) Hbk £17 95, $27 95, pbk £11 50 *Invertebrate Zoology*, 3rd Edn By J G Engemann and R W Hegner Pp 746 ISBN 0-02-333780-X (Collier Macmillan/Macmillan, New York 1981) £13 95, $20 95 *Invertebrate Respiration* By R M G Wells Pp 72 Pbk ISBN 0-7131-2806-2 (Edward Arnold 1980) £2 60 *Practical Invertebrate Zoology*, 2nd Edn Edited by R P Dales Pp 356 Pbk ISBN 0-632-00755-9 (Blackwell Scientific/Halsted 1981) £9 50, $32 95

A SYSTEMATIC and detailed study of the vast array of invertebrate animals continues to form a substantial part of undergraduate teaching in zoology The problem of striking a satisfactory balance between their anatomy, physiology, ecology and evolutionary relationships has become more acute as our knowledge in these areas has increased A sound and comprehensive textbook to supplement "the invertebrate course" is essential, and two which have built up a considerable reputation have recently appeared in new editions

Invertebrate Zoology, by Barnes, has reached its fourth edition Barnes claims that "there is no way a book of this sort can avoid growing to some extent", which is debatable to say the least, but most of the considerable increase in length of this edition comes from the many new drawings and photographs The new artwork by Mary Ann Nelson is excellent and she has made her drawings from actual specimens (a habit which seems, unfortunately, all too rare) The text is as clear and sound as ever Summaries have been added, a central section of over 40 colour photographs is a new feature, and there is now an interesting chapter on coral reefs Barnes still plays down the insects too much, however, allowing them only about 30 pages in a book of over a thousand The paperback version has a much smaller page size than the hardback and the consequent reduction in the size of typeface and diagrams tends to make the text hard to read and the illustrations less clear, but the paperback, being roughly half the bulk and weight of the hardback, is certainly easier to handle

The third edition of *Invertebrate Zoology* by Engemann and Hegner is also welcome (Engemann's name now precedes that of the late Robert Hegner) It is as concise and well organized as previous editions, with key words in italics and the material arranged in short, headed sections Engemann is a devotee of the "type approach", in which one species is treated in great detail to serve as an example of its group A drawback of this practice, it seems to me, is that every aspect of the selected type is described, whether it happens to be typical of the group or not, at the expense of more information on other members (The crayfish occupies as many pages as all other crustaceans put together, for example) An unusual feature is the new chapter on deep-sea invertebrates, in which the suggestion that these animals tend to be extremely long-lived is critically examined in order to discuss "a broad range of principles" of invertebrate zoology and to encourage the student to think more deeply A worthy aim, which Engemann achieves convincingly



The division of coelomates into protostomes and deuterostomes is coming under some attack nowadays, but it is a convenient and useful concept and both Barnes and Engemann retain it They disagree, however, over many points of classification For example, Barnes puts the pogonophorans among the protostomes, rightly I think, whereas Engemann still lists them among his deuterostome groups (although he acknowledges elsewhere that their position is puzzling) Engemann discusses the problems of protozoan relationships but in the end sticks to the system customarily used by zoologists, whereas Barnes now raises each of the major protozoan groups to the rank of phylum (in the Kingdom Protista) Such disagreements over classification are inevitable, but they can confuse students Barnes has dropped his earlier chapter on phylogeny, and Engemann also avoids, sensibly, a long consideration of possible evolutionary relationships between the phyla

In addition to comprehensive textbooks, there is now a wide variety of smaller works which cover specific aspects of invertebrate zoology *Invertebrate Respiration*, by Wells, is a fine example The author's lively style reflects his great enthusiasm for the subject, and the longest chapter deals effectively with the comparative physiology of blood pigments, Wells's own speciality Zoologists with no great feeling for the physical sciences will find the introductory chapter on the principles of gaseous exchange particularly valuable

Laboratory classes are an indispensable part of invertebrate courses They generally include an intensive study of anatomy (by microscopy and by dissection), demonstrations of specimens to illustrate the range of form within each group, and some simple experiments All these aspects are well served by the second edition of *Practical Invertebrate Zoology,* edited by Dales He and the six other authors are all experienced university teachers and each is an expert on one of the major invertebrate phyla The book is well written and the material sensibly arranged There is too much writing and not enough illustration for a laboratory manual, to my mind, but the book contains a great deal of valuable information The section on general methods, and the numerous suggestions for simple experiments, make the work a useful sourcebook for the teacher as well as the student ☐

Alan Brafield is a Senior Lecturer in the Biology Department of Queen Elizabeth College, University of London

Insects entomed

M.E.G. Evans

The Science of Entomology, 2nd Edn By William S Romoser Pp 575 ISBN 0-02-403410-X (Collier Macmillan/Macmillan, New York 1981) £13 95, $21 95 *Fundamentals of Entomology,* 2nd Edn By Richard J Elzinga Pp 422 ISBN 0-13-338194-3 (Prentice-Hall 1981) $22 95, £17 20 *Insect Physiology* By W Mordue *et al* Pp 108 Pbk ISBN 0-632-00385-5 (Blackwell Scientific/Halsted 1981) £5 75, $16 95

ENTOMOLOGY is one of the few component parts of zoology to be taught as a science in its own right Physiology, parasitology and cytology, for example, are major topics covering the whole of the animal kingdom, the Insecta and Chordata are the only individual groups to merit major topic treatment, and this is reflected by the large number of books concerned with their study One might wonder whether more entomology texts are really necessary — perhaps merely to include recent advances? — but since the fundamentals of insect biology do not change, a sensible solution is to rewrite the better books Two of the three texts reviewed here are second editions of books already established in North America All three are good examples of the recent generation of entomological texts which pack a large amount of information into a single, readable and well-illustrated volume Modern textbooks are not necessarily better than some of their predecessors, but they are often more lucid and are usually more attractive visually, studying is still hard work, but now it may be less painful

Romoser and Elzinga have each written comprehensive accounts which emphasize the general biology of insects rather than their classification or economic importance *The Science of Entomology* is the larger book and is clearly intended for intermediate or advanced courses (second or third years in Britain, for North America, the author suggests a one-semester course) It nas a rather academic approach of the sort found in a good standard text such as Richards and Davies's *Imms' General Textbook of Entomology* (10th Edn, Wiley/Chapman & Hall, 1977) Romoser ranges from morphology and physiology to ecology and evolution, allotting a chapter each to applied entomology and systematics For completeness, an entomology course would need a more extended treatment of systematics based on a text such as Richards and Davies or Borror, DeLong and Triplehorn's *An Introduction to the Study of Insects* (5th Edn, Holt, Rinehart & Winston, 1981) In fact, such back-up is emphasized throughout the book, as demonstrated by the introductory section on entomological literature and by the impressive number of references cited

Fundamentals of Entomology is an introductory-course book which aims to cover the whole of entomology at a more elementary level Again, it is based on general biology, but there is also a lengthy classificatory section with keys to both orders and major families It is profusely illustrated with line drawings and photographs, however, as in many zoological texts, the macrophotographs sometimes lack the clarity of the scanning electron micrographs and the precision of the line drawings Most of the topics have been treated by Elzinga in a compact and readable manner, although it might have been wiser to omit some sections rather than over-reduce them, for instance, it is difficult to explain population dynamics in eight pages

Insect Physiology is a multi-author paperback which deals with only part of a large subject It is a clear exposition of homeostatic problems — from cell metabolism to nerves and muscles — although only about one-fifth of the book deals with behavioural physiology In spite of four authors, the chapters link together well and the diagrams are excellent A few key references are quoted at the end of each chapter to guide the student to the more important literature, I would have preferred a few more in order to reach the most interesting topics more rapidly Although an introductory text, the book has the merit of conveying some of the fascination of recent research in this field

All three books are welcome additions to the field of insect biology Elzinga can be recommended for a short, introductory course, Romoser for a major part of a longer, more advanced course, and Mordue for the up-to-date physiology section of a general entomology course

Saline solutions

D.J. Crisp

Elements of Marine Ecology An Introductory Course, 3rd Edn By R V Tait Pp 356 ISBN 0-408-71054-3 (Butterworths 1981) £8 95, $22 50 *The Estuarine Ecosystem* By Donald McLusky Pp 150 Hbk ISBN 0-216-91115-X, pbk ISBN 0-216-91116-8 (Blackie/Wiley 1981) Hbk £12 75, $29 95, pbk £6 25 *The Ecology of Marine Sediments An Introduction to the Structure and Function of Benthic Communities* By John S Gray Pp 185 Hbk ISBN 0-521-23553-7, pbk ISBN 0-521-28027-3 (Cambridge University Press. 1981) Hbk £15, $34 50, pbk £6 95, $16 50

AN ELEMENTARY text should not only provide a clear and comprehensive account of its subject, but it should also stress those areas where there is a consensus of view and give less prominence to more controversial subjects where current research has yet to resolve the pattern In doing so it will provide the reader with an historical perspective, identify the founders of classical works and provide up-to-date reviews

The third edition of Tate's *Elements of Marine Ecology* achieves most of these objectives It differs little in content from earlier editions and fully meets the needs of elementary students of marine biology who seek only the minimum of understanding of chemical and physical oceanography The reference lists have been considerably enlarged and the division into books for general reading and specific references to textual matters has been eliminated Neither of these changes seems particularly beneficial, other than to a reference collector The majority of classical marine biology works are included but so also are a frightening number of minor papers The author therefore has done less than he might in guiding the student towards serious and essential reading Nonetheless, it remains a sound, well-ordered and very useful student text There are no obvious errors, except for the blatant misuse of the word "parameter" in the title of Chapter 4 — alas, a fault now almost sanctioned by usage

The Estuarine Ecosystem is aimed at a more specialized readership The first chapter includes some elementary consideration of the hydrography, sedimentary processes, species composition and food webs of estuaries It is a rather superficial account suffering from false simplification, perhaps on the wrong assumption that students of marine biology should not have to bite on hard science To take a simple example, sinking rates are discussed in relation to the impact law for large particles and Stokes' law for small ones, but the underlying reason behind the different approaches is not explained Neither the bounds over which the equations hold true nor their derivations are given, yet this information is exactly what the intelligent student needs in order to grasp the relevant scientific principles. In the same chapter, hydrographic features of estuaries are not fully discussed in terms of estuary size and salinity fluctuation, while recent work on the importance of rate of change of estuarine variables on the tolerance of animal species is not mentioned. Indeed the diagrams showing species penetration into estuaries are related to "salinity", not even "mean salinity" and certainly without reference to fluctuation.

Insufficient consideration is given to estuarine topography especially the influence of coastal emergence and submergence on estuarine form. The book as a whole deals almost exclusively with British and eastern American coasts, omitting any consideration of Arctic and tropical estuaries. In regard to the historical perspective of the subject, it fails dismally. The names of Bowden, Ketchum and Redfield, and Riley never appear, while in the place of the original figure depicting the mid-estuarine minimum in faunal diversity, given by Alexander *et al.* in their classical paper of 1935, the author quotes only from his own book of 1971.

The book includes a useful accumulation of productivity data for estuaries, with many food web diagrams, but little of novelty or abstracted wisdom which cannot be found elsewhere. The reference lists do not appear to be selective or exhaustive.

John Gray's *Ecology of Marine Sediments,* though less weighty in information, contains the essential material for the author's purpose and a good historical background. It aims to focus the minds of benthic ecologists on the interpretation of data in terms of modern ecological principles. Gray seizes on the linearity of the log–normal distribution of individual numbers in relation to species as a good measure of community equilibrium in the absence of disturbance. One would like to have seen a further extension of the philosophical basis of the idea, with a guess at the ecological meaning of the relevant statistics.

The book contains thoughtful discussions on niches, diversity and faunal stability — ideas that are currently being tested by ecologists in many environments. Finally, the author considers practical means of monitoring benthic communities in respect of long-term effects of pollution or of other factors that may control their structure.

This volume affords good reading for the above-average student of marine ecology who is prepared to sit and reflect, and is essential for those engaged in research on the fauna of sediments. It is a valuable contribution to ecological theory.

D.J. Crisp is Professor of Marine Biology at the Marine Science Laboratories, Menai Bridge, Gwynedd.

Aspects of environmental physiology

J.A. Riegel

Functional Adaptations of Marine Organisms. Edited by F. John Vernberg and Winona B. Vernberg. Pp.347. ISBN 0-12-718280-2. (Academic 1981.) $39.50, £26.20. *Animal Osmoregulation.* By J.C. Rankin and J. Davenport. Pp.202. Hbk ISBN 0-216-91014-5, pbk ISBN 0-216-91015-3. (Blackie/Wiley 1981.) Hbk £17.95, $39.95, pbk £8.95.

THESE two books have one common feature: they represent attempts to relate various aspects of organismal function to environmental variables. That edited by the Vernbergs is a multi-authored treatise whose main use will be as a source of reference. Rankin and Davenport's book is much more didactic in its approach, and it should find a wide audience amongst students and teachers of courses in environmental physiology.

Functional Adaptations of Marine Organisms contains chapters written by specialists on primary production, bacteria, zooplankton, meiofauna, benthic macrofauna, pelagic macrofauna and deep-sea organisms. In addition, the editors have provided an introductory chapter describing the ecological subdivisions of the marine habitat. This is both welcome and necessary for the non-specialist reader. Like most multi-authored works, however, the book's coverage is inadequate. For example, the discussion of zooplankton is confined to copepods, and primary producers are reviewed largely from an ecological viewpoint. Recent discoveries of communities of animals densely clustered around deep-sea, warm-water vents and dependent upon the primary production of chemosynthetic bacteria receive only brief mention. Nevertheless, the major shortcoming of the book is due to the inadequacy of the background data. Although more could have been done to round out the material, this deficiency is not altogether the authors' (or editors') fault — precious little is really known about the functional adaptations of marine organisms, especially those in the less-accessible parts of the sea.

Despite its shortcomings, the book should be a useful reference work for specialists and non-specialists alike. Although no chapter represents an exhaustive review of the literature, most authors have included references to reviews and papers covering aspects of their subjects not discussed extensively in their contributions.

Animal Osmoregulation presents a refreshingly uncluttered overview of not only the basic concepts of the subject, but also most of the currently-active fields of research. The book starts with a consideration of basic principles, the explanations of which should be of sufficient clarity to be understood readily by the average undergraduate. Following this come discussions of the adaptations of animals to various habitats, from the sea to brackish water, fresh water and land. Specialized adaptations of osmoregulatory mechanisms, such as the mammalian kidney, buoyancy and to life in acid and alkaline waters, are also covered. The examples used to illustrate the various adaptations are highly selective and several are drawn from the research of the authors and their associates. Perhaps it is this personal experience of much of the research underlying the material which gives the narrative an admirable lack of dogmatism. Aware of the highly-variable nature of most data, they tend to generalize with caution.

The final chapter of *Animal Osmoregulation* deals with some of the common physiological and behavioural techniques used in studies of osmoregulation. The description of physiological techniques may provide useful background, but the short discussion of behavioural techniques should prove more valuable, especially as the basis of classroom experiments or demonstrations. □

Adaptation to supply and demand

Garth Chapman

Animal Physiology: Adaptations in Function. By F. Reed Hainsworth. Pp.669. ISBN 0-201-03401-8. (Addison-Wesley 1981.) $25.95, £10.95.

HAINSWORTH'S *Animal Physiology* declares itself to be ecological and comparative by its subtitle but only discloses the fact that it is "organized around" an "economic theme for comparative physiology" in the preface. The animal's balance sheet of benefits and costs uses the currency of resources and concludes about joules and survival what Mr Micawber concluded about pence and happiness.

This is certainly an important theme but it becomes a little tedious by reiteration. However heuristically valuable such an approach may be when applied to resources such as oxygen, food, water and salts, it is less directly applicable to that large and distinctive part of animal physiology which is concerned with reception, co-ordination and response. Accordingly, perhaps, the section dealing with these topics is placed at the end of the book Although not neglected, less prominence is given to them and to the current tenets of membrane physiology on which they are based than in some recent texts such as Goldstein's *Introduction to Comparative Physiology* (Holt, Rinehart & Winston, 1977) and Eckert and Randall's *Animal Physiology* (W H Freeman, 1978) where they follow the opening chapters on physical and chemical principles

In style the book is densely and didactically written but the terse generalization is usually supported by example or the brief report of an observation or experiment Nevertheless, I found myself wondering whether an introductory text ought not to lead readers more gently along the path of interest rather than seek to impress them with sheer quantity of information Unlike some bulky and extravagant textbooks, this one is handy and well produced apart from a few gimmicks such as two contents lists, one short and obscure and one detailed and eleven pages in length! There is no indication of part or section in the running headlines, which makes cross-reference difficult since such references are frequently indicated by subdivision and not by page Bibliographical references (not indicated in the text) are divided into annotated, at the end of each part, and "credit" — whatever they may be — at the end of the volume

In short, this seems a somewhat daunting introductory text to read although good indexing increases its value to an industrious student for purposes of reference and study □

Garth Chapman is Professor of Zoology at Queen Elizabeth College, University of London

Enzymology: the general and the specific

R.N. Perham

Understanding Enzymes By Trevor Palmer Pp 405 Hbk ISBN 0-85312-202-4, pbk ISBN 0-85312-307-1 (Ellis Horwood, Chichester/Halsted 1981) Hbk £25, $80 95, pbk £9 50 *Molecular Enzymology* By Christopher W Wharton and Robert Eisenthal Pp 326 ISBN 0-216-91012-9 (Blackie/Wiley 1981) £19 75, $46 95 *Isoenzymes* By C C Rider and C B Taylor Pp 78 Pbk ISBN 0-421-15640-7 (Chapman & Hall/Methuen 1981) £2 45, $5 95 *Enzyme Kinetics The Steady-state Approach*, 2nd Edn By P C Engel Pp 96 Pbk ISBN 0-412-23970-1 (Chapman & Hall/Methuen 1981) £2 45, $5 95

THERE is hardly a corner of biochemistry or molecular biology — not to mention the cognate biological and chemical sciences — where modern ideas of enzymology have not intruded to good effect The study of enzymes is therefore properly an important part of all degree courses in these subjects, and there continues to be no shortage of authors willing to try their hand at providing the necessary textbooks

Dr Palmer's offering, *Understanding Enzymes,* attempts to cover all of the fascinating aspects of enzymes, from their biosynthesis to their structure, chemical mechanisms and kinetics, from their place in metabolism to their use in medicine and industry It is an heroic task but one of dubious practicability — witness how few authors have followed the trail so comprehensively blazed by Dixon and Webb in their classic first edition of *Enzymes,* published by Longman Thus one should not be surprised that in the volume under review, which is furthermore written by a single author, the coverage is uneven and appears to rely heavily on secondary sources It is sad to record that some of those sources are significantly out of date For example, in the short chapter on protein structure nothing published since 1970 is suggested for further reading, the chapter on biosynthesis of proteins (surely now misplaced in a book on enzymes) has no specialist reference later than 1974, and the chapter on metabolic regulation includes a diagram of the cell that places the cisternae of the rough endoplasmic reticulum in unrestricted communication with the extracellular environment The kinetics of enzymes are dealt with more extensively and sympathetically, and the later sections on technological and medical applications of enzymology cover a wide range of topics Each of the 20 chapters concludes with a useful summary of its contents and most carry a set of problems and answers In what I take to be an otherwise commendable attempt to lower costs, many of the illustrations, though clear, appear to have been left as sketches, which adds a slightly makeshift air to the printed page

All in all, I cannot see this book supplanting the more narrowly based texts on which the undergraduate teaching of enzymology normally rests, though the convenience of a broad range of topics falling within a single volume may commend it to those with less stringent needs

A new contender for a place among the more specialized texts is *Molecular Enzymology* by Wharton and Eisenthal, which assumes a basic knowledge of university biochemistry and chemistry The approach is first to tackle the chemical aspects of catalysis and the properties of enzymes as proteins, to develop ideas in enzyme kinetics and then to deal in some depth with the mechanisms of eight or nine selected enzymes as examples The book concludes with a return to the practical problems of studying enzyme kinetics in the laboratory The treatment is clear and conventional, cuts few corners and makes plain the complementarity of the different methods, it should appeal particularly to those with a background in the physical sciences The bibliography is sound and extensive The authors eschew the usual efforts to represent three-dimensional events on paper in favour of a more descriptive turn-by-turn account of the involvement of amino acid side-chains and other functional groups, an approach with which I do not altogether agree And at the risk of a charge of chauvinism, I suggest that any new text on molecular enzymology that largely neglects protein mobility and dynamics, multienzyme systems and multifunctional proteins cannot be regarded as complete These quibbles apart, I found little to quarrel with and expect the book to find an honourable place in university reading lists

Finally, it is a pleasure to notice two further additions to the series of *Outline Studies in Biology* The first, *Enzyme Kinetics* by Engel, is the second edition of his successful account of steady-state kinetics and their contributions to problem-solving in enzymology The second, *Isoenzymes* by Rider and Taylor, describes the importance of isoenzymes in a broad range of biochemical and medical contexts Both are clear, unpretentious and informative, in accord with the general style of this well-known series □

R N Perham is Reader in Biochemistry of Macromolecular Structures at the University of Cambridge, and a Fellow of St John's College, Cambridge

Spanning a bridge

Peter H.W. Butterworth

Biochemistry, 2nd Edn By Lubert Stryer Pp 949 Hbk ISBN 0-7167-1226-1, pbk ISBN 0-7167-1306-3 (W H Freeman 1981) Hbk $32 95, £24 40, pbk £12 95

THERE are a lot of biochemistry textbooks and, as the borders of the subject continue to be extended, there will be more Some adopt a particular emphasis, others attempt a comprehensive approach to the subject Lubert Stryer's text belongs to the latter genre and it is doubtful whether there will be another which will appeal to the student as strongly as this one does When the first edition appeared, immediate reaction was dominated by the impact of the remarkable illustrations and the succinct text Familiarity with the book brings with it the realization of how ingeniously interdependent these facets are the illustrations are not just attractive but they are required and used to support the concise style of the text At the same time, the student is provided with a graphic framework into which complex concepts often seem to sit with comfort

Every author of a basic biochemistry textbook is faced with two decisions first, at what level to pitch the book and second where to begin and end Stryer seems to aim unashamedly for the "early undergraduate", yet the brevity of the text often belies its depth· the author has a unique ability to expound difficult concepts in a few words As biochemistry constitutes a bridge between physical and biological sciences, the limits are difficult to define and, regardless of how far apart the covers are, it would be impossible to satisfy every whim Here the subject matter is very broadly based and the student is required to accumulate background knowledge of the physical sciences, organic chemistry, cell biology and basic molecular genetics from elsewhere Nevertheless, one of the strengths of this textbook is that it can be appreciated before the background is complete

It is not surprising that this second edition is bigger than the first Neither is it surprising that many of the illustrations in the first edition have been updated and many more have been added, a major effort has been made to get across the concept of the integration of metabolic processes and the text has been extended greatly to accommodate major advances in the subject, particularly in the area of molecular biology

Textbooks for major subjects often present a daunting prospect where they should foster the enthusiasm of the student and provide a realistic challenge. The response to Stryer is generally enthusiastic for a textbook, that is an accolade The only penalties for confronting so massive a task may be that the compact style sometimes excludes subtlety and may not leave room for mystery, the solving of which will provide the material for the next edition. □

Whole chemistry?

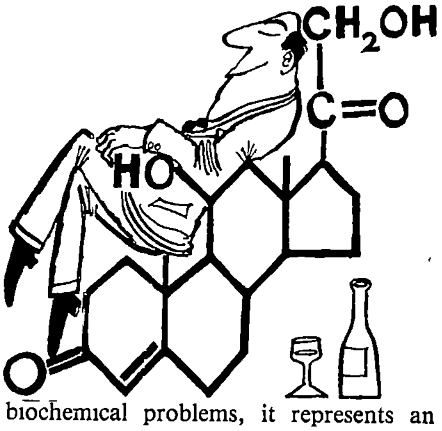
Peter Garratt

Chemistry: An Introduction to General, Organic, and Biological Chemistry By Joanne M Widom and Stuart J Edelstein Pp 799. ISBN 0-7167-1224-5 (W H Freeman 1981) $23 95, £16 60 *Atoms, Molecules, and Life: An Introduction to General, Organic, and Biological Chemistry.* By Michael S Matta and Antony C Wilbraham Pp 721 ISBN 0-8053-9640-3 (Benjamin/Cummings 1981) $22.95, £14 95 *Basic Chemistry of Life* By Milton Toporek Pp 521 Pbk ISBN 0-8016-5002-X (C V Mosby 1981) $7 95, £12

THESE three texts are all directed at North American students of the life sciences and each presupposes little previous exposure to chemistry *Chemistry* and *Atoms, Molecules, and Life* (AML) declare the same interest in their mutual subtitle, while the third, *Basic Chemistry of Life* (BCL), intends to provide a base in chemistry on which the student may build an understanding of the complex processes of life

How are they to do this in less (BCL considerably less) than 1,000 pages? Clearly there must be selection and much of the treatment must be superficial For example, atomic structure is treated by BCL in six pages and no student could have any basis for a further understanding of this subject after reading these Both of the other books treat this topic in more detail, *Chemistry* making a valiant attempt to promote the ideas of quantum mechanics, whereas AML is rather cloudy on this issue Chemical bonding is initially introduced in all three texts by "dot formulae", *Chemistry* and AML developing the subject further to indicate the three-dimensional shape of molecules All of the texts attempt to provide a foundation in physical chemistry, with an emphasis on those topics of interest to biologists Electrolytes and non-electrolytes, solubility, osmosis and pH are all discussed in some detail and illustrated with biological examples, thus, for example, osmosis is described by the effect of changes in extracellular salt concentration on the red blood corpuscles Each book includes a substantial section on organic chemistry, starting with methane and ending with nucleic acids and the genetic code Both AML and BCL have extensive sections on biochemistry

Of the three, BCL has the most medically orientated approach, the least basic chemistry and would require considerable elaboration on the part of the lecturer to give the student any real understanding of the subject It virtually ignores the three-dimensional structure of molecules, and conformation is no where introduced The consequences of three-dimensional structure is an area in which none of these texts is consistently satisfactory, thus although AML shows that the steroids are chair structures, it does not indicate how this influences the stereochemistry of the system, whilst *Chemistry,* though clearly indicating the stereochemistry, does not mention the conformational consequences All of the texts use Haworth formulae for the carbohydrates and although *Chemistry* does introduce the conformational formula for glucose it does not exploit it *Chemistry* as its title suggests, is most clearly directed towards the exposition of this science and, starting from the four elements and ending with global biochemical problems, it represents an impressive attempt to encompass both the essential and the exciting new aspects of the subject within a single volume



The print of all three books is excellent and chemical structures are clearly illustrated, *Chemistry* and AML in two-tone, BCL in monochrome Each provides problems, often with answers, and *Chemistry* has available both a study guide for the student and a manual for the instructor The latter provides answers for those questions without textual answers, test questions and suggestions for demonstrations □

Beyond description

H. Hassall

Basic Mathematics for Biochemists By Athel Cornish-Bowden Pp 137 Hbk ISBN 0-412-23000-3, pbk ISBN 0-412-23010-0 (Chapman & Hall/ Methuen 1981) Hbk £7 95, $17 95, pbk £3 95, $8 95 *Quantitative Problems in Biochemistry,* 6th Edn By Edwin A Dawes Pp 335 ISBN 0-582-44402-0 (Longman 1980) £13 95, $32 *Biochemistry A Problems Approach* By William B Wood *et al* Pp 498 ISBN 0-8053-9840-6 (Benjamin/Cummings 1980) $14 95, £8 95

YEAR after year, with only one or two exceptions, the questions that are done least well in biochemistry examinations are those involving calculations and data assessment Mass panic ripples through the examination rooms and those painstakingly constructed subtleties of the examiners, the diauxic inflections of the growth curve, the sigmoidicity of the Michaelis–Menten graph or the slight curvature of the Yphantis plot, are either missed or explained as experimental error

If these three books have a common objective, as I believe they have, then it is to encourage a more quantitative treatment of the subject However, each is different in its approach and has something unique to offer

Basic Mathematics for Biochemists is the shortest of the three and has a straightforward aim — to rectify deficiencies in the mathematics needed to understand modern biochemistry It begins reassuringly simply (almost too simply in that one is told that 2^2 means $2\times2=4$) but it does go on to cover integral and differential calculus, matrices and partial differentiation The examples used have a biochemical origin and, taken as a whole, one is impressed by just how much information the author has been able to get into a book of 137 pages Clearly, the students who assimilate its contents would have more than enough mathematics to cope with any first-degree course in biochemistry

The book by Edwin Dawes, *Quantitative Problems in Biochemistry*, should need no introduction It is now in its sixth edition and, coincidentally, in its sixth language At the time of the first edition it must surely have been one of the first books of its kind, and the familiar style and content have altered only little over the years despite some changes in format There is a new and useful chapter on membrane bioenergetics, this addition being balanced by a pruning of the text elsewhere With respect to the problems themselves, the book relies heavily on the presumably well-tried and tested finals examination questions from biochemistry degree courses in British universities Few of these, however, have been updated since the last edition

The third book, ***Biochemistry A Problems Approach,*** has a different emphasis to the others It is really a textbook of biochemistry using data assessment and questions to illustrate the principles, rather than just a book of problems with biochemistry as the source of material The approach, while clearly not new, is refreshing It has a chatty, personal style and although Fluhardy Pharmaceuticals, Dr F Holding Munney and Dr Klassik appear (but only briefly) as the bodies faced with problems, the information that is conveyed is no less valuable, who knows, perhaps interest actually is more readily stimulated this way Most of the questions are particularly searching and are balanced by full explanations in the answers The text is comprehensive, ranging in 21 chapters from the "Clinical Characteristics of Living Matter" through to "Recombinant DNA and Genetic Engineering" The treatment is even, and while the book is not meant to replace standard texts such as Lehninger or Stryer, it complements them well and is good value at the price □

H Hassall is Senior Lecturer in the Department of Biochemistry, University of Leeds

Physical chemistry: sugar in the medicine

S.P Spragg

Physical Chemistry With Applications to Biological Systems, 2nd Edn By Raymond Chang Pp 659 Hbk ISBN 0-02-321040-0, pbk ISBN 0-02-978355-0 (Collier Macmillan/Macmillan, New York 1981) Hbk £16 50, $24 95, pbk £10 50 *Physical Chemistry for the Life Sciences,* 2nd Edn By Garry M Barrow Pp 468 ISBN 0-07-003858-9 (McGraw-Hill 1981) $32 95, £18 25

IF ONE consults biological colleagues on what physical concepts they wish they had learnt as students, two extreme views appear there are those who feel they prospered without needing physical chemistry, while others consider that physical chemistry is central to their branch of biology The fact that two extremes are quoted by leaders in their fields confirms the view that some parts of biology can be pursued without an understanding of physical chemical principles, but if one is educating on a broad front then exposure to physical chemistry cannot be a bad thing The question is, should we apply the old adage often used when preparing medicines, namely it must be good because it tastes so bad? Personally, I feel this is not necessary because all principles of physics and biology can be explained attractively and clearly despite their complexity These thoughts were uppermost in my mind when reading the new editions of these two books

Both texts are written in attractive styles and each depends on the working of simple numerical examples to illustrate the principles The contents cover the full range of modern physical chemical ideas, carefully written using the properties of biological molecules for the examples The authors have made considerable improvements over the first editions, mainly by expanding the discussions on thermodynamics Both have rearranged the sequence of topics so that thermodynamics precedes spectroscopy There are also more worked examples in the texts and more problems for the students to tackle (with answers at the end of the book) here Chang differs from Barrow since he has indicated which problems are more advanced Chang has also expanded and moved the mathematical derivations of equations to the end of the appropriate chapters Barrow follows a similar arrangement but unlike Chang he mixes mathematics with the particular applications of the chapter

Both authors have introduced modern views into all topics, and I was particularly pleased to see that they have explained how transition state theory for solutions differs from that for a gas, as well as providing models for diffusion-controlled reaction (Chang is better here) They have also squeezed in descriptions of relaxation methods for studying rates of reactions

As one would expect when comparing the products of two experienced teachers, there are differences in presentation for example, Chang employs more diagrams than Barrow My lasting impression was that Barrow contained more detail than Chang on subjects embraced by hydrodynamics, however, aspects such as wave-mechanics appeared to be more complex in Barrow than Chang Also, I found that Chang's index was not as comprehensive as Barrow's Yet these are details and students are as different as reviewers in their selection of material So, since both books can be recommended, I suggest that prospective buyers dip into each of them before deciding which approach best suits their own personality □

Talking of organic chemistry

John Mann

The Vocabulary of Organic Chemistry By Milton Orchin *et al* Pp 609 ISBN 0-471-04491-1 (Wiley 1980) £18 75, $43 75 *Introduction to Organic Chemistry,* 2nd Edn By Andrew Streitwieser and Clayton H Heathcock Pp 1,258 Hbk ISBN 0-02-418050-5, pbk ISBN 0-02-978310-8 (Collier Macmillan/Macmillan, New York 1981) Hbk £18 95, $28 95, pbk £9 95 *A Guidebook to Mechanism in Organic Chemistry,* 5th Edn By P Sykes ISBN 0-582-44121-8 (Longman 1981) £7 50, $16 95

LINGUISTS have prepared lists of key words and expressions for most languages, but *The Vocabulary of Organic Chemistry* represents the first real attempt to do the same for organic chemistry The intention of the authors was to " identify the fundamental vocabulary of organic chemistry and then to present concise, accurate definitions with examples where appropriate ", and in this they have been eminently successful They define some 1,350 terms and concepts, with entries ranging in length from one line to a page

The compendium is organized into 15 chapters, and commences with a concise introduction to symmetry, followed by a series of mathematical definitions pertaining to wave and quantum mechanics In this second chapter the sections on bonding and orbitals are particularly good Structural aspects of hydrocarbons are covered in Chapter 3, followed by a comprehensive list of organic functional groups, including 35 containing sulphur and 24 containing phosphorus, this chapter thus provides a far better source of such information than any undergraduate textbook on the market

Stereochemistry and conformational analysis appear in Chapter 5, and this compilation of terms is most timely since there is ever-increasing attention paid to the stereochemical aspects of organic chemistry in the research literature In addition, many undergraduates have difficulty distinguishing between terms such as "stereoselective" and "stereospecific", or in understanding the significance of "prochiral hydrogens" and "asymmetric induction", and this chapter provides accurate and easily understood definitions for all of the commonly encountered terms

Polyfunctional compounds are dealt with in Chapter 6, and this includes coverage of sugars and amino acid derivatives Here, I feel too much stress is laid on Fischer projection formulae and there is scant mention of more realistic cyclic structures, also, the amino acid and protein section is too short to be really useful — surprisingly, the terms "enzyme" and "active-site" do not appear Chapter 7 contains a useful collection of terms pertaining to separation techniques, following which there is excellent coverage of ions and electron deficient species This is also timely since there is often confusion over the terms "carbocation", "carbonium ion" and "carbenium ion", and these are all unambiguously defined Essential thermodynamics (Chapter 9) then precedes a classification of organic reaction mechanisms, and this latter chapter should be particularly useful for undergraduates since it also includes 15 pages encompassing topics such as orbital correlation diagrams, the Woodward–Hoffmann rules, and the frontier orbital approach to mechanism It is interesting to note that the same number of pages is given over to these topics in Streitwieser and Heathcock, but the clarity of the coverage is greater in *The Vocabulary*

The outstanding chapter then follows, in which 159 name and type reactions are discussed, with a mechanism given for each of them This would make an excellent 90-page monograph in its own right, it certainly highlights the reason behind the oft-heard lament of the undergraduate "There's too much to learn in organic chemistry" Chapter 12 is entitled "Organometal Chemistry", but contains little of relevance to organometallic chemistry The term "cuprate", for example, does not appear, yet this is much more a part of the vocabulary of modern organic chemistry than are the terms "ligand field theory" and "edge-bridging ligand" Chapter 13 commences with a rather awkward definition of "natural product", and it would perhaps have been better to define the terms "primary metabolite" and "secondary metabolite" This said, however, the chapter has good sections on cofactors and on all of the major biosynthetic pathways and classes of secondary metabolites Finally, there are useful chapters on polymers and industrial processes, mainly those involving fossil fuels

There is perhaps only one major omission in the book (and the authors recognize this), and that is coverage of spectroscopic methods The book is beautifully produced with excellent structures throughout, and includes well-chosen examples and a good index In parts it is reminiscent of a book of revision notes, but this may endear it to undergraduates Overall, it is a unique and very useful reference work, all organic chemists should find something of interest within its pages

Streitwieser and Heathcock have made a number of changes of organization for the second edition of their popular textbook, and the sections on organometallic chemistry, ^{13}C-NMR, and sulphur and phosphorus chemistry have been expanded One omission is the useful appendix on functional group preparations which was popular with undergraduates using the first edition This book and Solomons's *Organic Chemistry* (for review see *Nature* **289**, 721) are two of the most popular organic texts on the market There is little to choose between them, though the two-tone illustrations in Solomons perhaps give it a slight edge

Finally, any book that has reached its fifth edition and been translated into six foreign languages must be rated a success Such is the volume by Peter Sykes — a text that has probably been used by most chemistry undergraduates at one time or another There were major revisions for the fourth edition, and the only important change for this edition is the inclusion of a chapter on linear free energy relationships, which further increases the utility of the book It will be interesting to see if *The Vocabulary* is read as widely and proceeds through as many editions — I see no reason why it should not achieve this distinction □

John Mann is a Lecturer in Organic Chemistry at Reading University

Theory guides, but experiment decides

Gary O. Spessard

Spectral and Chemical Characterization of Organic Compounds A Laboratory Handbook, 2nd Edn By W J Criddle and G P Ellis Pp 115 Hbk ISBN 0-471-27813-0, pbk ISBN 0-471-27812-2 (Wiley 1980) Hbk £13, $30 90, pbk £4 50, $10 70

Operational Organic Chemistry A Laboratory Course By John W Lehman Pp 671 ISBN 0-205-07146-5 (Allyn & Bacon 1981) $24 95, £9 95

THE task of introducing students to the experimental side of organic chemistry can be an awesomely difficult one, not only because of the wide variety of vocational goals and interests one encounters, but also because there are so many aspects of the subject which ought to be considered in any laboratory course These aspects essentially centre on the synthesis and characterization of compounds Criddle and Ellis in their *Spectral and Chemical Characterization of Organic Compounds* address the latter concern, while Lehman's *Operational Organic Chemistry* endeavours to cover both synthesis and characterization

The second edition of Criddle and Ellis's text is only slightly modified from the first which appeared five years ago For example, small additions and modifications appear in the notes explaining the chemical bases for the functional group tests in Chapter 2, in the section on interpretation of spectral data in Chapter 3 and in Chapter 5 where extensive tables of physical data are found Using a step-wise approach, hints on how to interpret the results of chemical and spectral tests in addition to compendia of physical data on compounds and their derivatives are presented in a compact style While concise and informative, the book must be supplemented, as the authors point out, with more comprehensive works on the chemical bases of function group tests, the chemistry of derivatization and practical spectroscopy No mention is made of the use of chromatography in analysing and separating mixtures, and only the briefest reference is given to safety in regard to handling reagents (often quite toxic) typical of the organic "qual" laboratory As long as access to more complete sources of information is possible, this text can usefully serve as a guide for students involved in the qualitative analysis segment of a regular organic laboratory course or in one concerned with characterization alone

Operational Organic Chemistry is another addition to the spate of laboratory manuals currently available The author suggests that working in the laboratory involves performance of a series of operations such as filtration, extraction or spectral analysis from the start to the finish of an experiment The student should gain an appreciation of these operations, described separately in the text, by learning to perform them within a series of preparative and analytical experiments Superb background essays are included which encourage student involvement in the chemistry behind each experiment by suggesting roles (such as working as a chemist for a perfume manufacturer) students may assume while working in the laboratory I especially like the emphasis on pre-laboratory preparation whereby students are directed to read certain text sections and to complete specific exercises *before* working on an experiment

The menu of practical exercises includes many of the "old reliables" as well as several new ones, suggestions for additional work are provided in the form of "minilabs" and "experimental variations" Potentially attractive to students with biologically-related interests is the extensive use of natural products because, as Lehman states, "they often cost less, smell nicer, and are more pleasant to work with than purely synthetic analogs" Safety is treated thoroughly and conscientiously throughout the book I do have reservations, however, about the pedagogical benefits to be gained from the synthesis of azo dyes or the use of toluene-2,4-diisocyanate for polyurethane synthesis in light of the chemical hazards involved The sections in the text on spectral techniques are adequate but not as good as those found in *Introduction to Organic Laboratory Techniques* by Pavia *et al* Nonetheless, in spite of these minor criticisms, the book is rather unique in its approach and one which is well worth considering for adoption ☐

Gary O Spessard is Associate Professor of Chemistry at St Olaf College, Northfield, Minnesota

Atkins anew

Maurice Rigby

Physical Chemistry, 2nd Edn By P W Atkins Pp 1,095 Hbk ISBN 0-19-855150-9, pbk ISBN 0-19-866151-7 (Oxford University Press/W H Freeman 1982) Hbk £25, $29 95; pbk £10 95 *Physical Chemistry* By J Philip Bromberg Pp 882 Hbk ISBN 0-205-06572-4, pbk ISBN 0-205-06867-7 (Allyn & Bacon 1980) Hbk $27 95, £22 25, pbk £9 95

In the past few years several candidates have presented themselves as potential successors to established and widely-used general textbooks of physical chemistry such as W J Moore's *Physical Chemistry* (Longmans/Prentice-Hall, 1972) and G M Barrow's *Physical Chemistry* (McGraw-Hill, 1979) One of the most successful has been that of P W Atkins, first published in 1978 and rapidly followed by a corrected reprint, which now appears in a second edition The first edition of this work was notable for a generally well-judged level of coverage of most aspects of the subject, and for the fresh and accessible presentation of difficult concepts

In the new edition these desirable qualities have been retained, and some omissions and slight imbalances have been rectified There is a completely new chapter dealing with macromolecules — a subject sadly neglected in the first edition — and many figures have been changed, with the introduction of computer graphics In addition the treatment of chemical bonding, which was previously rather brief, has been amplified, and the introductory material on statistical mechanics has been simplified Comparisons between corresponding sections of the two editions reveal numerous small changes, supporting the claim that all sections of the book have been reconsidered My overall impression is of an excellent textbook which has become even better, and which seems sure to enjoy continued popularity in the future Who, in any case, could resist a physical chemistry book which considers (p 103) the musical implications of a dying ocarina player?

Against such competition, yet another general textbook will have to be very good if it is to wean readers away from the established sources J Philip Bromberg has taken up this challenge but has not completely persuaded me The author claims to have aimed to present the subject at the mid-college level, and has consciously reframed from producing an encyclopaedia of physical chemistry For this ambition he should be congratulated — at least one recent text has seemed to be aimed more at the readership of *Annual Reviews of Physical Chemistry* than at an undergraduate audience

The book follows a fairly well-worn path from the gas laws through thermodynamics, statistical mechanics, quantum mechanics and reaction kinetics, giving quite formal and detailed coverage of the necessary theoretical development though not neglecting to draw attention to the practical relevance of the subject, where appropriate It is liberally interspersed with short biographical sketches of notable scientists, which may help to give students some feeling for the development of the subject The overall balance appears to emphasize thermodynamics and quantum mechanics, which are respectively developed classically and axiomatically Electrochemistry and surface chemistry appear as applications of thermodynamics, and there is no mention of catalysis or of non-equilibrium aspects of electrochemistry The treatment of reaction kinetics is short and repeatedly uses a rather laborious analogy with molecular effusion, the merits of which are not immediately apparent In short, although the book has some attractive qualities, and I shall try to arrange for a copy to be available in our college library, I do not believe that it will replace its rivals in a majority of chemistry departments ☐

NEW

GENETICS AND PROBABILITY IN ANIMAL BREEDING EXPERIMENTS

EARL L. GREEN

Director Emeritus of The Jackson Laboratory, Bar Harbor, Maine
Editor, Biology of the Laboratory Mouse, Second Edition

Contents

Probability and Statistics, Segregation of Alleles, Assortment of Non-Alleles, Linkage, Recombination and Mapping, Mating Systems, Appendix 1 – Mean and Variance of a Binomial Distribution, Appendix 2 – Estimation of a Parameter by the Method of Maximum Likelihood, Appendix 3 – Extensions of the Method of Maximum Likelihood, Appendix 4 – Comparative Efficiency of Matings for Detecting and Measuring Linkage, Appendix 5 – the Fibonacci Sequence, Appendix 6 – Systems of Mating, Appendix 7 – Numbers of Mating and Numbers of Mice per Mating, Appendix 8 – Nomenclature, Appendix 9 – Record Keeping, Appendix 10 – Mouseroom Layout and Procedures, Glossary of Signs, Literature Cited, Index

This book is a primer and reference on probability, segregation, assortment, linkage and mating systems for biomedical scientists who breed and use genetically defined laboratory animals for research

It is organised so as to be useful to 'novices' and 'experts' alike The former will find an orderly development of the probability aspects of transmission tests, segregation analysis, allelism tests, independence tests, linkage analysis and mapping They will see how to design genetic experiments to yield data which can be analysed and they will also find a clear exposition of the theoretical consequences of various breeding systems which will enable them to make rational choices as to the kinds of animals to use in their own research

Experts will find that the most frequently used formulae needed for estimating various genetic parameters and their random sampling variances are assembled in tables or are clearly set forth in the text and that the extensive table of contents and detailed index will enable them to find the necessary formulae quickly

ARTICLES

Convective growth rates of equatorial features in the jovian atmosphere

Garry E. Hunt, Jan-Peter Müller & Philip Gee

Laboratory for Planetary Atmospheres, Department of Physics and Astronomy, University College London, London WC1E 6BT, UK

The first results of measurements of divergence and vertical velocity of cloud features in the atmosphere of Jupiter are presented from analyses of Voyager images, performed using the interactive planetary imaging processing system at University College London Active equatorial plumes are found to have typical divergences of $\sim(1\text{–}2)\times10^{-5}\,s^{-1}$, *and vertical velocities of* $20\text{–}40$ *cm* s^{-1}, *during the observational periods examined These plumes are considerably more active than the bright albedo features in the turbulent regions of the jovian north and south equatorial belts*

OBSERVATIONS made by the Voyager imaging and IRIS instruments of the equatorial region of Jupiter have shown details of trains of white plume features moving in a westerly direction, with cloud material spreading out behind small bright centres of rising motion[1] The plume centres are positioned at about 9°N A total of 13 features were seen at the time of the Voyager 1 encounter, with four active centres[2] Four months later, in July 1979, at the time of the Voyager 2 encounter, the structure of this region had changed so that only 11 features were evident and three had active centres[3]

It has been suggested[1] that the plumes are mesoscale convective structures, formed as a travelling wave disturbance in a manner similar to that found in the Inter-Tropical Convergence Zone (ITCZ) of the Earth's atmosphere Indeed, there are indications[1,4] that these active plumes cause a major perturbation to the structure of the atmosphere from the cloud tops, throughout the troposphere and into the lower stratosphere This is a distance of at least 20 km, which is approximately the atmospheric scale height for Jupiter at this pressure level A major disturbance to the atmosphere of this type must be associated with rapid vertical motion in the atmospheric levels beneath the visible clouds themselves Furthermore, these plumes will have a significant effect on the energy budget of the equatorial region, through the mass transport of material associated with their morphological changes

We estimate in this article, for the first time, the divergence characteristics of these plumes using Voyager images analysed on the University College London (UCL) interactive planetary image processing system (IPIPS)[5] From this information, we calculate the vertical velocities which relate to the observed changes in the plume head structures These new measurements provide valuable insight into the development and variations in these mesoscale structures, which have an important role in the equatorial meteorology of the jovian atmosphere

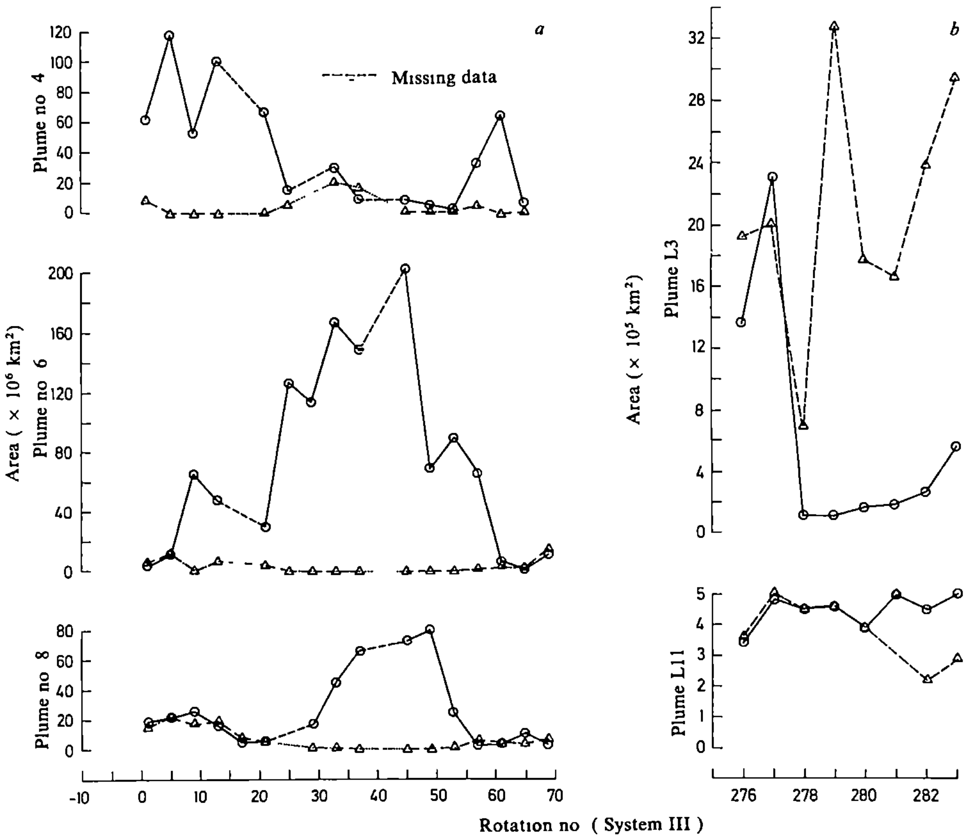

Fig. 1 The variation in the convective area of the three active plumes observed by Voyager 1(*a*) and for the two active plumes observed by Voyager 2(*b*) as a function of the rotation number for a single threshold level of brightness digital number (DN) = 185 (a, Δ) (b, Δ DN = 195) and the 90% contour level (O) of instantaneous maximum brightness

0028-0836/82/060491—04$01 00

Observations and data analysis

Observations obtained by the Voyager imaging system every 72° long (System III) during the observatory phases of each spacecraft encounter were used as a basis for this study The measurements for this investigation were taken from blue filter Mercator projection mosaics made from rotation periods 1–70 (6 January–2 February 1979) for Voyager 1, when the spatial resolution was 438 km per pixel with a temporal resolution of four rotation periods The rotation periods covered by Voyager 2 were 276–283 (24–28 May 1979), for which the spatial resolution was 138 46 km per line pixel, and the temporal resolution was every rotation period The images used were violet filter cylindrical map projection mosaics The rotation period reference system refers to the number of jovian days in System III longitude beginning with the first observations by the Voyager 1 spacecraft and continuing throughout the mission, concluding with the final measurements by Voyager 2 This is therefore a convenient scheme to represent the time variation of the observations during the 1979 Jupiter encounter

To remove the effects of the spacecraft viewing geometry and the illumination conditions, the full disk images were first radiometrically decalibrated and then map projected for the Voyager 2 observations The differences between these projections is negligible in the equatorial regions of Jupiter, where our analyses are performed The Sun angle illumination effects were removed at the Jet Propulsion Laboratory from these images using a Lambert function for Voyager 1, and a Hapke function for the Voyager 2 images (see, for example, ref 6) Then these photometrically decalibrated images were constructed into a mosaic to form sequential image maps of the entire planet for a full rotational period

With the observations in this format, we can carry out the meteorological investigations using the analysis techniques developed and carried out at UCL The bright albedo structures in the equatorial region certainly represent mesoscale convective structure[1] In the terrestrial atmosphere, Sikdar *et al*[7] and Sikdar and Suomi[8] have shown that the time variation of the visible brightness of a cloud anvil may be used to derive cloud-top divergences

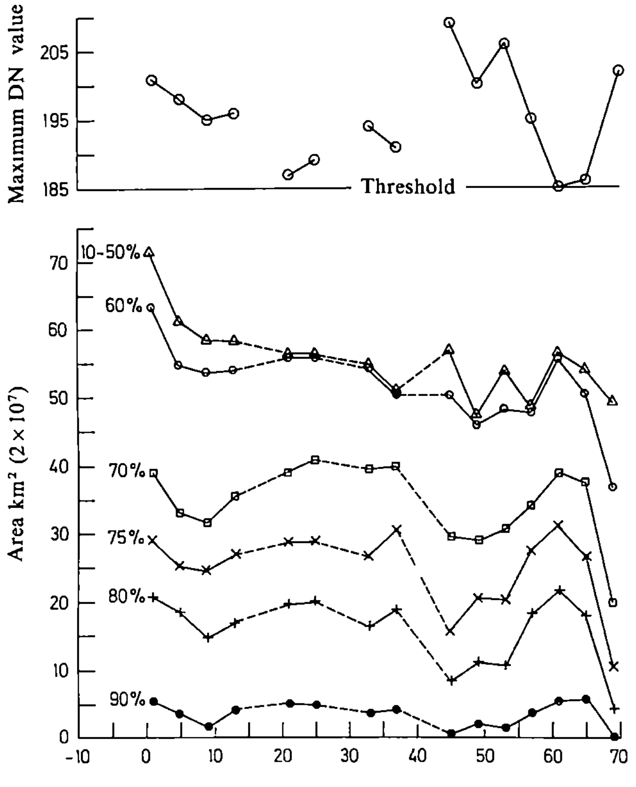

Fig. 2 The variation in the area of the bright albedo features in the turbulent region of the north equatorial belt (NEB) of Jupiter Individual contours are shown separately for areas calculated at 10–90% of the maximum brightness level for each rotation period, together with the value of the instantaneous maximum DN level

From the continuity equation, the rate of change of horizontal area, *A*, which represents the cross-section of the visible cloud system, is equal to the horizontal divergence This may be written as

$$\frac{1}{A}\frac{\mathrm{d}A}{\mathrm{d}T} = \mathrm{div_h}\,V \qquad (1)$$

Where $\mathrm{div_h}\,V = \partial u/\partial x + \partial v/\partial y$, and u, v are the x, y components of velocity[9,10] Then the time and area averaged divergence, $\mathrm{div_h}\,V$, is given by the expression

$$\frac{\ln(A_2/A_1)}{\Delta t} = \mathrm{div_h}\,V \quad \mathrm{s}^{-1} \qquad (2)$$

where the area of the layer of outflow has increased from A_1 to A_2 during the time interval $\Delta t = t_2 - t_1$

If we now use a scale analysis argument (see ref 10) and assume that the vertical motion in the layer of outflow takes place over less than or equal to a scale height *D*, then the vertical velocity required to produce the observed divergence field is given by

$$w \leq D\,\mathrm{div_h}\,V = \frac{D\ln(A_2/A_1)}{\Delta t} \quad \mathrm{ms}^{-1} \qquad (3)$$

We consider the measurement of the time rate of change of area of the ammonia cirrus anvil above the region of the updraft to be representative of the layer of outflow for the convective storm system and subsequently referred to as the 'convective area' Hunt *et al*[1] suggest that the main driving mechanism for the equatorial plume systems is provided by the latent heat released in the layers of water clouds that are thought to exist up to three scale heights beneath the visible ammonia clouds The depth of the total convective structure would therefore need to be a factor of two larger than terrestrial tropical cyclones

Fraedrich *et al*[9] showed that for tropical cloud clusters, the area of the convectively active region of a cloud system may be calculated using two methods Either (1) the brightness threshold remains constant throughout the sequence, or (2) the brightness threshold varies relative to the instantaneous maximum brightness in the cloud cluster We have examined these two procedures for the Voyager plumes using the IPIPS image processing facility[5] and find that procedure (1) is unsuitable for these studies Thus we have used procedure (2) to obtain divergence and vertical velocity estimates, as it was demonstrated to be more sensitive to the changes of the area of the convective core and not to gross brightness variations which were a function of the photometric decalibration, the mosaic image 'overlap' area of the errors inherent in the radiometric decalibration (see ref 6)

Results

We have studied the three active convective structures visible in the equatorial zone in the Voyager 1 sequence Figure 1*a* shows the considerable variation in the growth and dissipation of these active features Over the 70 rotation periods observed, two of these features changed in area by a factor of 40 The two sets of curves refer to the calculated areas for a threshold of 185 (on a maximum grey scale of 255) and the 90% of maximum brightness contour level The 90% contour level clearly shows the most active region of the convective structure, while the threshold reflects only gross brightness changes There were apparently less active plumes observed during the time period studied in the second Voyager encounter[1] We have measured two active plumes, shown in Fig 1*b*, and the 90% level seems again more representative of the areal changes in the convective area of these features than the threshold of 195 Once more, the rapid increase and decrease in the active areas is noticeable on relatively short time scales From the resolution of the images

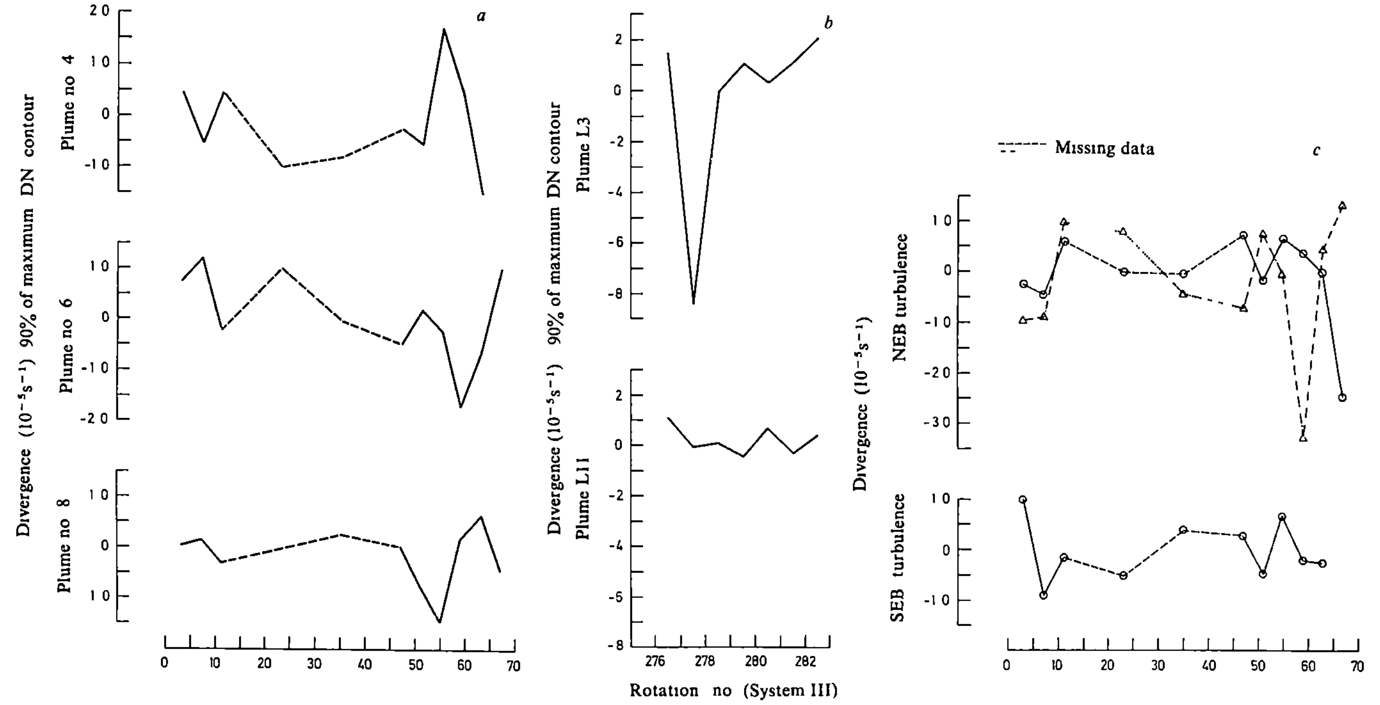

Fig. 3 The variation of divergence (10^{-5} s^{-1}) as a function of rotation number for *a*, the three active plumes observed by Voyager 1, *b*, the two active plumes observed by Voyager 2, *c*, the bright albedo features in the turbulent regions of north and south equatorial belts ○, 90% maximum DN contour, △, DN = 185 contour

used in this study the smallest area that may be resolved corresponds to ~4×10^4 km^2. This is ~10^{-2}% of the area of a whole plume. Smaller scale structure, such as the core of the 'convective area' cannot be resolved with this data set.

There are also regions of rapidly changing small-scale bright albedo features in the north and south equatorial belts of Jupiter (see, for example, refs 2, 3). To determine whether the variations of these features have any similarity with the plumes, we have analysed them using the same procedures. Figure 2 illustrates the changes in area of these active regions of the north equatorial belt. We show the variation in area for various percentages of the brightness maximum of the region along with the maximum brightness and the threshold level of 185 used. Although the actual areas are similar in magnitude (~10^7 km^2 for the 90% level) to the plume feature, there is a smaller variation in the area of the north equatorial belt. A similar situation is apparent from our analysis of the features in the south equatorial belt.

These changes in the convective areas of the plumes and features in the north and south equatorial belts may then be used to calculate the divergence from equation (2). Figure 3*a* shows the divergence variation for the three active plumes observed by Voyager 1. The maximum divergences are not in phase with one another and their values are not identical: the maximum value for plume 4 is 1.75×10^{-5} s^{-1} at rotation 55, while for plumes 6 and 8 the values are 1.25×10^{-5} s^{-1} at rotation 67, and 0.7×10^{-5} s^{-1} at rotation 63, respectively. The features observed during the Voyager 2 encounter have divergences of about $(1–2)\times10^{-5}$ s^{-1}. On rotation 1, the 'active' centres of plumes 4, 6 and 8 were located at approximately 138°, 197° and 267° long (System III). On rotation 276 the 'active' centres of plumes L3 and L11 were located at 317° and 131° long (System III).

The negative values of divergence which appear in Fig 3*a*, do not correspond to convergences, but to evaporation at the edges of the plume heads.

The analyses by Hunt *et al*[1] and Conrath *et al*[4] have shown that the plumes are mesoscale disturbances that cause a significant perturbation to the vertical temperature structure throughout the jovian troposphere above the visible clouds and into the lower stratosphere. It is possible that the entire region from 50 to 1,000 mbar may contain clouds of ammonia condensates of varying opacities as Sato and Hansen[11] suggest. The clouds which constitute the plumes, would therefore be contained in a larger portion of this region and may extend more than 40 km from the base of the water cloud to the base levels of the ammonia cirrus anvil. The anvil cloud itself will extend at least a further 20 km which is consistent with jovian cloud models[12]. The outflow from the convective disturbance which we see in the Voyager images as the plume tail is more than 500 times the possible vertical depth of the plumes. The jovian plume then closely resembles the terrestrial large scale convective cloud system, but on a much greater scale.

We therefore scale the measured divergence values by the minimum depth of the convective flow, which we estimate to be about 20 km. With this value, we see that the larger vertical velocities are about 20–40 cm^{-1}. These values represent the vertical motion of an area of the plumes whose cross-section is several thousand kilometres and certainly consistent with the values found in terrestrial convective storms (see for example, ref 10). Note that Adler and Fenn (see ref 12) showed that the maximum updraft may be as much as two orders of magnitude greater than that implied by the scaling argument used here. Our derived values may therefore be an underestimate of the true vertical motions. Furthermore, the magnitude of vertical motions, associated with individual cloud turrets in the convective area, would certainly be large enough to create 'horizontal' gravity waves downstream of the convective activity, as was observed[13] in the tail of one of these active plumes.

The major driving mechanism for these features must come from the latent heat released by condensation of water in the cloud layer, located some three density scale heights beneath the visible convective area[12]. The modelled top of the ice cloud was shown to be at a temperature of around 210 K (ref 12). Hunten *et al*[14] have modelled the observed IR opacities and produced a vertical temperature profile which shows that at this temperature the pressure is at ~2.5 bar. In addition, their calculations show that the dominant heating up to the 2 bar level is solar. At higher pressures, internal heating is the only possible source for triggering convective activity. It has been suggested[15] that only small amounts of internal heating anomalies are required to produce vertically propagating gravity waves which may trigger convective activity This may lead to further sub-cloud convergence due to the convective environment initiating in a wave-mean flow interaction This could then provide the necessary criteria for setting up an equatorially travelling-wave disturbance

Conclusions

We have measured for the first time the growth rate of convective cloud features in the equatorial region of the jovian atmosphere The equatorial plumes seem to possess many of the characteristics of the large-scale convective cloud systems observed in the Earth's tropical regions The vertical velocities associated with these features are similar in magnitude to the terrestrial systems However, the jovian clouds occupy a much larger spatial scale

The disturbances seen in the turbulent regions of the north and south equatorial belts are much less active than the equatorial features It is possible therefore that these features are shallower in this region of the atmosphere Furthermore, this situation may also be related to their shorter lifetime

In both situations, the convective activity seems to be generated from travelling wave disturbances in the jovian atmosphere The intensity of the convection in the equatorial plumes and the magnitude of the divergence and vertical velocities derived for these features is consistent with them being generated by large-scale convergence in deep cloud layers beneath the visible surface of the planet

Glacial to interglacial contrasts in the northern Indian Ocean

J. C. Duplessy
Centre des Faibles Radioactivités, Laboratoire mixte CNRS–CEA, 91190 Gif sur Yvette, France

Differences between the ^{18}O/^{16}O ratios of planktonic foraminifera deposited during the last glacial maximum, about 18,000 yr ago, and those deposited during the Holocene show that in the Indian Ocean, the south-west monsoon was weaker than today but that the north-east monsoon was stronger The upwelling observed in modern conditions along the southern coast of Arabia had disappeared because of the low speed of the southwestern winds during glacial summers. The reduction in rainfall and runoff over the continent caused a reduction of the salinity gradient in the Bay of Bengal and along the western coast of India Increased precipitation fell on the sea south of 10° N, while strong evaporation over the northernmost Arabian Sea produced an enhanced salinity gradient in that area

THE seasonally varying monsoon circulations associated with the annual heating and cooling of the Asian continent are important aspects of the general circulation of the atmosphere During the summer, as solar radiation warms the land and the ocean, the overlaying air is heated by conduction and expands because the land heats faster than the ocean The warmer air over the land rises and is replaced by denser ocean air which carries moisture evaporated from the ocean When the moist air moves inland, it too rises and its water vapour condenses causing heavy rain over the continent The circulation of the monsoon winds is deflected by the rotation of the Earth through the Coriolis force, which deflects winds to the right in the Northern Hemisphere so that summer monsoon winds essentially blow from the south-west With the onset of winter, both the land and the ocean lose heat by radiation to space The greater heat capacity of the ocean results in a greater cooling over the continent than over the ocean so that dry winds blow from the continent to the ocean Due to the rotation of the Earth, winter winds blow from the north-east The north-east monsoon continues in a steady state until solar heating of the spring dissipates the temperature gradient that powers the winter monsoon

This monsoon climate that prevails over the northern Indian Ocean produces large salinity gradients in surface waters, although sea-surface temperatures, which are largely determined by the amount of radiation received from the Sun, are much less variable As freshwater is depleted in the heavy isotopes of oxygen compared with seawater, the modern salinity pattern for surface waters is closely matched by the oxygen isotopic composition of recent Holocene calcitic tests of surface dwelling foraminifera such as *Globigerinoides ruber* During the

last ice age, which reached its maximum ~18,000 yr ago[1,2] only small changes in the northern Indian Ocean temperature pattern have been recorded[2–4], but important variations in the precipitation pattern over the surrounding continents have been evident[5–7]. I now reconstruct the major hydrological trends, essentially that of salinity, in the northern Indian Ocean during the last glacial maximum by comparing maps of the oxygen isotopic composition (δ^{18}O) of planktonic foraminifera that lived in surficial waters during the Holocene and at the last glacial maximum.

Modern hydrological setting

Today, the northern Indian Ocean is characterized by a strong salinity contrast between its two major basins, the Arabian Sea and the Bay of Bengal[8]. The heavy summer monsoon rain above the south-west Asian continent is collected by major rivers (Ganges, Brahmaputra, Irrawaddy and Salween) which drain into the northern end of the Bay of Bengal and the Andaman Sea. Because this area receives a large excess of direct precipitation, its low salinity surface water contrasts sharply with high salinity surface water of the Arabian Sea where evaporation is high (Fig. 1*a*). Due to this general pattern of evaporation–precipitation, isohalynes show generally east–west trends, but along the western coast of India they turn north–south. This local pattern is due to two major freshwater inflows[9]. The first is the heavy rain which falls above the western flank of the Dekkan Mountains during the summer monsoon and is drained to the sea along the coast of Kerala, south-west India, by a dense net of mountain rivers. The second is the transport of low-salinity water from the Bay of Bengal into the eastern Arabian Sea during the north-east monsoon. Thus low-salinity water is found along the coast from July to February[10], and means that the general pattern of mean annual sea-surface salinity in the northern Indian Ocean is closely related to the monsoon circulations.

The sea-surface temperature gradient is much weaker than that of salinity. During the north-east monsoon, a rather gentle phenomenon, the oceanic circulation is only moderately strong[8]. No striking upwelling areas develop and the sea-surface temperature pattern is essentially zonal, with temperature decreasing progressively towards the north[10]. The more vigorous atmospheric and oceanic circulation during the south-west monsoon causes intense upwelling along the coast of Arabia. This upwelling which brings cool, nutrient-rich deep water in the surface, is characterized by a strong drop of sea-surface temperature which falls below 24 °C in the proximity of the coast of Arabia north of 15° N (ref. 11). This produces a strong temperature gradient perpendicular to that coast. As the upwelling is restricted to the summer period, when the winds blow parallel to the coast, the sea-surface temperature gradient linked with the coastal upwelling is another good indicator of the intensity of the south-west monsoon circulation.

Isotopic strategy

The modern hydrological setting of the northern Indian Ocean is closely related to the monsoon. Therefore, the reconstruction of historical geographical variations of sea-surface salinity and upwelling areas should be an effective way of estimating the intensity of the south-west monsoon in climatic conditions different from those of today. Present palaeooceanographic reconstructions of the Arabian Sea and the Bay of Bengal essentially deal with sea-surface temperature[2–4], which show upwelling variations during the last climatic cycle[2,3,12], but past sea-surface salinity has been estimated along only one north–south transect in the Bay of Bengal[13]. We have mapped the geographical distribution of the oxygen isotopic composition (δ^{18}O) of planktonic foraminifera that lived in surficial waters during Holocene time and at the last glacial maximum. Planktonic foraminiferal δ^{18}O is controlled in a complex way by sea-surface water δ^{18}O and temperature[14–17]. In upwelling areas, the δ^{18}O variations should mainly reflect the sea surface temperature gradient, the slope of which is linked to the intensity of upwelling and the wind strength. Except for the Arabian coast, upwelling is not significant in the northern Indian Ocean, and temperature gradients are small in modern conditions[10], and have remained small during the Upper Quaternary while the global climate varied[1,2,4]. Hence geographical variations of planktonic foraminifera δ^{18}O in the northern Indian Ocean should essentially reflect the sea-surface water δ^{18}O.

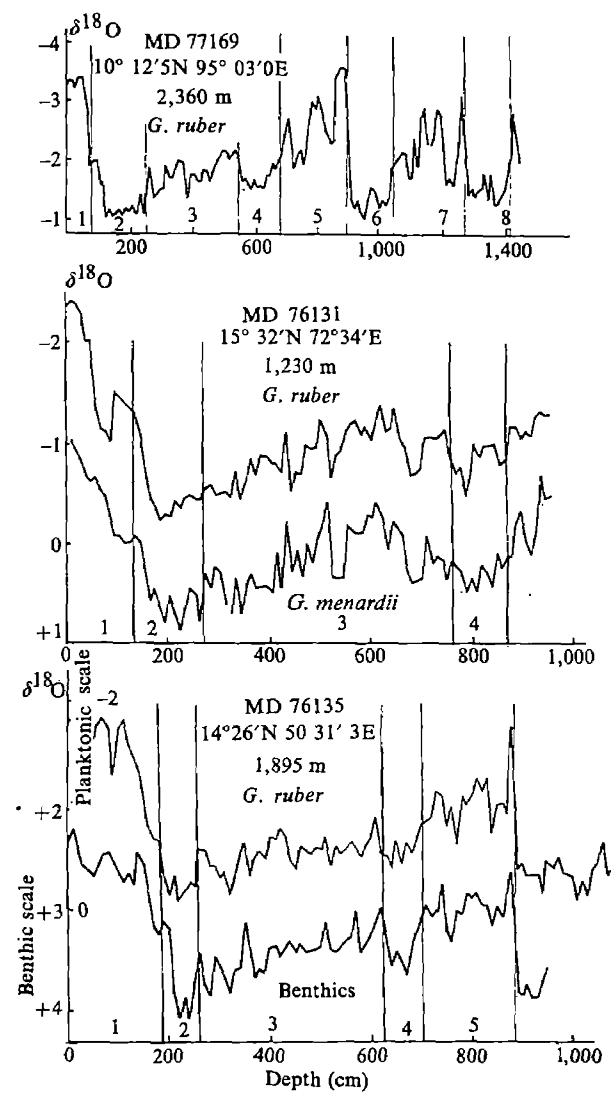

Fig. 2 Isotopic record of three cores from the northern Indian Ocean: cores MD 77169 (the Andaman Sea), MD 76131 (the Eastern Arabian Sea) and MD76135 (the Gulf of Aden). Odd and even numbers refer to interglacial and glacial stages as defined by Emiliani[27]. *Globorotalia menardii* is a deep foraminifera which, like benthic foraminifera, is not sensitive to the variations of temperature and salinity in the euphotic zone[14].

Surface waters of the oceans have widely different δ^{18}O which are related to salinity[17–20]. In general, tropical waters have a high salinity and are isotopically heavy, owing to the preferential loss of the isotopically light molecule $H_2{}^{16}O$ and the concentration of the isotopically heavy molecule $H_2{}^{18}O$ in the residual sea-surface water. In the atmosphere, cooling of the vapour causes condensation and precipitation. The oxygen isotopic composition of the first condensed rain will be enriched in ^{18}O compared with the atmospheric water vapour, but its δ^{18}O will be slightly lower than that of surficial sea water[21] due to the low condensation temperature and the relative humidity of the atmosphere which is far from saturation[18]. A further ^{18}O depletion in rain falling over the continent can be explained by considering the formation of precipitation as a Rayleigh process, whereby with continuing precipitation from an air mass the remaining water vapour is progressively depleted in ^{18}O (refs 18, 21).

Hence a linear relationship between sea-surface salinity and $\delta^{18}O$ is observed locally. The gradient of the isotope–salinity relationship depends on the mode of formation of the freshwater arriving into the sea: it is small for a first condensation rain falling over the ocean, whereas it is much larger for the outflow of rivers fed by rain falling over cold mountains[18,21,22]. This slope can be determined experimentally in modern conditions, but we have no way to determine it accurately in the past. Hence I consider only a qualitative discussion.

Data base

The oxygen isotopic composition of the foraminiferal species *G. ruber* was measured in 41 piston cores and 36 core-top samples from the Arabian Sea, the Bay of Bengal and the Andaman Sea, of which 12 are from ref. 3. This species was chosen because it secretes most of its carbonate in the surficial mixed layer[17]. About 30–40 shells were separated for each stable isotope analysis. The shells were roasted under vacuum at 50 °C and evolved CO_2 was analysed in a VG Micromass mass spectrometer[23,24].

Downcore analyses were performed every 10 cm to obtain an accurate stratigraphy for the deep-sea sediments. Isotopic stratigraphy is based on the demonstration that downcore variations in the oxygen isotope composition of foraminiferal shells reflect primarily variations in the continental ice volume[23,25,26]. Because these variations are synchronous within the mixing time of the world ocean, sediment deposited during the last glacial maximum can be recognized by the youngest $\delta^{18}O$ maximum in the isotopic record. Variations in local factors, such as temperature, evaporation–precipitation pattern and continental runoff, also affect the isotopic composition of planktonic foraminifera living in the most surficial water. This is the case for *G. ruber*. The pattern of isotopic changes in the northern Indian Ocean for this species was therefore checked to show that it was similar to that of the rest of the world ocean. First, for a few cores, downcore analyses were extended beyond the last climatic cycle. The isotopic records closely correlate with the standard sequence of stages defined by Emiliani[27], an indication that local effects in the northern Indian Ocean did not modify the generalized pattern of isotopic change during the Upper Quaternary (Fig. 2). Second, the isotopic record of *G. ruber* was compared with that of benthic or deep dwelling planktonic foraminifera. Although the amplitude of the *G. ruber* record was generally much larger than that of deep species (Fig. 2), the general trends of the records are similar. Therefore the last glacial maximum level in

The oxygen isotopic composition of *G. ruber* for Holocene and glacial times are reported as $\delta^{18}O$ versus PDB.

† Value taken from ref. 2.

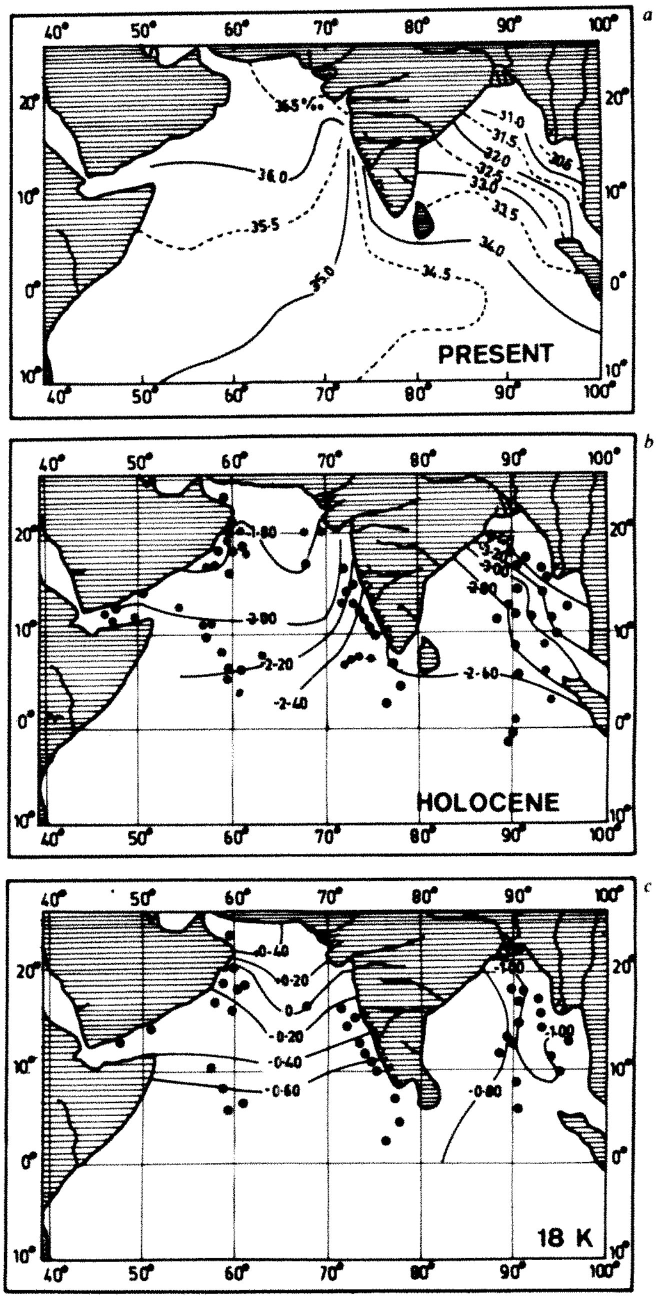

Fig. 3 Amplitude of $\delta^{18}O$ variations between the last glacial maximum (Isotope Stage 2) and the Holocene (Stage 1).

the sediment cores can be recognized from the planktonic record as well as from the benthic record.

The synchrony of the Indian Ocean isotopic records was recently checked by ^{14}C dating in six cores[2]. The mean age of the maximum glaciation was $\sim$18,000 yr BP with a standard deviation of 1,500 yr. If the climate and the global ice volume were changing rapidly around 18,000 yr BP, there might be serious inaccuracies in the estimates of the $\delta^{18}O$ value at the last glacial maximum. However, high sedimentation rate deep sea cores suggest that the interval 22,000–15,000 yr BP was characterized by relatively stable conditions[24,27–29].

Holocene reconstruction

The data used to construct the Holocene map (Fig. 1*b*) represent the mean value of Holocene levels for each piston core: digital values are reported in Table 1. In four cores, the uppermost levels show evidence of strong dissolution and a correlative $\delta^{18}O$ increase during the end of the Holocene. Such an increase can be explained by the preferential removal through dissolution of fragile individuals[31,32] whose tests were not overlain by a thick calcitic crust deposited during gametogenesis. As gametogenetic calcification occurs at great depth, below the euphotic zone, and in cold water, the tests under the thicker crust are also isotopically heavier[33]. Hence the fossil population remaining in a deeply dissolved sediment is isotopically heavier than the undissolved fauna. Such a $\delta^{18}O$ increase is not evidenced in other nearby cores that are free from dissolution. Therefore the enriched levels were rejected in calculating the mean Holocene $\delta^{18}O$ value. Core top samples were also used to complete the Holocene map but stratigraphical control for those samples is not available and some scatter is inevitable in such a data set. Nine core-tops were rejected because their $\delta^{18}O$ did not fall within the range of values for nearby core that were verified by oxygen isotope stratigraphy. These samples were collected from the 90° E ridge and from the central Arabian Sea, where sedimentation rates are very low, and probably did not represent the most recent sediment. Consequently, iso-$\delta^{18}O$ map for the Holocene (Fig. 1*b*) is based on measurements of *G. ruber* $\delta^{18}O$ from 68 locations. The standard deviation of a single analysis is 0.07‰ (ref. 24). Although most $\delta^{18}O$ values were calculated as mean value of several intervals, variations of 0.1‰ were not considered significant and iso-$\delta^{18}O$ lines have been drawn separated by 0.2‰.

The map of *G. ruber* $\delta^{18}O$ in the northern Indian Ocean during the Holocene (Fig. 1*b*) reveals the major features of the mean annual salinity in modern conditions. In the Bay of Bengal, the $\delta^{18}O$ values decrease progressively towards the mouth of the Ganges, Brahmaputra, Irrawaddy, Salween River system, clearly reflecting the salinity pattern. The low-salinity waters along the southwestern coast of India are also well recorded in the *G. ruber* $\delta^{18}O$ values that are $\sim$0.5‰ isotopically lighter than values from the same latitude in the central and western Arabian Sea. The general north–south $\delta^{18}O$ increase in the Arabian Sea also fits the salinity pattern and reflects the strong evaporation excess in this basin. The only misfit between the salinity and $\delta^{18}O$ patterns is observed in the western Arabian Sea along the coast of Arabia. As the oxygen isotopic composition of the foraminifera shells depends on the seawater temperature, the observed *G. ruber* $\delta^{18}O$ increase reflects the strong temperature drop due to coastal upwelling which brings cool, nutrient-rich deep waters in the surface[38]. To summarize the Holocene pattern, from south to north, *G. ruber* $\delta^{18}O$ values decrease by 1.1‰ in the Bay of Bengal and increase by 0.8‰ in the Arabian Sea whereas mean annual sea-surface salinity decreases by 3‰ in the Bay of Bengal and increases by 1.5‰ in the Arabian Sea. The proportionality coefficient between $\delta^{18}O$ and salinity is not the same in the two basins because the mechanisms which produce the isotopic changes are different: dilution with freshwater in the Bay of Bengal and evaporation in the Arabian Sea.

Isotopic pattern during the last glacial maximum

$\delta^{18}O$ values for the last glacial maximum (Fig. 1*c*) were calculated as mean values of the isotopic stage 2 maximum and are reported in Tables 1 and 2. Dissolution was systematically lower during glacial time than during Holocene time and no sample was rejected for dissolution bias, so that iso-$\delta^{18}O$ map for glacial conditions is based on measurements of *G. ruber* $\delta^{18}O$ for 41 locations.

Glacial *G. ruber* $\delta^{18}O$ values are significantly heavier than those of Holocene time. This strong isotope enrichment primarily reflects the waxing of large continental ice-sheets, depleted in ^{18}O, and which extensively covered northern Europe and North America[1,25,26]. The amplitude of this glacial effect is $\sim$1.6‰ (refs 24, 28, 34), the remaining part of the ^{18}O enrichment is due to local surface seawater salinity and temperature changes. Temperature changes have been rather small in the northern Indian Ocean during the past 25,000 yr (ref. 2). At the last glacial maximum, mean annual sea-surface temperatures for the Bay of Bengal were $\sim$1 °C lower than modern values, while those from the Arabian Sea were almost the same or warmer than those of today. Geographical variations of *G. ruber* $\delta^{18}O$ values at the last glacial maximum will therefore mainly reflect the mean annual sea-surface salinity pattern.

The ice-age *G. ruber* $\delta^{18}O$ map (Fig. 1*c*) reveals striking differences with the modern pattern.

(1) A marked reduction in the $\delta^{18}O$ gradient observed in the Bay of Bengal and the Andaman Sea is probably associated with

* Value taken from ref. 3.

† Rejected value.

a decrease in river discharge into the northern end of this basin. The isotopic result supports independent sea-surface salinity estimates deduced from faunal analysis[13]. The shape of the tongue of low salinity water (marked by the line $\delta^{18}O = -1‰$) suggests that in the Bay of Bengal the clockwise circulation linked to the north-east monsoon[35] dominates the mean annual water circulation. The occurrence of a strong north-east monsoon during glacial conditions is supported by independent pollen evidence[30].

(2) The glacial *G. ruber* $\delta^{18}O$ pattern for the Arabian Sea is much more zonal than the modern one because within the same latitudinal belt, *G. ruber* $\delta^{18}O$ values are similar. This uniform latitudinal distribution is related to the disappearance of both the low salinity–low $\delta^{18}O$ area along the southwestern coast of India and the cool-high $\delta^{18}O$ upwelling area along the coast of Arabia[3]. Both trends are likely to be associated with a reduction of the south-west monsoon wind regime.

(3) A marked increase in the *G. ruber* $\delta^{18}O$ gradient is observed in the Arabian Sea. This strong glacial isotope gradient which is larger than 1‰ (compare with the modern one which is only 0.8‰) is not related to the geographical distribution of the sea-surface temperatures which have been shown to be more uniform than today[24] but indicates a strong salinity increase from south to north. The map of the amplitude of $\delta^{18}O$ change between the last glacial maximum and the Holocene (Fig. 3) shows marked latitudinal variations. In the Arabian Sea, this amplitude is lower than the ice volume effect alone (1.6‰) south of 10° N. Such a low amplitude is not due to bioturbation as it is found in cores with sedimentation rates larger than 2–3 cm kyr^{-1} (core V 19 188; V 2930). Because no major rivers outflow south of 10° N in the northern Indian Ocean, this low amplitude would reflect a marked precipitation increase over oceanic regions south of 10° N. Towards the north, the glacial–interglacial $\delta^{18}O$ amplitude increases. In the Bay of Bengal, this pattern clearly reflects the low river discharge during glacial conditions. In the Arabian Sea, it reflects stronger evaporation over its northernmost area and the Gulf of Oman. This stronger evaporation is probably linked to reinforced dry northeastern winds which blew from the continent to the ocean and to the warming of the Arabian Sea resulting from the reduction of the upwelling along the coast of Arabia which is clearly marked in Fig. 3 by an area of reduced $\delta^{18}O$ amplitude.

Conclusions

The isotopic reconstruction of the last ice age for the northern Indian Ocean indicates a weaker south-west monsoon. This would cause less precipitation over the Indian subcontinent, much of the Himalayas, the eastern and southern Tibetan uplands and Bangladesh which are drained by the Ganges, Brahmaputra, Irrawaddy and Salween rivers. This pattern is confirmed by continental evidence which shows that, at this time, the Persian Gulf region[36] and the Rajasthan[37] were dry, the Zagros Mountains in the north were drier than they are today[38] and strong loess storms occurred in the cold sand deserts of Inner Asia[39–41]. This result is consistent with the widespread aridity in tropical Africa[5,6,42,43] and dune activity in Arabia and northwestern India[41]. Continental aridity contrasted sharply with heavy oceanic precipitation south of 10° N, a pattern which supports the simulation of the tropical climate of the last ice age made with the GFDL general circulation model of the atmosphere[44]. The oceanic reconstruction provides weak indications that the north-east monsoon was stronger than today in glacial conditions. The occurrence of strong north-east dry winds is supported by the large influx of pollen from the Irano–Turanian steppe of the north and north-east[30] and the higher percentage of quartz[45] in Arabian Sea sediments.

In the glacial world, the contrast between a weak south-west monsoon and a strong north-east monsoon is probably related to the environmental conditions prevailing over the Asian continent. In modern conditions, the central and southeastern Tibetan plateau which remains free of snow throughout the year, seems to accelerate the onset of the Asian monsoon and to increase its ultimate intensity because it must be rapidly heated during the spring in the Northern Hemisphere[46]. During the last ice age, these mountains were covered with glaciers[47,48]. This permanent ice coverage would have prevented any marked warming of the Asian continent at high altitude during the summer. Thus, the pressure difference between the Asian continent and the Indian Ocean would be smaller than today and the south-west monsoon weaker. By contrast, during winter, the presence of permanent ice would have helped to maintain a continent much cooler than today in the vicinity of a warm ocean, a mechanism that would have enhanced the north-east monsoon.

I thank J. Labeyrie, C. Lalou, A. W. H. Bé, W. Dudley and W. Prell for discussions, W. Prell and C. H. Hendy for a careful review. Cores for this study were collected during cruises OSIRIS II and III of the French M/S *Marion Dufresne* sponsored by TAAF or came from Lamont Doherty Geological Observatory collections. J. Antignac and B. Le Coat helped for the analyses. Financial support by CEA, CNRS and DGRST is acknowledged.

Protochordate allorecognition is controlled by a MHC-like gene system

V. L. Scofield, J. M. Schlumpberger, L. A. West[*] & I. L. Weissman

Laboratory of Experimental Oncology, Department of Pathology, Stanford University School of Medicine, Stanford, California 94305, USA and Hopkins Marine Station of Stanford University, Pacific Grove, California 93950, USA

Colonial tunicates, unlike vertebrates, undergo transplantation in nature. Rejection or acceptance between colonies of Botryllus *is controlled by a single gene locus with multiple alleles. The same genetic region apparently maintains this polymorphism by preventing fertilization between gametes sharing alleles. The* Botryllus *histocompatibility system may reflect the original adaptive function of ancestral MHC genes.*

In vertebrates, immune recognition of tissue antigens is responsible for rejection of transplanted allogeneic organs, tissues and cells[1]. Prompt rejection of allotransplants by the cell-mediated immune system usually occurs when donor and host differ genetically at the major histocompatibility complex (MHC)[2,3]. It appears that all vertebrate species may have MHC genes and the capacity for response to MHC-disparate antigens[4], but the extent to which the MHC and adaptive immunity are found in invertebrate metazoans is unclear[5]. While vertebrate species exist normally as individuals which encounter foreign transplantation antigens only as a consequence of experimental transplantation, some members of invertebrate phyla allow the coexistence or fusion of individuals (or of groups of individuals, or of newly budded offspring to their parents) to form colonies. In fact, colonial forms are found in virtually all metazoan branches leading to the vertebrates. Recent studies have established the capacity for tissue transplant histocompatibility discrimination in both solitary and colonial members of diverse invertebrate animal phyla[6,7]. Because of their phylogenetic position as the most primitive chordates, certain colonial tunicates provide a very interesting example of colony specificity, where fusion of neighbouring individuals or colonies is under strict genetic control[8–10], and where, by contrast to the vertebrate situation, transplant rejection may be essential for survival. We set out to test the hypothesis that allorecognition in colonial tunicates is controlled by genes of an ancestral MHC gene complex[7].

Botryllus colonies are usually clones of individuals (zooids) sharing a common vascular network and covered by a gelatinous tunic. Colonies grow by budding from a founder individual (oozooid), which arises by metamorphosis from a swimming tadpole-like larva. Production of new buds, resorption of old individuals, ovulation and sperm release occur synchronously for all individuals in a colony and are apparently controlled by blood elements[11,12]. In the natural environment, ovulation occurs immediately on 'takeover' by a new generation of buds. Eggs are fertilized by sperm which enter from the surrounding seawater when the siphons of the new buds open. Embryonic development is phase-locked to the budding cycle, so that developed tadpoles hatch and swim away shortly before their parent zooids are resorbed and replaced by the next generation of buds. The hatched tadpoles, in turn, settle and metamorphose to become oozooids, and begin budding to produce new colonies.

Studies of the genetic control of intercolony fusibility by Watanabe and Oka[9] performed with cut pieces from grown *Botryllus* colonies have established (for *Botryllus primigenus*) that each colony gathered from the marine environment is heterozygotic at a single fusibility gene locus represented in natural populations by many codominant alleles, and that two colonies must share one allele in order to fuse[9,10]. The fusion itself involves apposition of two colonies, dissolution of the intervening tunic, contact between extracorporeal blood vessel termini (ampullae) and fusion (or nonfusion) of the contacted blood vessels to form a multi-individual chimaeric colony with a common blood circulation[13,14]. In this study we have developed a rapid fusion microassay which uses pairs of newly metamorphosed individual oozooids from *in vivo* or *in vitro*[12] crosses. *Botryllus* oozooids possess eight vascular microampullae which are involved in fusion or rejection reactions identical in appearance and time course to those described for ampullae from growing edges of adult colonies (refs 13, 14; Fig. 1). Our results show that allorecognition and control of fertilization, two phenomena characteristic of the murine MHC-bearing chromosome 17, are present as linked characters in two species of the colonial tunicate *Botryllus*.

Colony fusion is controlled by a single, highly polymorphic genetic region

To examine the suitability of this microfusion assay for genetic studies and to determine whether genetic control of fusibility in Monterey *Botryllus* is similar to that described for *Botryllus schlosseri*[10], we first examined fusibility frequencies for pairs of oozooids hatched from colonies fertilized in the natural environment. If colonies are heterozygotic at one locus determining fusibility (that is, *AB*; Fig. 2) at which there are many codominant alleles (*A*, *B*, *C*, *D*...) and if they are fertilized by sperm carrying a large number of (unknown) fusibility alleles (designated x_1, or x_2, or $x_3 \ldots y$), then 25% of random pairs of oozooids hatched from this wild-fertilized colony will be composed of Ax_1, or Ax_2, or $Ax_3 \ldots Ay$ (designated $Ax \ldots y$), all of which will fuse with each other due to sharing of the *A* allele; another 25% of random pairs will be composed of Bx_1, or Bx_2, or $Bx_3 \ldots By$ (designated $Bx \ldots y$), all of which will fuse with each other due to sharing of the *B* allele; and 50% of the random pairs will be $Ax \ldots y$ paired with $Bx \ldots y$, none of which will fuse with each other due to non-sharing of *A* or *B* alleles, and non-sharing of the $x \ldots y$ alleles if a large number of distinct sperm donors ($x \ldots y$) are involved in the fertilization.

Table 1 Fusion frequencies for *a*, oozooid pairs from single wild-fertilized *Botryllus* colonies, and *b*, oozooid pairs from single wild-fertilized *Botryllus* colonies from crowded locations

*After data from different colonies in each of the studies were found to be homogeneous, χ^2 was computed and the *P* value determined. χ^2 for each study was calculated from individual samples as $\chi^2 = -2\Sigma \ln P$, where *P* is the *P* value corresponding to the value of χ^2 (for goodness of fit) for individual experiments.

Colonies of *Botryllus* were collected from the Monterey Marina (designated *Botryllus* sp.) or from the Green Pond at Falmouth or the Eel Pond at Woods Hole, Massachusetts (*B. schlosseri*). Embryonic development of wild-fertilized eggs was completed in the laboratory, and progeny oozooids were paired immediately after hatching and scored for fusion or rejection 48 h later. In both studies, colonies gathered from scattered locations consistently yielded oozooid progeny with a fusion frequency of ~50% (Table 1). This system thus gives results which parallel those obtained by other methods[9,10].

If fusibility in Monterey *Botryllus* is controlled by a single polymorphic gene locus, and one shared allele is required for fusion, then crosses between any two colonies collected from different locations (represented by *AB* × *CD*) will provide progeny oozooids which are *AC*, *AD*, *BC* and *BD* at the fusion locus, and 75% of random pairs of the hybrid oozooids should fuse; this was the case with crosses at *Botryllus* colonies from both locations (Table 2*a*). Late in the growing season (February), many *Botryllus* colonies are crowded together and fertilizing sperm come predominantly from one or a few neighbouring colonies. One would thus expect newly hatched oozooids from these matings to give fusibility frequencies of 50–75%; in fact, fusion frequencies of 60–80% were obtained in such cases (Table 1*b*).

Fusibility alleles are not homozygous lethals

In no case did sampled colonies from East and West coast collecting sites give fusibility frequencies significantly above

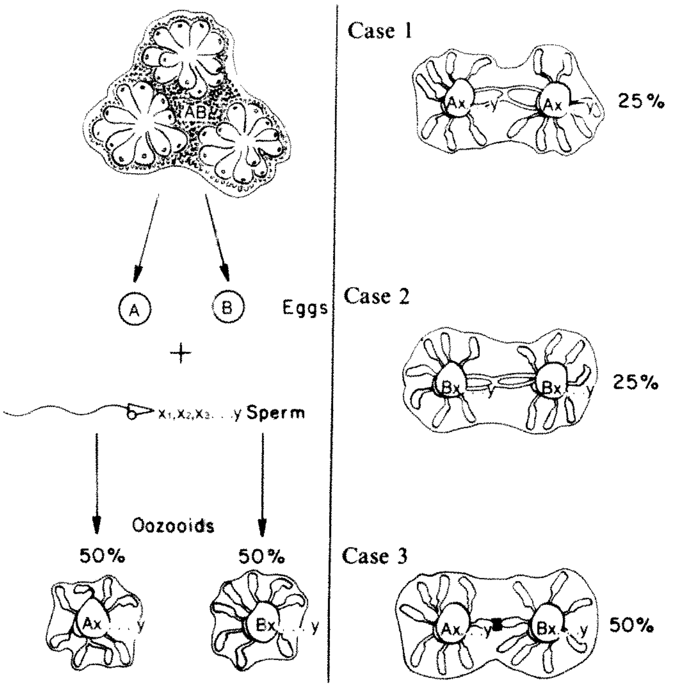

Fig. 2 Testing of the one locus, multiple-allele model for genetic control of colony specificity using the oozooid microassay. Paired oozooids for any crossed *Botryllus* colony will show at least 50% fusions, regardless of the number of alleles involved in the fertilization (above). As the number of sperm alleles participating in the fertilization is decreased, the probability that any two pairs will share a paternal allele increases, and fusibility frequency approaches the 75% frequency for a defined cross (*AB* × *CD*, see text and Table 2).

50–75% (Table 1), so we conclude that homozygotes at the fusibility locus may be rare or nonexistent in natural populations of both North American *Botryllus* species, as may be the case for *B. primigenus* in Japan[9]. Although they are hermaphroditic, colonies of *B. primigenus* have been claimed to be incapable of self-fertilization[9] despite simultaneous ovulation and sperm release. In the two *Botryllus* species studied here, ovulation and fertilization by exogenous sperm occur before endogenous sperm release (protogyny), thus limiting self-fertilization in natural conditions (ref. 15, and V.L.S., unpublished results). When protogyny is circumvented by crossing between separated pieces of the same colony which have been phase-separated by temperature, self-fertilization does occur, but a large proportion of the resulting embryos undergo developmental arrest, or fail to complete metamorphosis after hatching[15].

To test whether embryonic maldevelopment which occurs in the progeny of self-crosses in *B. schlosseri*[15] and Monterey *Botryllus* (V.L.S. and J.M.S., unpublished) replaces the self-sterility operating in *B. primigenus*, we isolated seven colonies, allowed them to self-cross ($AB \times AB$) and counted the fusion frequencies of the few surviving oozooids. If homozygotes (AA and BB) fail to develop, all the survivors should be identical (AB) and the fusion frequency should be 100%. However, none of the self-crosses gave this result (Table 2*b*). Thus, although it is possible that the fusion locus causes late maturation and differentiation effects in homozygotes[15], the fusibility locus cannot be the major determinant in inbreeding depression. It was, therefore, necessary to find another explanation for the puzzling absence of homozygotes in the two *Botryllus* populations studied.

Fusibility locus affects self-fertilization by sperm–egg incompatibility

We have observed that in Monterey *Botryllus*, as in *B. schlosseri*[15], self-fertilizations do not occur synchronously and immediately after ovulation as do cross-fertilizations; in colonies isolated for selfing, the cleavages begin at scattered times and some eggs are never fertilized. We therefore designed experiments to test the hypothesis that there is a gametic barrier to fertilization which breaks down in time to allow self-fertilization in laboratory conditions of isolation. At Woods Hole, 18 colonies of *B. schlosseri* were isolated, 5 of which were early ovulating and fertilized by exogenous sperm brought in from the collection site. In these 5 colonies fertilizations were synchronous, and gave large hatches of oozooids whose fusibility frequency was ~50%. The other 13 late-ovulating colonies were placed *in vitro* in conditions allowing self-fertilization. In these conditions early embryonic cleavages were scattered in colonies whose eggs were ovulated after 2 days of isolation, and 7/13 of these colonies showed delays of 2–4 days after ovulation before the first fertilizations occurred. This occurred despite sperm-producing testes being present in each colony from 1 day after ovulation onwards (data not shown). It seems likely that *Botryllus* eggs resist fertilization by sperm from the same colony for varying periods of time after ovulation.

To extend this observation to the Monterey species, paired colonies at ovulation were divided in half, with one of the subcolonies (A_1 and B_1) from each pair placed in isolation and the others (A_2 and B_2) placed together. In all experiments, cross-fertilization (A_2/B_2) occurred between the paired pieces 1–2 days before self-fertilization (A_1/A_1 and B_1/B_1) occurred in the isolated controls (data not shown), indicating that sperm-producing testes and fertilization-competent eggs are present in both colonies at a time when self-fertilization cannot occur.

To determine whether this barrier to self-fertilization is controlled by the fusibility locus, colonies from the same algal blade were crossed. Our sampling data for colonies with contacted borders indicate that, in these conditions, >20% of such defined crosses should be between sibling colonies sharing at least one fusibility allele. We expected for such semiallogeneic crosses ($AB \times BC$) that sperm carrying the shared allele (B)

When two colonies are crossed ($AB \times CD$), not only is the maternal allele shared in 50% of the oozooid pairs (above), but the paternal allele is also shared in 50% of the pairs (half of which are pairs not sharing a maternal allele); thus the fusibility frequency for these oozooids is 75% (Table 2*a*). All oozooid pairs hatched from a self-fertilization (except the 1/8 which are composed of two homozygotes for opposite alleles—AA to BB) share at least one allele; thus 87.5% will fuse (Table 2*b*).

*Data were analysed as described in Table 1 legend.

For all data, $\chi_1^2 = 17.58$ ($P = 0.005$); thus we reject the null hypothesis that no gametic barrier to fertilizations by sperm carrying the shared allele exists between crossed sibling colonies (see text).

From an *AB* × *CD* defined cross, four classes of offspring, present in equal numbers, are expected: *AC*, *AD*, *BC* and *BD*. Random crossings of the grown progeny colonies from such a cross were expected to be of three kinds: (1) one-half should be crosses where one fusibility allele is shared, and only sperm carrying the non-shared allele can fertilize the eggs, giving offspring which are 100% fusible with one another; (2) one-quarter should be crosses where both fusibility alleles are shared, giving oozooid progeny which are 87.5% fusible (Table 2*b*) and small hatches because fertilization is delayed for 24–48 h until the gametic barrier has broken down; (3) one-quarter should be crosses where no alleles are shared, giving the expected 7.5% fusible progeny (Table 2*a*). 'a' And 'b' notations denote reciprocal crossings between the same two colonies.

should not fertilize any of the eggs of the crossing partner, thus allowing all eggs to be fertilized by the sperm carrying the nonshared allele (all by *A* or all by *C*, depending on which colony serves as a sperm donor). All offspring from such a cross should share a fusibility allele. Table 3 shows the results of fusion analysis of oozooids from the 17 crosses performed in this study. Although 11 of the 17 crosses produced oozooids whose fusion frequencies were close to those expected for cross-fertilizations (75%), 6/17 gave frequencies of 100% (Table 3). The above data are most consistent with a model for self-sterility in which the haploid expression of fusibility allele patterns by sperm is recognized by the diploid, maternally derived egg envelopes[9], resulting in selective fertilization by sperm bearing new fusibility alleles.

To test these findings further, sibling *B. schlosseri* colonies, grown from the F_1 oozooid progeny of a defined cross (*AB* × *CD*) were crossed with one another. Two of the eight crosses performed produced F_2 oozooids whose pairs gave fusibility frequencies close to 75% (Table 4). This is consistent with the expectation that 25% of such crosses will involve no shared alleles (this is the proportion of the grown colonies which would not have fused as oozooids; Table 2*a*). Paired oozooids hatched from all but one of the remaining six crosses (a frequency consistent with that proportion of defined-cross F_1 oozooids which fuse; Table 2*a*) gave fusibility frequencies of 100%. Fertilizations between colonies sharing both fusibility alleles (which should comprise 25% of the crosses between sibling colonies in this experiment) can occur only after the selfing barrier has broken down, after which scattered, asynchronous fertilizations lead to small hatches (Table 2*b*). The expected fusibility frequency for such oozooids is 87.5% (Table 2*b*). Very small hatches, giving fusibility frequencies of 90%, 100%, and 100% respectively (Table 4), resulted from three of the eight crosses in this experiment (Table 4). On the other hand, fertilizations between colonies sharing one fusibility allele, a group which should comprise one-half of the crossings between F_1 progeny of a defined cross, should yield oozooids whose pairs give 100% fusions, as was found in three of the eight defined crosses between sibling colonies shown in Table 4. These data support our hypothesis for genetic control of colony specificity tested in other experiments (Tables 1, 2) and, with the results shown in Table 3, confirm the prediction by Watanabe and Oka[9] of a gametic barrier to fertilization by sperm carrying shared fusibility alleles.

Discussion

The *Botryllus* fusibility gene locus shows the same degree of polymorphism as the genes of the vertebrate MHC[14] and the self-incompatibility systems of plants[16,17]. Because *Botryllus* histocompatibility genes control both somatic tissue recognition and response, as does the vertebrate MHC, and gamete behaviour at fertilization, as does the Ss system in the angiosperms, our findings support hypotheses[16,18,19] that vertebrate histocompatibility genes evolved from gametic self–nonself recognition systems which prevented self-fertilization in hermaphroditic organisms. It seems likely that self–nonself discrimination in *Botryllus* may represent the evolutionary precursor(s) to the MHC[7]. Polymorphism at the *Botryllus* and vertebrate loci may be maintained through linkage of histocompatibility genes with elements which enforce the heterozygous condition through control of fertilization[20–22] or development[22–24].

Despite the similarities between the vertebrate MHC and the *Botryllus* fusion systems, several major differences have yet to be reconciled. For example, fusion is allowed between ampullae of *Botryllus* colonies sharing one allele. In vertebrate allorecognition, by contrast, lymphocyte clones recognize and eliminate cells carrying non-shared histocompatibility antigens, even in the presence of one shared allele. However, events subsequent to a fusion between semiallogeneic *Botryllus* oozooids or colonies (that is *AB* fused to *BC*) frequently lead to the complete resorption of one member of a fused oozooid pair (V.L.S., in preparation) or to the disappearance of germ cells of one of two fused colonies (A. Sabbadin, personal communication). Further studies of these delayed (or induced) responses to contact between semiallogeneic cells may therefore disclose even more similarities between both the native immune reactivities (for example colony specificity and the natural killer cell reactivities of mammals) and the induced allogeneic recognition responses in these two chordate systems. For these purposes, it will be important to determine whether *Botryllus* allorecognition is a capacity possessed by all cells, or only by ampullar and blood cells[13,14].

We thank D. P. Abbott for advice and editorial assistance, D. Epel, C. Pittendrigh, C. Nottenburg and E. Pillemer for critical reading of the manuscript, C. Lambert and G. Freeman for valuable discussions, and C. Patton for photography. Part of this study was completed while V.L.S. was an investigator at the Marine Biological Laboratory, Woods Hole. This work was supported by NSF grant PCM78-10345 and by NIH grant GM 25902. V.L.S. is a NIH Postdoctoral Fellow.

A cDNA sequence coding for human immune interferon (IFN-γ) has been identified in a cDNA library prepared from gel-fractionated IFN-γ mRNA. The DNA sequence codes for a polypeptide of 166 amino acids, 20 of which could constitute a signal peptide. The polypeptide produced through expression of this DNA sequence in Escherichia coli *or cultured monkey cells had properties characteristic of authentic human IFN-γ.*

INTERFERONS (IFNs) are secreted proteins which induce an antiviral state in their target cells, and which have immunomodulatory and antitumour properties[1]. On the basis of antigenicity and biological and chemical properties, human interferons have been grouped into three major classes: IFN-α (leukocyte), IFN-β (fibroblast) and IFN-γ (immune)[2]. Considerable information has accumulated on the structures and properties of the virus-induced acid-stable interferons (IFN-α and -β). These have been purified to homogeneity and partial amino acid sequences determined[3–7]. Analyses of cloned cDNA and gene sequences for IFN-β_1 (refs 8–10) and the IFN-α multigene family[11–16] have permitted the deduction of the complete amino acid sequences of many of these interferons. In addition, efficient synthesis of IFN-β_1 (ref. 10) and several IFN-αs[13,16] in *Escherichia coli* and IFN-α_1 in yeast[17] have now made possible the purification of large quantities of these proteins in biologically active form.

Much less data are available concerning the structure and properties of IFN-γ. IFN-γ is generally produced in cultures of lymphocytes exposed to various mitogenic stimuli, is acid labile and does not cross-react with antisera prepared against IFN-α or IFN-β (ref. 1). Molecular weights ranging from 35,000 to 70,000 have been reported for IFN-γ (refs 18–21). Recently, a quite extensive, but still partial, purification of IFN-γ has been reported[20], and IFN-γ mRNA has been isolated and translated in *Xenopus laevis* oocytes[22,23]. A broad range of biological activities have been attributed to IFN-γ, including potentiation of the antiviral activities of IFN-α and -β (ref. 24), and it differs from these interferons in its virus and cell specificities and in the antiviral mechanisms it induces[25]. However, *in vitro* studies performed with crude preparations suggest that the primary function of IFN-γ may be as an immunoregulatory agent[26]. The antiproliferative effect of IFN-γ on transformed cells has been reported to be 10–100-fold greater than that of IFN-α or -β (refs 25, 27), suggesting a potential use in the treatment of neoplasia. Indeed, murine IFN-γ preparations have been shown to have significant antitumour activity against mouse sarcomas[28]. However, the poor availability of purified IFN-γ has precluded the unambiguous determination of its physicochemical and biological properties.

We describe here the first isolation and characterization of a recombinant plasmid containing a cDNA sequence coding for human IFN-γ. Expression of this sequence in *E. coli* and cultured monkey cells gives rise to a polypeptide having the properties of authentic human IFN-γ.

Construction and identification of bacterial clones containing induced cDNA sequences

Human peripheral blood lymphocytes (PBLs) from healthy donors were stimulated to produce IFN-γ by treatment with staphylococcal enterotoxin B (SEB) and desacetylthymosin α_1 as described by Svedersky *et al.*[29]. Cell cultures from individual donors were collected 48 h after induction and used to prepare polyadenylated RNA[30,31] which was fractionated by electrophoresis through denaturing agarose gels[32,33]. Interferon mRNA activity was determined by injecting aliquots of each fraction into *X. laevis* oocytes[34–37] and after 24 h assaying the incubation medium for antiviral activity[36,37]. One peak of activity was consistently observed which co-migrated with 18S RNA (Fig. 1). Using different procedures for sucrose density gradient centrifugation, Wallace *et al.*[22] and Taniguchi *et al.*[23] have reported single peaks of IFN-γ mRNA activity sedimenting at 18S and 15S respectively. RNA from our most active 18S gel fraction (600 units ml^{-1} when 0.5 μg was injected into 15 oocytes at a concentration of $0.5\ \mu\mathrm{g}\ \mu\mathrm{l}^{-1}$) was used to prepare double-stranded cDNA by standard procedures[38,39]. The cDNA was fractionated according to size and material longer than 800 base pairs (bp) was extended with deoxy(C) residues, annealed to deoxy(G)-tailed *Pst*I-cleaved pBR322 and used to transform *E. coli* K-12 strain 294 (ref. 40) as described previously[13,19].

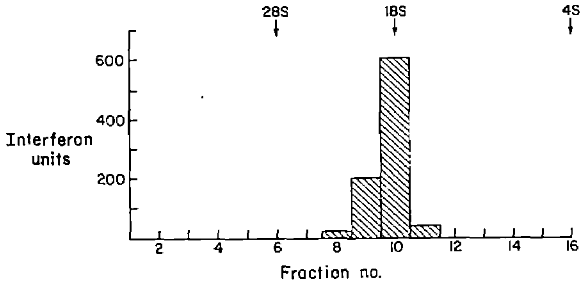

Fig. 1 Gel electrophoresis of induced lymphocyte polyadenylated RNA. Peripheral blood lymphocytes (PBLs) derived from individual human donors by lymphophoresis were purified by centrifugation on a Ficoll–Hypaque gradient and induced for IFN-γ production with staphlococcal enterotoxin B ($1\ \mu\mathrm{g\ ml}^{-1}$) and desacetylthymosin-$\alpha_1$ ($0.1\ \mu\mathrm{g\ ml}^{-1}$)[29]. Total RNA was extracted[30] from PBL cultures and poly(A)-containing RNA was purified by oligo(dT) cellulose chromatography[31]. 200 μg of mRNA was fractionated by electrophoresis through a denaturing agarose gel (1.75% agarose, 0.025 M sodium citrate (*p*H 3.8) and 6 M urea) for 7 h at 25 mA and 4 °C (refs 32, 33). The slab gel was sectioned with a razor blade and individual slices were melted at 70 °C and extracted twice with phenol and once with chloroform. Fractions were precipitated with ethanol and subsequently assayed for IFN-γ mRNA by injection into *X. laevis* oocytes[34–37] at a concentration of $0.5\ \mu\mathrm{g}\ \mu\mathrm{l}^{-1}$. After 24 h incubation at room temperature the antiviral activity of the translation products in the incubation medium was determined by the cytopathic effect (CPE) inhibition assay using vesicular stomatitis virus or encephalomyocarditis virus on WISH (human amnion) cells[1]. All IFN-γ units are expressed with reference to the NIH IFN-α standard (G-023-901-527), because no internationally accepted IFN-γ standard was available. In this assay system 0.2 units of the standard results in a 50% reduction in cytopathogenic effect. A single peak of activity was observed which co-migrated with 18S ribosomal RNA. The positions of ribosomal RNA markers which were electrophoresed in an adjacent lane and visualized by ethidium bromide staining are labelled above the activity profile. The activity seems to be due to IFN-γ, as no activity was observed when the same fractions were assayed on a bovine cell line (MDBK) which is not protected by IFN-γ (ref. 29). Both IFN-α activity and IFN)-β activity would have been easily detectable with the MDBK assay[10].

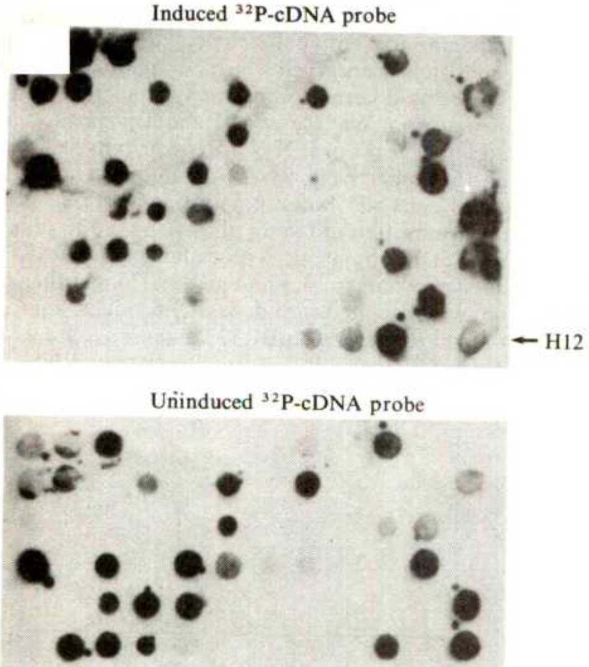
0028-0836/82/060503—06$01.00

We screened 8,300 bacterial clones from the cDNA library for the presence of specifically induced cDNA sequences by the following procedure. Two copies of the colony library were grown up on nitrocellulose filters and DNA was fixed to the filters for *in situ* colony hybridization[41,42]. One set of filters was hybridized with a ^{32}P-labelled cDNA probe prepared using the same 18S gel-fractionated mRNA (induced) used to prepare the colony library. The second set of filters was hybridized with ^{32}P-labelled cDNA prepared using 18S gel-fractionated poly(A) RNA isolated from unstimulated PBLs. The hybridization intensity of each colony with the two probes was compared, as IFN-γ sequences should only hybridize with the induced probe. 124 colonies hybridized with the induced probe but undetectably or weakly with the uninduced probe (see Fig. 2). Plasmid DNA was isolated from each of these colonies[43], bound to nitrocellulose filters[44] and hybridized with the same induced and uninduced probes. DNA from 22 colonies hybridized specifically with the induced probe in this rescreening.

The cDNA inserts from several of these 'induced' colonies were mapped using restriction endonucleases and found to contain common *Dde*I, *Hin*cII and *Rsa*I sites (Fig. 3*a*). A ^{32}P-labelled DNA probe was prepared[45] from one of the plasmids using two internal *Dde*I fragments (130 and 600 bp) and hybridized to DNA from the 124 colonies selected in the first round of screening. Only the 22 induced clones were found to hybridize with this probe, establishing their relatedness. Subsequent rescreening[41,42] of the cDNA library with this same probe revealed that approximately 1 in 120 *E. coli* clones contained related sequences. Digestion of plasmid DNA from these clones with *Pst*I showed that clone 69 contained the largest cDNA sequence (~1,250 bp).

Induced ^{32}P-cDNA probe



Uninduced ^{32}P-cDNA probe

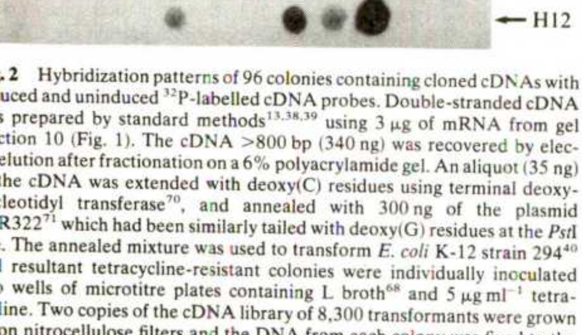


Fig. 2 Hybridization patterns of 96 colonies containing cloned cDNAs with induced and uninduced ^{32}P-labelled cDNA probes. Double-stranded cDNA was prepared by standard methods[13,38,39] using 3 μg of mRNA from gel fraction 10 (Fig. 1). The cDNA >800 bp (340 ng) was recovered by electroelution after fractionation on a 6% polyacrylamide gel. An aliquot (35 ng) of the cDNA was extended with deoxy(C) residues using terminal deoxynucleotidyl transferase[70], and annealed with 300 ng of the plasmid pBR322[71] which had been similarly tailed with deoxy(G) residues at the *Pst*I site. The annealed mixture was used to transform *E. coli* K-12 strain 294[40] and resultant tetracycline-resistant colonies were individually inoculated into wells of microtitre plates containing L broth[68] and 5 μg ml^{-1} tetracycline. Two copies of the cDNA library of 8,300 transformants were grown up on nitrocellulose filters and the DNA from each colony was fixed to the filter[41,42]. ^{32}P-labelled cDNA probes were prepared from 18S size gel-fractionated mRNA from induced and uninduced PBL cultures. Oligo(dT)$_{12-18}$ was used as a primer and reaction conditions have been previously described[13]. One set of 86 filters (96 colonies per filter) containing the entire cDNA library was hybridized[72] to 2×10^7 c.p.m. of the induced ^{32}P-cDNA. The duplicate set of filters was hybridized with 2×10^7 c.p.m. of uninduced ^{32}P-cDNA. After 16 h at 45 °C, filters were washed extensively[72] and exposed to X-ray film. The two filters shown here are representative of 86 such sets: approximately half the colonies hybridize with both probes, while half fail to hybridize with either probe, and ~1% hybridize with only the induced probe. An example of an 'induced' clone is labelled as H12.

Sequence analysis of the cDNA insert of plasmid p69

The complete nucleotide sequence of the *Pst*I insert from plasmid p69 was determined by the Maxam–Gilbert chemical procedure[46] and by the dideoxynucleotide chain termination method[47] after subcloning fragments into the M13 vector mp7 (ref. 48). The presence of 19 consecutive A residues corresponding to the 3' poly(A) terminus of the mRNA permitted us to orient the 1,200 nucleotide long sequence as shown in Fig. 3*b*. As IFN-γ mRNA co-migrates with 18S ribosomal RNA (>2,000 nucleotides) on denaturing agarose gels, it was important to see whether the 1,200 bp insert of p69 represented a full-length copy of its respective mRNA. To measure the length of this mRNA the synthetic tridecanucleotide dTCGTTTCCGAGAG, complementary to nucleotides 98–110 of the p69 insert (Fig. 3*b*), was chemically synthesized[49], 5' ^{32}P-labelled and used to prime the reverse transcription of induced lymphocyte poly(A) RNA into single-stranded ^{32}P-cDNA. The cDNA product was sized on a polyacrylamide–urea gel[46] and found to be 125–130 nucleotides long (unpublished results), indicating that the cDNA insert of p69 lacks only about 15–20 nucleotides of 5' mRNA sequence. Induced poly(A) mRNA was also fractionated on a denaturing agarose gel[33,34], transferred to nitrocellulose paper[50] and hybridized with ^{32}P-labelled cDNA insert from p69. A single hybridizing band, with the same mobility as 18S rRNA, was observed. Therefore, the mRNA corresponding to the p69 cDNA insert co-migrates with IFN-γ mRNA activity.

The DNA sequence of the p69 cDNA insert contains a single large open reading frame, beginning with the ATG codon at nucleotides 110–112 from the 5' end. This ATG is followed, 166 codons later, by a TAA termination triplet at nucleotides 608–610. This ATG is the first one encountered, consistent with the observation that the first ATG codon from the 5' end of mRNA usually serves as the site of translation initiation in eukaryotes[51]. The 3'-untranslated region of 587 nucleotides contains the hexanucleotide AATAAA (position 1,173–1,178) which precedes the site of polyadenylation in many eukaryotic mRNAs[52]. The 20 N-terminal amino acids encoded by the cDNA insert of p69 may constitute a signal peptide which is involved in the secretion of the mature polypeptide from lymphocytes. This putative signal sequence is strongly hydrophobic, having features common to eukaryotic secretory protein signal peptides in general[53,54] and more specifically to the IFN-αs for which DNA sequences have been determined[11–16]. It has the same potential cleavage site (Gly-Cys) that is likely to be the signal peptide cleavage sequence common to all IFN-αs[14]. Furthermore, the three amino acids (Ser-Leu-Gly) preceding this potential cleavage site are identical to those encoded by 10 of the 11 IFN-α genes sequenced to date[11–16].

The only other homology between this potential IFN-γ sequence and IFN-α or IFN-β covering more than three consecutive amino acids occurs at amino acids 15–18 (Lys-Lys-Tyr-Phe). These same four amino acids are found at positions 121–124 of two IFN-αs (IFN-αD and -αF; ref. 14). The 146 amino acid polypeptide estimated to constitute the mature protein has a calculated molecular weight of 17,110, much smaller than the molecular weights reported previously for IFN-γ (refs 18–21). The reasons for this discrepancy are not clear, but it should be noted that the molecular weights reported previously represent the size of the undenatured active species, which could exist as a multimer of individual subunits. Addi-

An overnight culture of *E. coli* W3110/pIFN-γtrp48 in Luria broth[68] containing 5 μg ml^{-1} tetracycline was diluted 1 : 100 in M9 medium[68] containing 0.2% glucose, 0.5% casamino acids and 5 μg ml^{-1} tetracycline at a 1 : 100 dilution. Indole acrylic acid was added to a final concentration of 20 μg ml^{-1} when A_{550} was 0.1–0.2. Samples (10 ml) were collected by centrifugation at A_{550} = 1.0 (~3.5 × 10^8 cells ml^{-1}) and resuspended immediately in 1 ml phosphate-buffered saline containing 1 mg bovine serum albumin (PBS–BSA). Cells were opened by sonication and cleared of debris by centrifugation. The supernatants were stored at 4 °C until assay. The plasmid pSVγ69 was introduced in COS-7 cells[62] using a modification of the DEAE-dextran technique[69]. Fresh monolayers of COS-7 cells in 6-cm diameter plates were transfected with 1 μg of pSVγ69 in 1.5 ml of Dulbecco's minimal essential medium (DMEM; Gibco), 200 μg ml^{-1} DEAE-dextran (500,000 molecular weight; Pharmacia), 0.05 M Tris-HCl (*p*H 7.5). After 16 h at 37 °C, the plates were washed twice with DMEM, and 1.5 ml of fresh DMEM supplemented with 10% fetal bovine serum, 2 mM glutamine, 50 μg ml^{-1} penicillin G and 50 mg ml^{-1} streptomycin was added to each plate. The medium was replaced the following day with serum-free DMEM. Fresh serum-free medium was then added every day. The collected media were stored at 4 °C until assayed. IFN-α and IFN-β control samples were NIH reference standards. The IFN-γ control was partially purified (~10^6 units per mg) from induced PBLs. The anti-IFN-α and -β were obtained from the National Institute of Allergy and Infectious Diseases. The anti-IFN-γ antisera was prepared using authentic IFN-γ (5–20% purity) purified from stimulated PBLs. Samples for antibody neutralizations were diluted, if necessary, then incubated for 2 h at 4 °C with 1 : 20 dilutions of rabbit anti-human leukocyte, fibroblast or immune interferon antisera. Samples were centrifuged for 3 min at 12,000*g* before assay. To test *p*H 2 stability, samples were adjusted to *p*H 2 by addition of 1 M HCl, incubated for 2 h at 4 °C and neutralized by addition of 1 M NaOH before assay. To test SDS sensitivity, samples were incubated with an equal volume of 0.2% SDS for 2 h at 4 °C before assay. The IFN assay was performed as described in Fig. 1 legend.

tionally, IFN-γ is glycosylated *in vivo*[20,21,55], which could affect molecular weight estimates. Consistent with this observation is the presence of two potential *N*-glycosylation sites[56] in the predicted protein sequence, at amino acids 28–30 (Asn-Gly-Thr) and 100–102 (Asn-Tyr-Ser). As the only two cysteines present in the deduced amino acid sequence occur at positions 1 and 3, the tertiary structure of the polypeptide is probably not dependent on intramolecular disulphide bonds. This is in agreement with the finding that, in contrast to IFN-α and IFN-β, disulphide linkages are not critical for the antiviral activity of IFN-γ (ref. 21). The mature protein sequence shown in Fig. 3*b* is quite basic in character, having 27 basic amino acids (Arg+Lys) and 19 acidic residues (Asp+Glu). This is consistent with the observation of Yip *et al.*[20] that IFN-γ has a high isoelectric point (*p*I = 8.6–8.7), whereas IFN-α and IFN-β have been shown to have distinctly lower *p*Is[20,57].

Synthesis of IFN-γ in *E. coli* and monkey cells

As IFN-γ has not been purified to homogeneity, nothing is known directly about its amino acid sequence. Therefore, the only direct means of proving that the cDNA sequence of p69 actually codes for IFN-γ is by demonstrating that the polypeptide obtained through expression of this cloned gene has the properties of natural IFN-γ. Two independent expression systems involving *E. coli* and monkey cells were used for this purpose. The *E. coli* system was selected because it has been used to produce biologically active IFN-αs and IFN-β (refs 10, 13). The mammalian cell system was chosen because, unlike *E. coli*, it should be able to perform specific processing (for example, glycosylation) which might be required for the expression of a biologically active product.

Fig. 3 *a*, Restriction endonuclease map of the cDNA insert of p69. The cDNA insert is bounded by *Pst*I sites (dots at both ends) and poly(dG-dC) tails (single lines). The number and size of fragments produced by restriction nuclease cleavage were estimated by electrophoresis through 6% polyacrylamide gels. Positions of sites were confirmed by nucleic acid sequencing (presented below). The shaded region indicates the coding sequences of the putative mature protein, the cross-hatched region represents the putative 20 residue signal peptide coding sequence, and the open regions show the 3'- and 5'-noncoding sequences. *b*, Nucleotide sequence and deduced amino acid sequence of plasmid p69 cDNA insert. The putative signal sequence is represented by the residues labelled S1 to S20. The entire sequence was determined by both the dideoxynucleotide chain termination method[47] after subcloning fragments into the M13 vector mp7[48] and the chemical method of Maxam and Gilbert[46]. Numbers above each line refer to amino acid position (S refers to presumed signal peptide) and numbers below each line to nucleotide position.

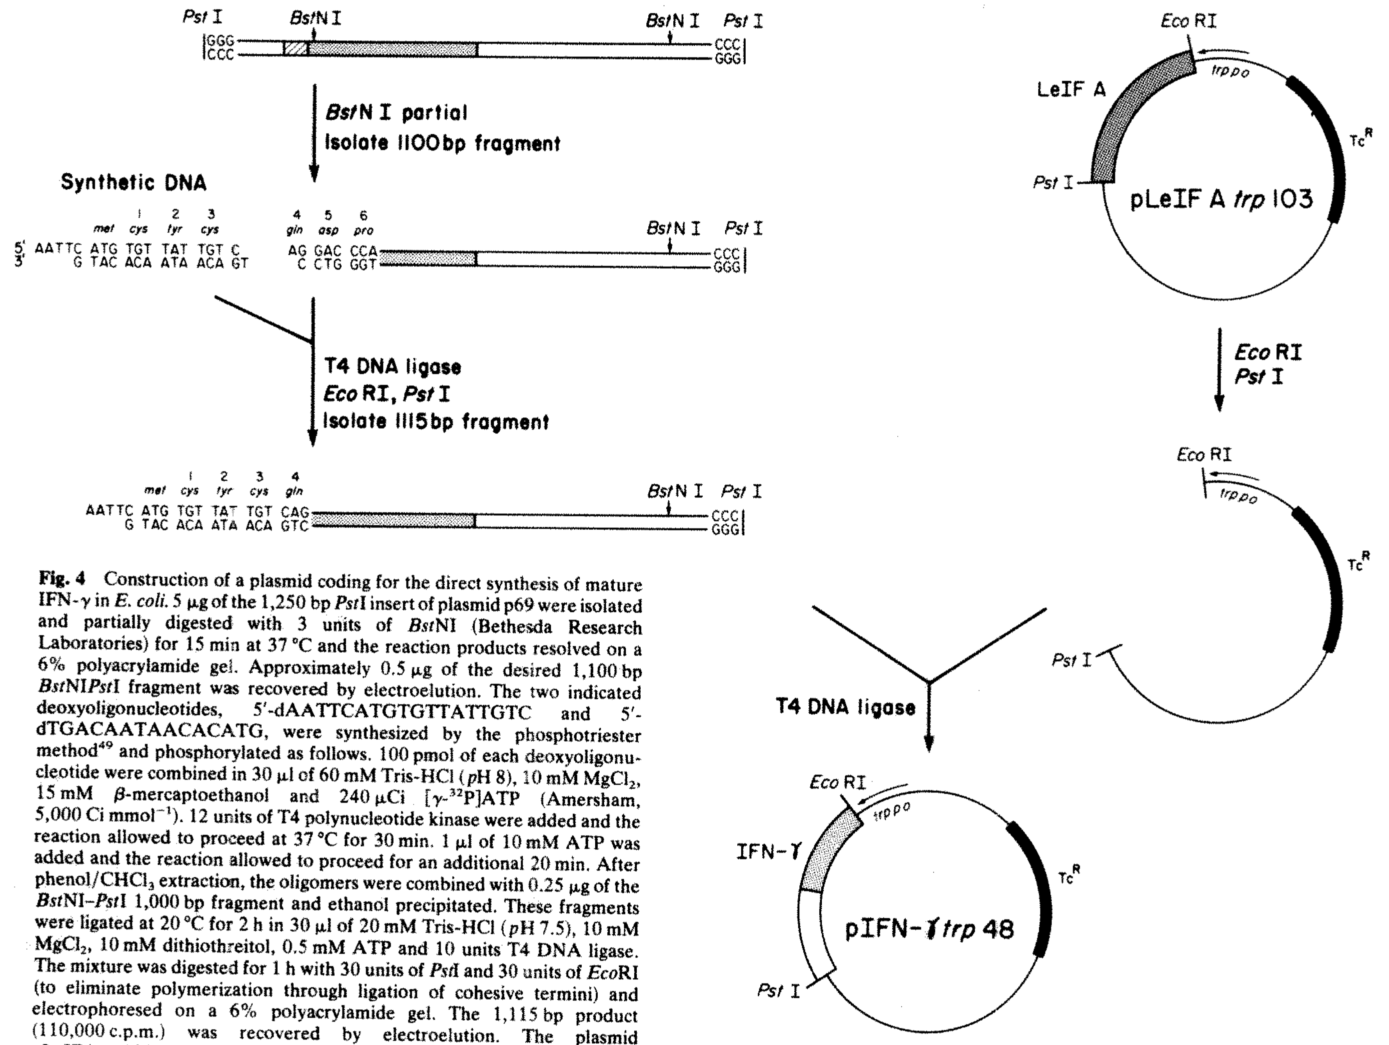

Fig. 4 Construction of a plasmid coding for the direct synthesis of mature IFN-γ in *E. coli*. 5 μg of the 1,250 bp *Pst*I insert of plasmid p69 were isolated and partially digested with 3 units of *Bst*NI (Bethesda Research Laboratories) for 15 min at 37 °C and the reaction products resolved on a 6% polyacrylamide gel. Approximately 0.5 μg of the desired 1,100 bp *Bst*NI*Pst*I fragment was recovered by electroelution. The two indicated deoxyoligonucleotides, 5′-dAATTCATGTGTTATTGTC and 5′-dTGACAATAACACATG, were synthesized by the phosphotriester method[49] and phosphorylated as follows. 100 pmol of each deoxyoligonucleotide were combined in 30 μl of 60 mM Tris-HCl (*p*H 8), 10 mM $MgCl_2$, 15 mM β-mercaptoethanol and 240 μCi [γ-^{32}P]ATP (Amersham, 5,000 Ci $mmol^{-1}$). 12 units of T4 polynucleotide kinase were added and the reaction allowed to proceed at 37 °C for 30 min. 1 μl of 10 mM ATP was added and the reaction allowed to proceed for an additional 20 min. After phenol/$CHCl_3$ extraction, the oligomers were combined with 0.25 μg of the *Bst*NI–*Pst*I 1,000 bp fragment and ethanol precipitated. These fragments were ligated at 20 °C for 2 h in 30 μl of 20 mM Tris-HCl (*p*H 7.5), 10 mM $MgCl_2$, 10 mM dithiothreitol, 0.5 mM ATP and 10 units T4 DNA ligase. The mixture was digested for 1 h with 30 units of *Pst*I and 30 units of *Eco*RI (to eliminate polymerization through ligation of cohesive termini) and electrophoresed on a 6% polyacrylamide gel. The 1,115 bp product (110,000 c.p.m.) was recovered by electroelution. The plasmid pLeIFAtrp103 is a derivative of the plasmid pLeIFA25 (ref. 13) in which the *Eco*RI site distal to the LeIF A gene has been removed. 3 μg of pLeIFAtrp103 were digested with 20 units of *Eco*RI and 20 units of *Pst*I for 90 min at 37 °C and electrophoresed on a 6% polyacrylamide gel. The large (~3,900 bp) vector fragment was recovered by electroelution and the 1,115 bp *Eco*RI–*Pst*I IFN-γ DNA fragment ligated into 0.15 μg of this prepared vector. Transformation of *E. coli* K-12 strain 294[40] gave 120 tetracycline-resistant colonies. Plasmid DNA was prepared from 60 of these transformants and digested with *Eco*RI and *Pst*I. Three of these plasmids contained the desired 1,115 bp *Eco*RI-*Pst*I fragment. DNA sequence analysis verified that these plasmids had the desired nucleotide sequence at the junctions between the *trp* promoter, synthetic DNA and cDNA. One of these plasmids, pIFN-γtrp48, was chosen for additional study.

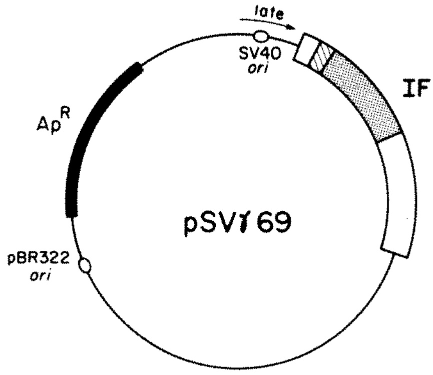

Fig. 5 Plasmid constructed for the expression of IFN-γ in monkey cells. The 342 bp *Hin*dIII–*Pvu*II fragment encompassing the SV40 replication origin[60] was converted to a fragment bounded by *Eco*RI restriction sites. The *Hin*dIII site was converted to an *Eco*RI site by addition of a synthetic oligomer (5′dAGCTGAATTC) and the *Pvu*II site was converted by ligation to an *Eco*RI site which had been filled-in using DNA polymerase I (Klenow fragment). The *Eco*RI fragment containing the SV40 origin was ligated into the *Eco*RI site of pML-1[59]. The resulting expression vector was chosen which contained the SV40 late promoter oriented to read away from the ampicillin-resistance gene of pML-1. The *Eco*RI site nearest the ampicillin-resistance gene was destroyed by partial *Eco*RI digestion, filling in with the Klenow fragment of DNA polymerase I, and subsequent ligation (as outlined in ref. 73). The 1,250 bp *Pst*I insert of p69 was converted to a fragment bounded by *Eco*RI sites by insertion in the *Pst*I site of pNCV[13], as the *Pst*I site of pNCV is flanked by *Eco*RI sites. The *Eco*RI-flanked cDNA insert was ligated into the single *Eco*RI site of the pML-SV40 expression vector to give the plasmid shown.

The procedure followed to express the cDNA insert of p69 directly in *E. coli* was similar to that used previously for human growth hormone[39], IFN-β (ref. 10) and several IFN-αs[13,16], and is outlined in Fig. 4. A *Bst*NI restriction site located at codon 4 of the presumed mature coding sequence was used to remove the signal peptide coding region. Two synthetic deoxyoligonucleotides were designed which restore the codons for amino acids 1–4, incorporate an ATG translational initiation codon and create an *Eco*RI cohesive terminus. These two oligomers were ligated to the remainder of the cDNA insert to construct a 1,115 bp synthetic–natural hybrid gene coding for a polypeptide of 147 amino acids and bounded by *Eco*RI and *Pst*I sites. This gene was inserted into the plasmid pLeIFAtrp103 (a derivative of pLeIFA25 (ref. 13) in which the *Eco*RI site distal to the LeIF *A* gene was destroyed) between the *Eco*RI and *Pst*I sites to give the expression plasmid pIFN-*γtrp48*. In this plasmid the cloned gene is transcribed under the control of a 300 bp fragment of the *E. coli trp* operon[13]. This fragment contains the *trp* promoter, operator and the Shine–Dalgarno sequence of the *trp* leader peptide[58], but lacks the ATG sequence for initiation of translation of the leader peptide. *E. coli* W3110 strains transformed with either pIFN-γtrp48 or p69 were grown and extracted for interferon assay (see Table 1). Extracts from cultures of W3110/pIFN-γtrp48 exhibited definite interferon activity (~250 units per ml of extract), whereas no activity (<3 units per ml) was detected in extracts of W3110/p69.

To express the putative IFN-γ coding sequence of p69 in mammalian cell culture, the expression vector pSVγ69 (Fig. 5)

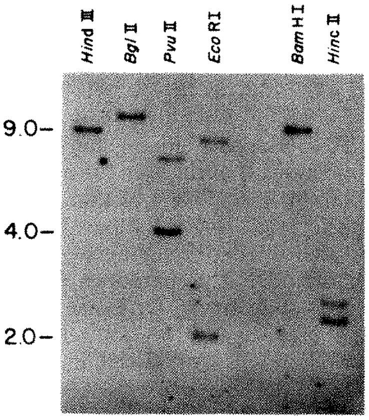

Fig. 6 Hybridization of human genomic DNA with a ^{32}P-labelled cDNA probe from plasmid p69. High molecular weight human lymphocyte DNA (5 μg) prepared by the procedure of Blin and Stafford[74] was digested to completion with various restriction endonucleases, electrophoresed on 1.0% agarose gels and blotted to a nitrocellulose filter[67]. The ^{32}P-labelled DNA probe was prepared from a 594 bp *Dde*I fragment (nucleotides 266–860 of Fig. 3*b*) of the cDNA insert of p69 as described previously[45]. 1 × 10^7 c.p.m. of the probe were hybridized with the filter for 16 h and then washed as described elsewhere[14]. Two hybridizing DNA fragments were observed with three endonuclease digests: *Pvu*II (6.7 and 4.0 kbp), *Eco*RI (8.8 and 2.0 kbp) and *Hinc*II (2.5 and 2.2 kbp). Three endonuclease digestion patterns provide only one hybridizing DNA fragment: *Hin*dIII (9.0 kbp), *Bgl*II (11.5 kbp) and *Bam*HI (9.5 kbp).

was constructed from the following three components: (1) the plasmid pML-1 (pML-1 is a derivative of pBR322 in which sequences known to inhibit the replication of SV40–pBR322 recombinants in simian cells have been deleted, but which still contains the ampicillin-resistance selectable marker and an *E. coli* replication origin[59]); (2) a 342 bp *Pvu*II–*Hin*dIII fragment of SV40 virus providing the replication origin of SV40[60] and which is thought to encompass the promoter for both the early and late SV40 transcriptional units[61]; and (3) the entire cDNA insert from plasmid p69.

The cDNA insert and the SV40 origin region were oriented in pSVγ69 such that the interferon structural gene should be transcribed from the promoter for the late transcriptional unit (Fig. 5). This vector was introduced by DNA transfection into the transformed monkey cell line COS-7 (ref. 62). COS-7 endogeneously expresses SV40 large T antigen and has been shown to permit the propagation of recombinant plasmids containing pML-1 and SV40 origin sequences[59,60]. Cell media from transfected cultures were assayed daily for the presence of interferon activity. Yields of 50–100 units per ml were obtained 3 or 4 days after transfection, indicating that the interferon was being secreted into the culture medium by the COS-7 cells. No interferon activity was observed in the media from cells transfected with plasmids in which the cDNA coding region was inserted in the opposite orientation to that shown in Fig. 5 (data not shown).

Characterization of interferon activity produced by *E. coli* and monkey cells

The properties of the interferon activity present in extracts of *E. coli* W3110/pIFN-γtrp48 and secreted from COS-7/pSVγ69 cells were compared with authentic human IFN-γ produced by stimulated PBLs and with authentic IFN-α and IFN-β. Distinguishing characteristics of IFN-γ include *p*H 2 lability and lack of neutralization by antisera prepared against human IFN-α or IFN-β (ref. 2). As indicated in Table 1, the interferon produced by *E. coli* and monkey cells, like the IFN-γ produced by SEB/desacetylthymosin α_1-stimulated PBLs, was not neutralized by antisera to either IFN-α or IFN-β, although these antisera were effective in neutralizing authentic IFN-α or IFN-β. Antisera prepared against partially purified PBL-produced IFN-γ (E. Rinderknecht and V. Anicetti, unpublished results) completely neutralized the interferon activity synthesized by *E. coli* and monkey cells while having no effect on the activity of IFN-α and IFN-β (Table 1). Furthermore, the complete loss of activity observed when these interferon preparations were treated with *p*H 2 or 0.1% SDS is characteristic of IFN-γ, and distinct from IFN-α and IFN-β. Therefore, the polypeptide encoded by the cloned cDNA sequence of p69 has the same immunological and chemical properties as authentic IFN-γ.

A single gene for IFN-γ

The human interferon gene family comprises 12 or more distinct IFN-α genes having 80–95% DNA sequence homology[11–16,63] and at least one IFN-β gene (IFN-β_1; refs 64–66) which is 40–50% homologous with the IFN-α genes. To estimate the number of related IFN-γ genes in the human genome, human DNA of one individual was digested with several restriction enzymes, electrophoresed through agarose gels, transferred to nitrocellulose paper[67] and hybridized to a ^{32}P-labelled IFN-γ cDNA probe (Fig. 6). *Hinc*II is the only one of the six restriction enzymes used that cleaves the IFN-γ cDNA sequence, but the *Hinc*II site is not located in the DNA fragment which was used as probe. A unique, intronless gene would thus have appeared as a single hybridizing DNA fragment in each lane of the gel. Instead, two hybridizing DNA fragments were observed for three of the endonuclease digestions (*Pvu*II, *Eco*RI, *Hinc*II) and single hybridizing fragments of about 9 kilobase pairs (kbp) each were found for the other digestions (*Hin*dIII, *Bgl*II, *Bam*HI). Similar genomic blots using DNA from other individuals gave the same hybridization patterns. There are two possible explanations for these results: first, there are two homologous and closely linked (<8 kbp apart) IFN-γ genes separated by *Pvu*II, *Eco*RI and *Hinc*II sites, and second, there is a single IFN-γ gene which contains one or more introns containing *Eco*RI, *Pvu*II and *Hinc*II sites. This second possibility was supported by repeating the hybridizations with a ^{32}P-labelled probe prepared from the 3′-untranslated region of IFN-γ cDNA. In this experiment only single *Pvu*II, *Eco*RI and *Hinc*II fragments hybridized to the probe (data not shown). The gene structure of IFN-γ is therefore distinctly different from that of IFN-α and IFN-β, which contain no introns[15,63–66].

Discussion

Poly(A) mRNA from human lymphocytes producing IFN-γ was fractionated on a denaturing agarose gel. The 18S size fraction was used to prepare a cDNA library in *E. coli*. Twenty-two bacterial clones containing potential IFN-γ sequences were identified by specific hybridization to ^{32}P-cDNA probes prepared using mRNA from induced lymphocytes and failure to hybridize to similar probes prepared from uninduced mRNA. Restriction mapping and DNA hybridization experiments revealed that all 22 induced cDNA clones were related and that the frequency of these clones in the cDNA library was about 1:120. Therefore, the frequency of IFN-γ mRNA in our most active poly(A) RNA preparation is ~1:2,400 because the mRNA used to prepare this cDNA library had been enriched about 20-fold in IFN-γ sequence by the agarose gel fractionation procedure.

The 1,194 bp cDNA insert (excluding poly(A) sequence and dG·dC tails) of p69 codes for a polypeptide of 166 amino acids, 20 of which are probably cleaved during the process of secretion of mature IFN-γ from lymphocytes. The encoded amino acid sequence, which bears little resemblance to those of IFN-α or IFN-β, has two potential glycosylation sites and is quite basic in character. Identification of this sequence as IFN-γ was obtained by expression of the cDNA sequence of p69 in bacterial and mammalian cells. In both systems the expression product was shown to have antiviral activity which was immunologically indistinguishable from that of the IFN-γ produced by stimulated human lymphocytes. Additionally, the SDS and *p*H 2 sensitivity observed for the IFN-γ produced by bacteria and monkey cells are distinguishing features of authentic IFN-γ (refs 2, 18–21).

The amounts of antiviral activity recovered from *E. coli* producing IFN-γ are significantly lower than those obtained for IFN-α or IFN-β using similar expression vectors[10,13,16]. If a specific activity range of 10^8–10^9 units per mg is assumed for IFN-γ (ref. 20), between 8 and 80 active molecules are present per cell. However, if the specific activity of the interferon depends to some degree on its state of glycosylation, considerably more interferon molecules could be present per cell. Additionally, if we were incorrect in our assumptions about which amino acids constitute the signal peptide, the molecule expressed in *E. coli* may not exhibit the same specific activity as natural IFN-γ. If one assumes that authentic mature IFN-γ is a 146-amino acid polypeptide, its molecular weight, minus carbohydrate, would be 17,110. The difference between this value and the published molecular weights of 35,000–70,000 for IFN-γ probably cannot be accounted for by glycosylation alone. It is conceivable that authentic IFN-γ is associated with carrier proteins in serum or exists as a multimer of identical subunits. The purification and sizing of IFN-γ synthesized by *E. coli* and monkey cells should help resolve this discrepancy in molecular weight.

The human IFN-γ gene corresponding to the cDNA sequence described here seems to contain at least one intron and to have no additional genomic homologues. It remains to be determined, however, whether additional nonhomologous genes exist which code for proteins meeting the criteria required for classification as IFN-γ (refs 1, 2).

We thank Dr Lloyd Svedersky and Anna Hui for processing PBLs, Eileen Cunningham for performing *Xenopus* oocyte injections, Laurie May for interferon assays, Dr Nowell Stebbing for his support of those aspects of the work which were performed in the Biology Department at Genentech, Mark Vasser for deoxyoligonucleotide synthesis, Shirley Norton for plasmid DNA preparations, Dr Peter Seeburg for help with the DNA sequencing, Dr Ernst Rinderknecht and Vince Anicetti for preparing IFN-γ antiserum and Dr Yakov Gluzman for providing the COS-7 cell line.

Is the remnant of SN1006 composed of iron?

A. C. Fabian & G. C. Stewart

The remnant of the supernova explosion of AD 1006 (the brightest in recorded history) has a shell-like appearance at both radio and X-ray wavelengths. Einstein X-ray observations by Pye *et al.*[1] show a soft (photon energy $\varepsilon \leqslant \frac{1}{4}$ keV) filled interior surrounded by a harder ($\varepsilon \geqslant 1$ keV) unresolved ring of emission of radius ~15 arc min. Superficially it appears to be similar to most supernova remnants for which many studies have shown that the X-ray emission is thermal radiation from gas shock-heated by high-velocity ejecta. The spectrum[2] of parts of the edge of the remnant in the range $0.75 \leqslant \varepsilon \leqslant 10$ keV shows, however, no evidence for line emission. The spectral shape is consistent with a power-law perhaps due to a non-thermal mechanism. Moreover, the total mass of gas[1] required exceeds ~10 $M_\odot$ if it is of normal cosmic abundance. This is much greater than that expected for a remnant several hundred parsecs above the galactic plane. As no pulsar (or Crab-like morphology) is evident in the remnant of SN1006, Reynolds and Chevalier[3] have proposed that relativistic particles are being efficiently accelerated in shocked gas, and provide the major source of X rays through synchrotron emission. SN1006 is then an important region for the study of such acceleration processes. Here we reinvestigate a thermal interpretation and show that the element abundances associated with a Type I supernova[4–7] may provide an alternative explanation.

First we note that the observed lack of line emission from the edge of the remnant requires that sulphur, silicon and iron be at less than half their cosmic value relative to hydrogen[2]. We suggest that SN1006 was a Type I supernova of a few solar masses exploding into its own stellar wind (outer density $\rho \propto$

0028-0836/82/060508—02$01.00

r^{-2}). If the progenitor star was a pop II object (appropriate for its galactic position) then it is quite reasonable to suppose that the metal abundances are lower than the cosmic values. It is also possible that most of the metals are in the form of grains, which have not yet had time to combine with the hot gas. The stellar wind may have been associated with a red-giant phase (compare with the formation of planetary nebulae) or mass-transfer from a binary companion. The unresolved outer ring of emission[1] is then due to the shocked wind material. Gas shocked earlier (and closer to the contact discontinuity) is now denser and cooler than gas that is now just being shocked and swept up. Bremsstrahlung from a range of densities and temperatures in the shocked wind can then mimic a power-law spectrum.

The mass of the interior region has been estimated[1] as $\sim 6M_{\odot}$, if due to a gas of cosmic abundance (the temperature is $\sim 10^6$ K). Most of the emission is strongly peaked below 0.25 keV and could be completely due to lines. (The spectral resolution of the detector used for these observations is ~100% at these energies.) It has been widely suggested[4-7] that $\sim 1M_{\odot}$ of ^{56}Fe is ejected in a Type I supernova explosion. Line emission from such material can easily provide the interior X-ray flux from SN1006 if it has a distance of ~1 kpc. Interstellar absorption corresponding to a column density of $N_{\rm H} \approx 5 \times 10^{20}$ cm^{-2} is required to make this hypothesis consistent. One clear prediction is the possibility of detecting coronal line emission from the interior of the remnant in the optical. We expect a flux of $\approx 2 \times 10^{-7}$ erg s^{-1} cm^{-2} sr^{-1}.

The overall 0.2–2.5 keV spectrum[8] of SN1006, after subtraction of a contribution due to the Lupus Loop, does show evidence of an emission feature at ~0.6 keV. This is identified in ref. 8 as oxygen line emission, but we note that line emission due to calcium, which is also likely to be produced in a Type I outburst, occurs at a similar energy.

One major problem with any thermal interpretation of the X-ray observations lies in maintaining the interior of the remnant at 10^6 K. Adiabatic cooling on the expansion time scale erases all memory of the initial phase of expansion of the remnant. All but large scale velocity inhomogeneities should have decayed and the effects of radioactivity will have died away. We propose that a reverse shock[6] propagated back through the material at an age of a few hundred years. This requires the ejecta to have collided with roughly its own mass in that time. Perhaps the pre-supernova was surrounded by a wind with $\rho \propto r^{-2}$ at large radii ($R \leqslant 10^{18}$ cm), but with ρ constant (and total mass $\sim 1\,M_{\odot}$) at small radii (the wind velocity may have decreased and $\dot{M}$ increased) just before the supernova explosion. We have verified that present-day interior temperatures of $\sim 10^6$ K and reasonable luminosities are obtainable from such a situation by numerical computation of a spherically-symmetric explosion. The remnant is now freely expanding. No definite conclusion may be drawn, although the structure of young remnants depends strongly on the initial conditions in the ejecta and surrounding material. We consider that a complex structure is quite likely and that the appearance of young supernova remnants may be quite variable. The unusual properties of SN1006 discussed here may be partly due to its galactic location. The low temperature interior can be easily detected as the line-of-sight column density is low, and the expected low density of the surrounding interstellar medium allows a stellar wind to propagate freely to relatively large radii.

Optical confirmation that the interior of SN1006 is mostly composed of iron would strongly support the ^{56}Ni–^{56}Co–^{56}Fe radioactive interpretation of Type I light curves[4-7] and the related theoretical interpretation of the explosion itself. It would also make a more detailed discussion of the above admittedly *ad hoc* picture worthwhile. As discussed earlier, any more-normal abundance of a thermal gas requires that the progenitor was $>10\,M_{\odot}$, although it is out of the galactic plane by several hundred pc. This seems most unlikely and suggests that failure to detect coronal lines will provide support for rapid and efficient acceleration of cosmic rays in shocks (see ref. 3).

We conclude by considering the cup-shape appearance of the remnant of SN1006, as it appears in the X ray[1]. This could partly be due to the exploding star having been a member of a close binary system. The flow and subsequent shocks surrounding the companion could well have slowed the ejecta down in one direction, provided that the ejecta was roughly at its final velocity by the time it had crossed the binary orbit (say $\sim 10^{11}$ cm).

Asymmetric Balmer line profiles in Seyfert galaxies

A. Lawrence*

Center for Space Research, Massachusetts Institute of Technology,
Cambridge, Massachusetts 02139, USA

The profiles of the broad Balmer emission lines in Seyfert galaxies are often asymmetrical in the sense that the red wing extends further than the blue wing[1]. Explanations of the observed asymmetry have involved relativistic effects[2,3], infalling clouds immersed in an absorbing medium[4], and radially expanding clouds that are bright only on the side facing the ionizing source[4,5]. In all these hypotheses, the fact that only some galaxies have asymmetric emission lines was not considered important. Here I present evidence that both the degree of asymmetry and the difference between Hα and Hβ profiles are correlated with the overall line width. I also argue that current evidence is most compatible with an expanding system of optically thick clouds, in which the thickest clouds are moving fastest.

In his study of 36 Seyfert galaxies, Osterbrock[1] classified each Hβ profile as either symmetric, slightly asymmetric, or asymmetric. Figure 1 shows that all the 'asymmetric' objects have large values of the full width at zero intensity (FWZI) of Hα. There is a large overlap between the 'symmetric' and 'slightly asymmetric' populations, but in a probabilistic sense the 'slightly asymmetric' objects have values of FWZI (Hα) intermediate between the 'symmetric' and the 'asymmetric objects'. The profiles were not corrected for the instrumental resolution of the Lick scanner. As the instrumental profile[1] has FWZI ~2,000 km s^{-1} at Hβ, it is clear that the narrowest lines would always appear symmetric. However, most of the lines concerned are well resolved, and some of the observed asymmetries are very strong; the resolution effect cannot explain the proposed correlation.

Osterbrock[1] noted that an apparent asymmetry may actually be due to the broad weak feature Fe II λ4,924 appearing in the red wing of Hβ. I considered the strength of the well observed feature Fe II λ4,570, assuming it to correlate with Fe II λ4,924. There is no significant difference between the three populations (symmetric, slightly asymmetric, and asymmetric) for their distributions of the value of Fe II λ4,570/Hβ (not shown). Thus, an apparent asymmetry is probably not caused by FeII emission dominating the wings of Hβ. Of course, some extra, as yet undetected, component could appear redward of Hβ, and thus also increase the apparent overall line width. The FWZI is very difficult to measure, so that there may be important unknown systematic errors. However, I shall assume that the asymmetry, and its dependence on line width, is a real feature of the Balmer line profiles, and attempt to explain it in terms of the properties of the emission line cloud system as a whole. Let us reconsider the three categories of explanation mentioned above in the context of a dependency on line width.

---

* Present address: Royal Greenwich Observatory, Herstmonceux Castle, Hailsham, East Sussex BN27 1RP, UK.

(1) Objects with extremely broad lines must contain emission line gas moving at mildly relativistic velocities. Furthermore, if the clouds are bound to a massive central object and have virialized velocities, those moving fastest also have the largest gravitational redshift, and transverse Doppler shift (also always a redshift). We need not assume, as did Netzer[2] that the clouds are rotating in a disk, but only that typical velocities at each radius are comparable with the orbital velocity at that radius. These assumptions do predict that excess redward emission is increasingly important for objects with very fast moving clouds. Unfortunately, however, the effect is probably too small to explain at least some asymmetries. For clouds orbiting a massive body at ~15,000 km s^{-1}, we would expect that the red wing may extend ~10% further than the blue wing, whereas in some cases the red wing actually extends twice as far as the blue wing (see, for example, the profile of MKN374 reproduced in Fig. 1 of ref. 4, or the profile of PHL1093 reproduced in Fig. 1 of ref. 3). For instance, the profile of PHL1093 extends to −5,000 km s^{-1} and +10,000 km s^{-1}. This would require that clouds exist within 30 Schwarzchild radii of the massive central object, but move slower than the corresponding orbital velocity by a factor of 7.

(2) A consensus is forming that the anomalous ratios of Lα/Hα/Hβ observed in QSOs and Seyfert galaxies imply that the broad line emitting clouds are optically thick to the Balmer lines[5-12]. This means that the inner, ionized face of the cloud (that closest to the nucleus) will be brighter in the Balmer lines than the outer face. Most Balmer line photons detected by the observer will thus have originated in clouds on the far side of the ionizing source. A red excess then implies that the clouds on the far side are moving away from us; that is, the system is expanding radially outward[4,5]. The correlation found here between the degree of asymmetry and FWZI (Hα) (Fig. 1), further requires that faster moving clouds have a larger contrast in brightness between inner and outer faces, and thus presumably a larger Balmer line optical thickness (see Fig. 1 of ref. 5).

(3) Alternatively, one may consider isotropically emitting clouds immersed in an obscuring medium (for example, dust). Clouds on the far side of the system are seen through a larger column of the obscuring material, and are thus fainter. A fainter blue wing then means that clouds on the far side are moving towards us; that is the system is moving radially inward. The correlation between asymmetry and line width would then imply that objects with very wide lines have a larger overall amount of obscuring material. However, where those 'asymmetric' galaxies (all except MKN374) have been measured in X rays, they are all as luminous as, or more luminous than, the average Type 1 Seyfert galaxy[13,14]. By contrast, much evidence now suggests that only low luminosity Seyfert galaxies have appreciable amounts of obscuring material[15].

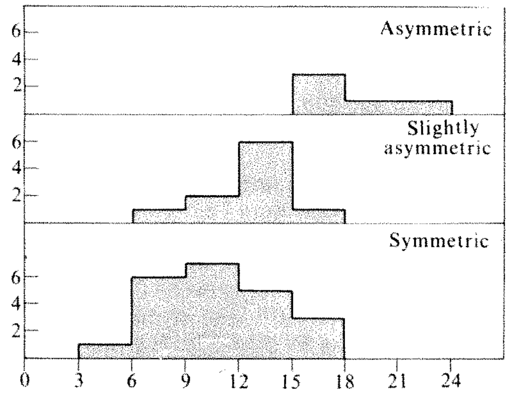

Fig. 1 Distribution of the values of the full width at zero intensity of Hα for the three different profile symmetry classes defined by Osterbrock[1].

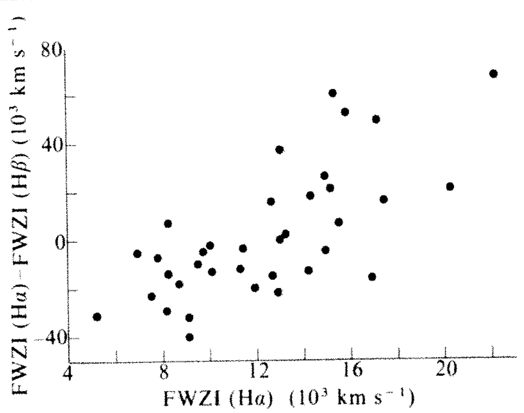

Fig. 2 The difference in full width at zero intensity between Hα and Hβ as a function of the full width at zero intensity of Hα. Values are from ref. 1.

There is further evidence that supports model (2). Figure 2 shows that the line-width difference, FWZI (Hα) − FWZI (Hβ), is an increasing function of FWZI (Hα). Such a correlation must be treated cautiously, as FWZI is difficult to measure. The value of FWHM is less ambiguous, but will be dominated by the relative strength of the narrow component of the emission line, which will have little bearing on the dynamics of the region forming the broad lines.

Line profiles have been described as 'logarithmic'[4] or 'triangular'[16]. In the latter case, FWZI is a better defined quantity than in the former case; but in general one may suspect that the measured value of FWZI is as much a function of the signal-to-noise ratio as intrinsic line width. In this situation FWZI could correlate with line strength; a strong line may be traced out further from the line centre. The difference in FWZI between Hα and Hβ could then correlate with the ratio of line strengths. However, from Osterbrock's data, there is no correlation between $I(\text{H}\alpha)/I(\text{H}\beta)$ and FWZI (Hα) − FWZI (Hβ) (not shown). Such signal-to-noise effects may still cause a correlation of line width difference with overall line width if, regardless of the total line intensities, Hα 'fades out' more slowly far from the line centre than does Hβ; that is to say, if the Balmer decrement is a function of cloud velocity. This suggests that, in general, different objects all have the same 'potential' profile; it is just a question of how much of the 'iceberg' is above water.

A consistent physical picture is that clouds are moving outward; that faster moving clouds are optically thicker; and that therefore they have a larger brightness contrast between inner and outer faces, and larger values of Hα/Hβ. Examination of these questions at higher resolution and sensitivity is desirable, as is examination of other spectral lines.

A molecular interpretation of stress corrosion in silica

Terry A. Michalske* & Stephen W. Freiman

Fracture and Deformation Division, National Bureau of Standards,
Washington DC 20234, USA

The mechanical strength of many glasses and ceramic materials decreases with time under static loading and ambient environments. This strength loss is associated with slow growth of pre-existing surface flaws due to a stress-corrosion process. To make long-term strength predictions for ceramic components, it is important to understand the stress-corrosion mechanism. We have studied stress corrosion in vitreous silica exposed to water and several non-aqueous environments and report here that environments which enhance stress corrosion are composed of molecular groups with electron donor sites on one end and proton donor sites at the other. These results suggest a detailed chemical model for the interaction of the environment with mechanically strained bonds in the solid at the tip of a crack. The proposed model also has implications for the long-term strength behaviour of a wide variety of brittle materials.

Several generalized mechanisms have been proposed to explain the effect of water-containing environments on crack growth in glass, for example, surface energy reduction[1], stress-enhanced dissolution[2], or dielectric charge compensation[3]. None of these models attempts to explain why water is such an effective stress-corrosion agent for glasses and ceramics nor does any suggest a specific stress-enhanced reaction. We now describe, on a molecular scale, a specific chemical reaction between strained bonds in vitreous silica and water, which can be used to explain environmentally enhanced crack growth. Experimental support of this model will be presented.

Previously published results[4] have shown that slow extension ($<10^{-2}$ m s^{-1}) of a crack in vitreous silica is facilitated by water in the environment. In the present study, crack growth data were taken in N_2 gas containing a small amount of water as well as in liquid water and other environments. Crack velocities were obtained by visual observation of crack extension in a double cantilever beam specimen[5], and the data plotted as crack velocity (V) versus stress intensity factor (K_I), where K_I is a measure of the stress field at the crack tip (Fig. 1). The important features are:

(1) In a water-free environment such as vacuum, spontaneous failure is observed when K_I reaches a critical value[4] (shown as a vertical line in Fig. 1).

(2) When small amounts of water vapour are present (moist N_2 gas), crack growth in the low velocity regime is enhanced (curve is shifted to lower K_I and V is a measurable function of K_I).

(3) A plateau in crack velocity is observed in water-containing environments (such as moist N_2). This plateau has been linked to crack growth limited by the rate of water transport to the tip of the moving crack[6]. At sufficiently high V, the plateau behaviour ends and rapid fracture is observed.

(4) Liquid water enhances crack growth over the entire range of crack velocity (10^{-9}–10^{-2} m s^{-1}).

Highly concentrated tensile stress fields are produced at a crack tip in a stressed brittle solid. Continuum approximations indicate that the bridging Si—O bond experiences strains >20%. The effect of this strain on the bonding molecular orbitals is not easy to predict but can be discussed in terms of a decrease in the overlap between atomic orbitals, thus increasing their availability for bonding with other species.

The molecular structure of water is the key to its ability to cause stress corrosion in vitreous silica. Oxygen atomic orbitals 2s, $2p_x$, and $2p_y$ form three hybrid orbitals—two of which σ-bond with hydrogen atoms. The remaining lone pair orbitals (one hybrid and the remaining p_z) are directed away from the hydrogen atoms. This arrangement results in a positive charge centre at the hydrogen end of the water molecule and a negative charge centre on the opposite end of the molecule where the lone pair orbitals are located.

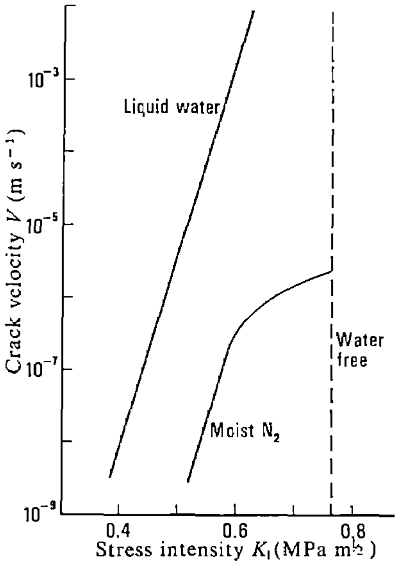

Fig. 1 Effect of water on slow crack growth in vitreous silica (curves represent best fit to experimental data).

Interaction between strained bridging bonds at a crack tip in silica and water from the environment can be represented by a three-step process (see Fig. 2).

Step 1—a water molecule from the environment attaches to a bridging Si—O—Si bond at the crack tip. The water molecule is aligned by: (1) formation of a hydrogen bond with the O_{br} atom; and (2) interaction of the lone pair orbitals from O_w with the Si atom. The lone pair orbital interaction may involve either Van der Waals attraction or some covalent bonding with unoccupied d orbitals of Si.

Step 2—a concerted reaction occurs in which proton transfer to the O_{br} is accomplished simultaneously with electron transfer from the O_w to the Si atom. As a result of this reaction, two new bonds are formed (one between O_w and Si and one between hydrogen and O_{br}; the original bridging bond (between O_{br} and Si) is destroyed.

Step 3—rupture of the hydrogen bond between O_w and transferred hydrogen occurs to yield surface Si—O—H groups on each fracture surface. As the hydrogen bond is weak, this step is expected to occur immediately after proton transfer. (Budd[7] has proposed a similar mechanism for the dissolution of silica in water; however, note that the present model for crack growth is not contingent on the removal of material from the fracture surface.)

Reaction rate theory[8] can be used to show how the proposed mechanism for bond rupture leads to enhanced crack growth rates. In vacuum, the entire energy of the bridging bond must be overcome before bond rupture can occur. (This energy is supplied in part by mechanical strain as well as by thermal contributions.) When water is present, the height of the energy barrier to bond rupture is reduced because charge transfer (step 2) provides an alternative, lower energy, reaction path. As the rate of a chemical reaction (in this case bond rupture) is reciprocally dependent on the exponent of the energy barrier, mechanisms that provide a lower energy activated state will enhance crack growth rates. We have omitted factors resulting from changes in the energy of the Si—O—Si bond due to adsorbed water (step 1) and the energy of the reaction products (step 3); these terms are not critical to this discussion.

---

0028-0836/82/060511—02$01.00

Experimentally, the role of the concerted reaction (simultaneous electron and proton transfer) as the rate of limiting step to fracture can be borne out through isotopic effects. Results of fracture experiments performed in deuterated water produced crack velocities consistently lower than those attained in normal water. This result can be analysed in terms of the different ground state vibrational energies of deuterium and protium resulting in different activation barriers for the two isotopes. The lower crack velocities measured in deuterated water agree with the larger energy barrier expected for deuteron transfer[9].

This model for chemical bond rupture presents some interesting implications. First, it suggests that environments other than water should enhance cracking in silica glass, if the species possess structural and bonding features similar to water, that is proton donor sites at one end of the molecule (or group) and lone pair orbitals at the other. The environmental molecule must also fit between the Si—O bond ($\approx$1.63 Å). To test this hypothesis, crack growth studies were conducted in vitreous silica exposed to gaseous ammonia (NH_3). Ammonia has a structure similar to water except that it has three orbitals σ-bonded to hydrogens leaving one lone pair orbital directed away from the hydrogen atoms (the N—H bond length is 0.94 Å). Figure 3 shows that NH_3 enhanced crack growth over the entire velocity range. When evaluating such data, it is important to be aware that small amounts of water in an inert carrier (N_2) can have large effects on crack growth rates. However, the enhancement due to small amounts of water is limited in velocity. As the NH_3 gas used in this experiment contained less H_2O than the N_2+H_2O gas mixture, the absence of a plateau indicates that the NH_3 was controlling the fracture behaviour. Crack growth experiments in hydrazine (N_2H_4) and formamide (CH_3NO) showed that these environments also controlled crack growth over the entire velocity range (Fig. 3). However, these environments were less effective (V–K_I curve shifted to higher K_I) then either water or ammonia, possibly due to steric hindrance and/or delocalization of lone pair orbitals. Note also that other non-aqueous environments such as carbon monoxide (contains lone pair orbital but no proton donor site) or acetonitrile (has high dipole moment, 3.92 D, but no localized lone pair orbital) have no measurable effect on crack growth rates.

This chemical model and its supporting experimental data represent an important step in the understanding of stress corrosion and the mechanical durability of materials. First, knowing that an effective stress-corrosion environment must have an electron donor site as well as a proton donor site allows for qualitative predictions of those environments which will decrease the long term strength of silica. As the structural bonds in the solid must also engage in the stress-corrosion reaction, qualitative predictions of the susceptibility of a range of solids to stress corrosion are also possible, that is the more covalent the solid the less susceptible it is to stress corrosion. This is supported by experimental evidence that single crystal silicon shows little, if any, susceptibility to stress corrosion with water (E. R. Fuller, personal communication). The ability to make such qualitative predictions is an advance over previous models which were intended only to explain stress corrosion in water.

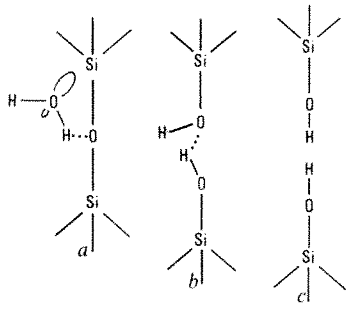

Fig. 2 Representation of the proposed reaction between water and a strained Si—O—Si bond at the crack tip. Reaction steps involve; (*a*) adsorption of water to Si—O bond, (*b*) concerted reaction involving simultaneous proton and electron transfer, and (*c*) formation of surface hydroxyls.

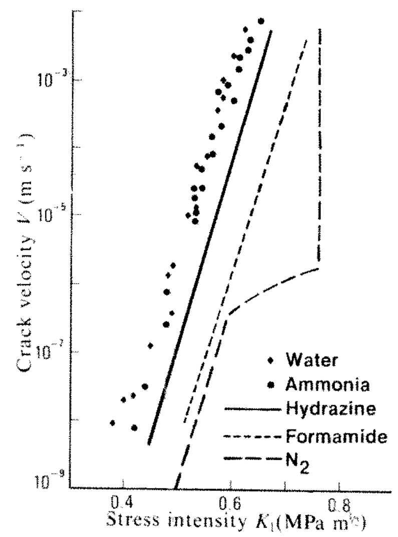

Fig. 3 Comparison of the effects of various environments on slow crack growth in vitreous silica at room temperature.

Second, this attempt at analysing the molecular interaction involved in the stress-corrosion process opens the door for detailed molecular calculations. Results of such calculations could allow quantitative predictions of the response of any solid material with any particular stress-corrosion environment.

Errors and resolution of thermal techniques for obtaining the geomagnetic intensity

D. Walton*

Physics Department, McMaster University, Hamilton, Ontario,
Canada L85 4L8

Techniques designed to obtain the intensity of the geomagnetic field by thermal demagnetization are subject to error due to differences between the ancient and laboratory cooling rate[1–3] and alteration in the physical and chemical properties of the magnetic grains which can lead to a systematic overestimate of the field by as much as 50%. A new technique is proposed here which uses the change in moment with time at a fixed temperature in conjunction with the magnetization acquired on cooling to determine the ancient field and ancient cooling rate. This new technique also appears to be able to detect alteration with greater sensitivity.

0028-0836/82/060512—04$01.00

It has been found that the magnitude of both the above errors increases with temperature. Alteration often begins at relatively low temperatures, and increases smoothly as the temperature increases. The cooling rate correction in effect also increases with temperature. If alteration results in a decrease in magnetization the result is an accelerating decrease in moment with increasing temperature. Consequently the abrupt change in the slope of a natural remanent magnetism (NRM)/palaeothermal remanent magnetism (PTRM) plot which has been used to signal the onset of alteration is not always present. This will result in an accelerating apparent increase in the intensity of the ancient field. An extreme example of this behaviour is shown in Fig. 1: while the NRM/PTRM plot settles down to a straight line above 300 °C the grains involved have probably undergone alteration. Thus the reliability of using the slope of the straight line portion is questionable.

The technique described here not only corrects for the difference between laboratory and ancient cooling rates, but enables the ancient cooling rate to be estimated. Preliminary results indicate that the ancient cooling rate could vary by more than an order of magnitude. Thus the error due to differences in cooling rate can be random even for pottery. These results will also reveal that alteration begins to appear at surprisingly low temperatures.

As derived in ref. 1, the moment produced on cooling is

$$M = H_A \int_{v_1}^{v_2} \frac{J_B J}{3kT_B} v^2 N(v)\,\mathrm{d}v \qquad (1)$$

where H_A is the ancient field, J_B the saturation magnetization at the blocking temperature T_B, v is the grain volume, $N(v)$ the grain size distribution and v_2 and v_1 the volumes of grains blocked at the higher temperature and lower temperature respectively.

The quantities J_B and T_B depend on the rate of cooling[1]. Let a variable α be defined as

$$\alpha = \frac{\mathrm{d}}{\mathrm{d}t}\left(\frac{K}{T}\right) \qquad (2)$$

where K is the anisotropy constant.

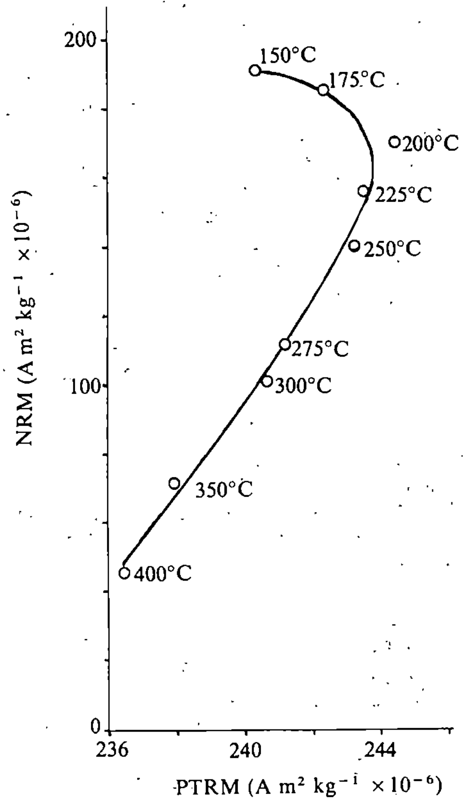

Fig. 1 The change in moment of a sample of Attic pottery after successive heatings to the temperatures (O). Two coolings are performed from each temperature, the first in a field of 70 μT, the second in zero field to establish the loss of the NRM.

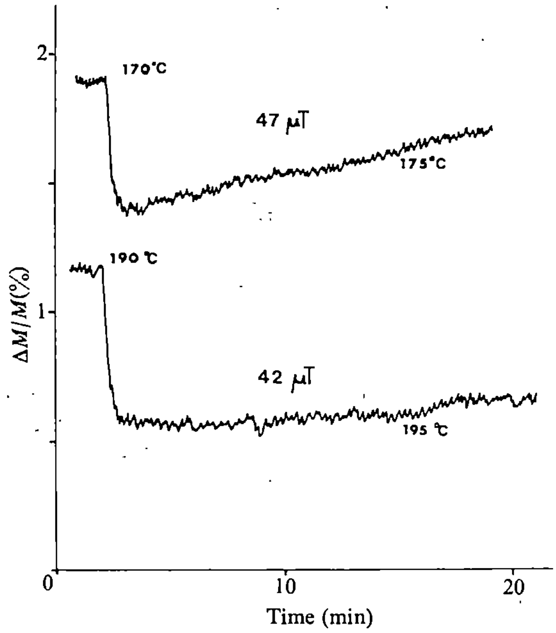

Fig. 2 The change in moment, M, with time of a sample of Attic pottery on heating by 5 °C from two temperatures at two different fields. The zero level for both curves has been shifted by an arbitrary amount.

The moment is then proportional to $(\ln ck/v\alpha)^n$ where c is a frequency factor.

A cooling time constant τ can be defined as

$$\tau = \frac{k}{v\alpha} \qquad (3)$$

In general τ is temperature dependent. In particular if the sample cools according to Newton's law of cooling, τ decreases as the temperature increases.

The coefficient n results from approximating the temperature dependence of J as

$$J = J_0(1 - T/T_c)^n \qquad (4)$$

For magnetite $n \cong \frac{1}{2}$ while for haematite it is $\frac{1}{4}$.

The thermal techniques for obtaining the ancient field pioneered by Thellier, involve comparing a moment introduced on cooling in the laboratory field with that removed on heating to successively higher temperatures. A knowledge of the ancient cooling rate is necessary for an accurate determination of the ancient field intensity. This knowledge need only be approximate because the function $(\ln c\tau)^n$ is only weakly dependent on τ.

Assuming that the sample is heated rapidly from a temperature T_0 to a higher temperature T, when the sample reaches T part of the magnetic moment will reside in grains whose blocking temperatures are both above and below T. Those grains whose blocking temperatures are lowest will first come to equilibrium with the applied magnetic field. But the approach to equilibrium of grains whose blocking temperatures are less than T will result in a loss of moment; this produces a decrease in moment followed by an increase when the distributions of those grains with blocking temperatures higher than T begin to reach equilibrium.

The rate of change of the moment[1] with ln ct is

$$\frac{\partial M}{\partial \ln ct} = \frac{\pi\sqrt{2}}{e}(n_0 - n_{\mathrm{eq}})J\left(\frac{kT}{K}\right)^2(\ln ct)\left[N\left(\frac{kT}{k}\ln ct\right)\right] \qquad (5)$$

n_0 is determined by the moment distribution produced on cooling and is

$$n_0 = \frac{J_B v H_A}{3kT_B} \tag{6}$$

and

$$n_{eq} = \frac{J^v H_L}{3kT} \tag{7}$$

where H_L is the laboratory field.

As the sample is held at the temperature T, initially smaller grains will come to equilibrium followed by grains of increasingly larger volume. Initially, then, the distribution of the grains with low blocking temperature come to equilibrium followed by grains which blocked at higher temperatures. Since T_B increases and J_B decreases as v increases, n_0 will decrease with time. On the other hand, n_{eq} increases with time as v increases.

Now $\partial M/\partial \ln ct$ will be zero when $n_{eq} = n_0$, when

$$\frac{H_A}{H_l} = \frac{JT_B}{J_B T} \tag{8}$$

Now

$$\frac{\bar{K}_B v}{3kT_B} = \ln c\tau \quad \text{and} \quad \frac{\bar{K} v}{3kT} = \ln ct \tag{9}$$

where t is the time at which $\partial M/\partial \ln ct = 0$ and $\bar{K}_B$ is the anisotropy constant evaluated at the blocking temperature.

So if

$$\bar{K} = aJ^p \tag{10}$$

$$\frac{J}{J_B} = \left(\frac{T \ln ct}{T_B \ln c\tau}\right)^{1/p} \tag{11}$$

Using equation (4)

$$\frac{J_B}{J} = \left(\frac{1 - T_B/T_c}{1 - T/T_c}\right)^n = \left(1 + \frac{T - T_B}{T_c - T}\right)^n$$

Bearing in mind that T_B is close to T this equation may be expanded. After some algebra equation (8) becomes

$$H_A \ln c\tau_A = H_L \ln ct\left\{1 + \left[\frac{(p-1)n}{(pn-1) + T/Tc}\right] \times [\ln (t/\tau_A)/\ln c\tau_A]\right\} \tag{12}$$

where τ_A is the ancient cooling time constant.

Figure 2 displays the moment as a function of time for a sample of Attic pottery. The data were obtained with a highly sensitive magnetometer capable of obtaining moments, while the sample is held at an elevated temperature, with an accuracy of better than 0.1%. It will be described in detail elsewhere.

Since there are two values for H and two values of t, an approximate value for c may be deduced, if the second term in the brackets in equation (12) is neglected, c is $\sim 7 \times 10^7\ \mathrm{s}^{-1}$.

It is impossible to obtain the ancient field unless τ_A is known, although it need not be known precisely because it enters equation (12) as $\ln c\tau_A$. This requires another relation which can be obtained from the dependence of the moment on the laboratory cooling rate, as the moment gain on cooling is proportional to $(\ln c\tau_L)^n$. For example, on further heating to 250 °C the sample revealed a decrease in moment when cooled to 190 °C relative to that observed after it had been cooled from 195 °C. On decreasing the cooling rate by an order of magnitude (increasing τ_L by a factor of 10) half the lost moment was recovered. Thus a two order of magnitude increase in τ_L would be required to restore completely the moment lost between 195 and 250 °C. As shown in ref. 1 the moment introduced on cooling is proportional to $H_L(\ln c\tau_L)^n$. Hence,

$$H_A(\ln c\tau_A)^n = H_L(\ln c\tau'_L)^n \tag{13}$$

where $\tau' L$ is that cooling time constant that would be required to restore completely the moment lost by heating to 250 °C.

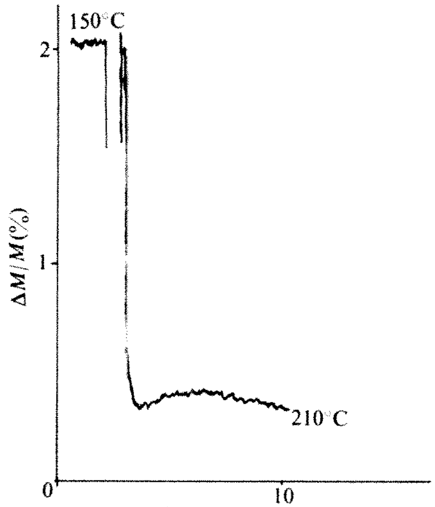

Fig. 3 The change in moment, M, with time of a sample of Attic pottery on heating to 210 from 150 °C. The zero is arbitrary, and two changes of zero suppression were made to keep the recorder pen on scale. The decrease in moment apparent after about 7 min is due to alteration of the magnetic constituents.

Using equation (12), and taking $n = \frac{1}{2}$ which is appropriate for magnetite, $\tau_A \sim 100$ s—a rather low value. Other samples of Attic pottery yielded values about an order of magnitude higher. Typically τ_A appears to be of the order of 1,000 s for this pottery.

H_A for this sample is 46 μT. The modified Thellier method used for a previous determination yielded $H_A = 63$ μT for a sample from the same sherd. The difference is rather more than can be accounted for by differences in cooling rate. Alteration probably affected the old result.

This technique consists of holding the sample at an elevated temperature and monitoring the change in its moment with time. If the laboratory field is within ~10% of the ancient field the moment will show a characteristic decrease followed by an increase. The time at which the inflection occurs yields the product $H_A \ln c\tau_A$. The values for $\ln c\tau_A$ and H_A can be separated by obtaining the laboratory cooling rate for which no change in moment occurs on cooling to a fixed temperature in the chosen laboratory field.

With this particular material the onset of mineral alteration seems to result in a net loss of moment by the grains. This has manifested itself by an anomalously large τ_L. Thus in the second step of the method either a proportionally greater decrease in rate or a larger H_L is necessary to restore the lost moment. Further heating again requires either a further increase in τ_L or an increase in H_L.

It is possible for alteration to result in an increase in moment; in that event H_L or τ_L must be continually decreased. If when alteration is in progress the moment should decrease with time it can sometimes be identified as follows: if H_L is chosen so that the moment shows the characteristic decrease followed by an increase when alteration is absent at lower temperatures, the moment will decrease when alteration begins. Then it is possible for the moment to decrease then increase and then decrease again, due to alteration. An example of this behaviour is shown in Fig. 3.

Probably the most surprising aspect of the alteration is that it has manifested itself at temperatures as low as 210 °C. Also, of 18 samples of Attic pottery 15 showed evidence of alteration at temperatures below 250 °C.

Most investigators obtain the ratio of the ancient to laboratory fields from the slope of a 'best' straight line drawn through the points in a plot of the natural remanent moment against the moment introduced by a laboratory field at successively higher temperatures. Unfortunately, in most cases it is difficult to demagnetize the sample sufficiently to draw a meaningful line unless temperatures above 300 °C are used, where the present results indicate that alteration may be present. In the event that those points are displaced from their true positions by increasing amounts the slope will be wrong.

The effect of cooling rate has been thought to introduce a correction which would be a constant fraction of the ancient field, assuming that the ancient cooling rate was within a factor of 2 or 3 for all pottery (at least those fired in the same area). Unfortunately the preliminary results obtained with Attic pottery indicate rather more variability. One advantage of the present technique is that measurements at low temperatures yield the ancient field. Thus, provided alteration does not begin before all viscous moments are removed, a value for H_A can always be obtained. If an accurate value of H_A is not required it is possible to assume a value for τ_A, in which case one, or at most two, temperatures are all that is necessary.

Finally, the previous measurements[4] on Attic pottery should be repeated, as they use values obtained above 300 °C. These measurements are in progress, and the results will be published in due course. Preliminary results indicate that the shape of the curve of intensity plotted against time has not changed radically, but that the values of intensity have decreased by ~15–25%.

I thank the National Science and Engineering Research Council of Canada for support.

Sm–Nd dating and cooling history of Scourian granulites, Sutherland

F. J. Humphries & R. A. Cliff

Department of Earth Sciences, The University of Leeds,
Leeds LS2 9JT, UK

The Scourian gneisses of the Lewisian complex of north-west Scotland have been the subject of many geochronological investigations. Sm–Nd whole-rock measurements suggest that the protoliths of the Lewisian complex differentiated 2.92±0.05 Gyr ago from an approximately chrondritic mantle[1]. Rb–Sr and Pb–Pb whole-rock ages between ~2.8 and 2.6 Gyr reflect subsequent depletion in Rb and U (refs 2, 3) which has generally been associated with granulite facies metamorphism. Zircons which are thought to have crystallized during this metamorphism have also given U–Pb ages of 2.66 Gyr (ref. 4). This granulite facies metamorphism, involving pressures in excess of 10 kbar and peak temperatures estimated between 820±50 °C (ref. 5) and 1,250 °C (refs 6, 7), affects a terrain including supracrustal rocks[7] and thus implies a major tectonic event. We report here the first geochronological data measured on mineral assemblages that have also provided estimates of the conditions of metamorphism. Such measurements are possible because the major minerals of granulite facies assemblages show an unusually favourable spread in Sm/Nd ratios; garnet, especially, is strongly enriched in Sm (ref. 8). Data for three garnetiferous basic gneiss assemblages suggest that closure of the Sm–Nd system occurred significantly later than the peak of the metamorphism.

The textures of Scourian basic gneisses are complex and it has been suggested that three stages of granulite facies mineral growth can be recognized[6,9]. The earliest assemblage consists of garnet and clinopyroxene with minor plagioclase and hornblende. During the second stage garnet broke down to form coronas of plagioclase, orthopyroxene and magnetite. Subsequently regrowth of garnet, especially rimming grains of orthopyroxene and magnetite, occurred. Locally, much coarser (up to 150 mm) aggregates of garnet and clinopyroxene occur within the garnetiferous basic gneisses; it has been suggested that these are the result of exsolution from an Fe–Al rich amphibole[10]. Sample 3966 'coarse' is an example of these aggregates, occurring in a typical basic gneiss represented by 3966 'fine'. There is a sharp contact between the two assemblages. The third sample, 40117, is also a typical garnetiferous basic gneiss. All three assemblages show, to varying degrees, the three stages of mineral growth noted above.

The results of the isotopic analyses are given in Table 1 and are plotted on Sm–Nd isochron diagrams in Fig. 1. In each case the data show some scatter in excess of analytical error but the three calculated ages are similar. 40117 gives an age of 2.49 ± 0.12 Gyr with an initial $^{143}Nd/^{144}Nd$ ratio of 0.50944 ± 0.00016, 3966 'fine' gives 2.49 ± 0.03 Gyr with an initial ratio of 0.50949 ± 0.00009 and 3966 'coarse' gives 2.49 ± 0.03 Gyr with an initial ratio of 0.50973 ± 0.00008. The garnet and clinopyroxene in the analysed mineral separates are from the earliest stage of mineral growth whereas the other analysed mineral separates also include grains from the later stages. The isotopic relationships between the minerals show that the different stages of mineral growth cannot be resolved with the present data. Moreover, the earliest formed minerals, garnet and clinopyroxene, systematically give ages that are up to 0.05 Gyr younger, rather than older, than those calculated for the complete mineral assemblage; thus the excess scatter in the calculated errorchrons does not simply reflect differences in the age of formation of the various minerals.

The consistency of the ages from all three samples may reflect a relatively short overall duration for the granulite facies metamorphism, or they may date closure of the Sm–Nd system at some stage in the post-metamorphic cooling. The latter is strongly supported by the interpretation of the 2.66-Gyr zircon age as the result of zircon growth during granulite facies metamorphism[4], and by 2.56 Gyr Rb–Sr ages on pegmatites[11] which intruded the basic gneisses after the granulite facies metamorphism[12]. Theoretical closure temperatures can be calculated from experimentally determined diffusion coefficients[13], but such data are only available for Sm in grossular and pyrope at temperatures between 1,100 and 1,500 °C (see ref. 14 and

GT, garnet; CPX, clinopyroxene; OPX, orthopyroxene; PLAG, plagioclase; MT, magnetite; HB, hornblende. Most of the analytical uncertainty on the $^{147}Sm/^{144}Nd$ ratio is from isotope dilution analysis of the Sm. For many of these analyses, Sm was run on a single Ta filament. Greater precision (± 0.05%) has since been obtained by running Sm on a triple filament assembly with a central Re and side Ta filament. The high concentrations in plagioglase from sample 3966 'coarse' reflect the presence of small discrete grains of apatite within the sample.

0028–0836/82/060515—03$01.00

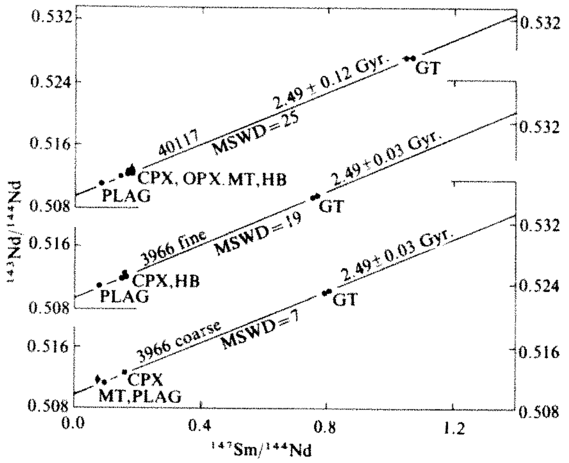

Fig. 1 Sm–Nd diagrams. $\lambda^{147}\text{Sm} = 6.54 \times 10^{-12}\,\text{yr}^{-1}$. The regression errors have been multiplied by $\sqrt{\text{MSWD}}$ to make allowance for the excess scatter. The magnetite (MT) data were omitted from the regression analysis of sample 3966 'coarse'.

Table 2). To apply these data to Nd isotopes it must be assumed that (1) the diffusion behaviour of Nd is similar to that of Sm, (2) extrapolation from the experimental to geological temperature ranges using the Arrhenius equation is valid, and (3) the difference in diffusion coefficients between pure grossular and pure pyrope encompasses the value appropriate to the dated garnets ($\text{Alm}_{1.6}\text{Pyr}_{0.9}\text{Gross}_{0.5}$). Consideration of anion porosity[15] suggests that Sm diffusion coefficients should increase systematically across the solid solution series from pyrope to grossular and for the end members this is confirmed by the experimental data (Table 2). Because of the variation in activation energy with composition, at the temperatures of interest it is expected that D_{pyrope} will be greater than $D_{\text{grossular}}$; closure temperatures based on these values should bracket the closure temperature for the analysed garnets.

Calculated closure temperatures are given in Table 2. The result for pyrope does not exceed 600 °C even in conditions of very rapid cooling (100 °C Myr^{-1}); for grossular the corresponding value is 775 °C. In each case a slower cooling rate reduces the calculated closure temperatures. These temperatures are below even the lowest estimated conditions at the peak of the granulite facies metamorphism (820 °C)[5] so that the available diffusion data also suggest that the measured ages should be interpreted as cooling ages.

While the concordant Sm–Nd ages indicate a close approach to isotopic equilibrium within the individual assemblages, that is between grains of 1–5 mm diameter, the initial ratios for the two assemblages from 3966 are significantly different, thus showing that the scale of diffusion 2.49 Gyr ago was ≪ 100 mm. The higher initial ratio of 3966 'coarse' also shows that the higher bulk Sm/Nd ratio of this assemblage was established appreciably earlier than 2.49 Gyr. Figure 2 shows the evolution of ^{143}Nd/^{144}Nd with time for 3966. Because 3966 'coarse' contributes insignificantly to the Sm–Nd mass balance for the whole sample, the pre-metamorphic evolution of this sample is approximately represented by the growth line for 3966 'fine'. The fact that this line intersects the error ellipse for the Lewisian whole-rock suite[1] supports this interpretation. During metamorphism at ~2.62 ± 0.12 Gyr, 3966 'coarse' was formed as an isolated sub-system with higher Sm/Nd and its ^{143}Nd/^{144}Nd began to grow at a correspondingly faster rate. In view of the difficulties in estimating modes in coarse-grained rocks, this estimate of the time of segregation is very tentative, although the intersection age agrees well with the 2.66 Gyr age of metamorphic zircons[4].

Table 2 Diffusion in garnet

Mineral	Species	D_0 (m^2 s^{-1})	E (kJ mol^{-1})	Ref.	T_c*
Pyrope	Sm	2.6×10^{-12}	140	14	480
Grossular	Sm	4.3×10^{-4}	331	14	700
Almandine-pyrope	Fe–Mg inter-diffusion	6.11×10^{-4}	344	17	725

Diffusion rate, D, at temperature T is given by the Arrhenius relationship:

$$D = D_0 \exp(-E/RT)$$

where R is the gas constant. Theoretical closure temperature, T_c is related to the cooling rate $\dot{T}$ by:

$$E/RT_c = \ln(-AD_0RT_c^2/E\dot{T}a^2) \qquad \text{(ref. 13 equation (11))}$$

where a is the radius of the grain; A is a geometric factor, equal to 55 for radial diffusion in a sphere.

* Closure temperature calculated for a cooling rate of 5 °C Myr^{-1}.

The relation between the isotopic ages and the temperature history based on conventional geothermometry is not as clear as the above discussion would suggest. Temperature estimates for the metamorphic peak have been based on feldspar thermometry[6], pyroxene exsolution[6,7] and Fe–Mg binary exchange equilibrium between garnet and clinopyroxene[5]. In conditions of slow cooling, these reactions are also likely to continue after the metamorphic peak, like diffusion of Nd isotopes, until the relevant closure temperature is reached and the compositions of the minerals are frozen in. Realistic closure temperatures for the metamorphic reactions are difficult to estimate as the commonly used reactions involve major components whose diffusion rates may be strongly coupled with diffusion of other major components which do not directly participate in the reaction[16].

For binary exchange reactions there may be further problems where the two minerals involved have different closure temperatures. Consider the Fe–Mg exchange between garnet and clinopyroxene. Apparent equilibration temperatures for this reaction in rocks from Scourie are typically between 750 and 850 °C (refs 5, 10, and F.J.H. unpublished data on the dated samples). Experimental data on the interdiffusion of Fe and Mg in garnet[17] (Table 2) indicate a closure temperature of 725 ± 30 °C for 5 °C Myr^{-1} cooling rate. Diffusion is likely to be slower in clinopyroxene which would therefore close at a higher temperature than garnet. Below the closure temperature of clinopyroxene, garnet may potentially exchange with other Fe–Mg minerals, for example orthopyroxene in the coronas around garnets. This would result in a more Fe-rich garnet and lead to erroneously low temperature estimates. The consistency of temperatures calculated from garnet–clinopyroxene pairs and

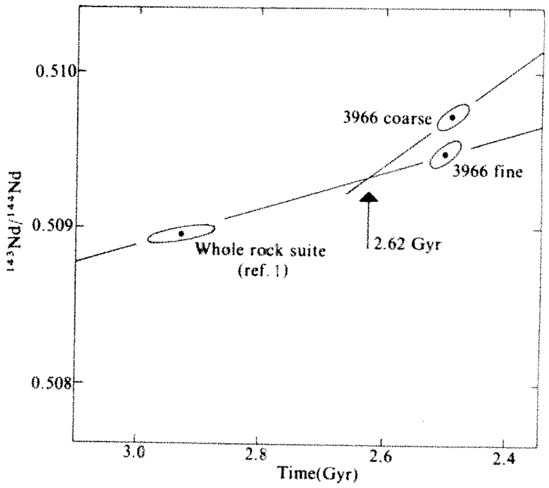

Fig. 2 Nd isotopic evolution in sample 3966. The data points for 3966 'coarse' and 3966 'fine' are the ages and initial ratios of the respective mineral isochrons. The data point for Lewisian whole rocks is the age and initial ratio of the whole-rock isochron from ref. 1. The 95% confidence ellipses were calculated following ref. 18. The lines representing the growth of ^{143}Nd/^{144}Nd with time were calculated from estimated 'whole-rock' Sm/Nd ratios for 3966 'coarse' and 3966 'fine', based on modal analyses and the Sm and Nd contents of the analysed minerals.

likely closure temperatures perhaps indicates that this is not a major problem in the rocks considered here, although it may explain some of the lower temperatures that have been reported[5]. From the above discussion we know that binary exchange thermometers will not record the peak metamorphic temperatures if the relevant closure temperatures are exceeded. Thus neither the estimate of 820 °C based on such reactions[5] nor the higher estimate of 1,250 °C (refs 6, 7), which was criticized on other grounds by Rollinson[5], are well founded and the peak conditions of Scourian metamorphism remain uncertain.

From the estimated closure temperatures for Nd and Fe-Mg in garnet it is suggested that the temperatures recorded by the garnet–clinopyroxene geothermometer date from a time before 2.49 Gyr. After the metamorphic peak close to 2.66 Gyr, the Scourian complex cooled at such a rate that temperatures did not drop below ~600 °C until after 2.49 Gyr.

Our data confirm the potential of Sm–Nd dating in basic granulites and the ability to determine metamorphic conditions and isotopic ages on the same samples. However, diffusion of rare earth elements between mineral grains is sufficiently rapid in granulite facies conditions to prevent the preservation of Sm–Nd crystallization ages. Also the uncertain relationships between closure of different geochemical systems is a fundamental limitation on our ability to determine metamorphic conditions.

Isotope geochemical research at Leeds is supported by the NERC. F.J.H. acknowledges receipt of a NERC research studentship. We thank Professor M. J. O'Hara for sample 3966, and Dr M. H. Dodson for constructive criticisms.

Asphalt in carbon-14-dated archaeological samples from Terqa, Syria

Mahalakshmi I. Venkatesan*, Timothy W. Linick†, Hans E. Suess*† & Giorgio Buccellati‡

Institutes of *Geophysics and Planetary Physics and ‡Archeology, University of California, Los Angeles, California 90024, USA
† Department of Chemistry, University of California, San Diego, La Jolla, California 92093, USA

The presence of fossil fuel compounds in archaeological samples giving ages much higher than expected has long been suspected but never proved by appropriate chemical analyses. An excessively high conventional ^{14}C age was found in an archaeological charcoal sample from Terqa, Syria[1] (S313, Table 1). Its ^{14}C age of 28,700 yr BP was at variance with the archaeological context, and with the ^{14}C age of several other samples[1] (such as S283, Table 1) obtained from the same area and expected to date from ~3000 BC or younger. The inconsistency can be explained by assuming contamination with geologically old material—either industrial petroleum products or ancient asphalt. We report here organic geochemical investigations of the sample S313 and of sample S267, which gave a ^{14}C age ~2,000 yr too old. A third charcoal sample (S283) from the same area, whose ^{14}C age was consistent with its known historical age, and an asphalt sample found stuck to the bottom of a goblet from another site in the area dated at 1700 BC on typological grounds, were also analysed. Similar studies of used crankcase oils from motor vehicles, weathered 0–2 yr, and of hydraulic transmission fluid show that modern motor oil cannot be the contaminant at this excavation site. Our data clearly indicate that ancient asphalt must be the source of contamination. Caution should be exercised, therefore, in interpreting ^{14}C dates of archaeological samples from areas containing asphalt or other fossil fuel deposits.

Fine charcoal samples were collected by D. Berry from and around an ancient dumpsite outside the ancient city wall of Terqa, Syria and stored in glass jars (see ref. 1 for details). Obvious extraneous matter, such as rootlets, was removed; the samples were converted to acetylene via lithium carbide[2] and counted in stainless-steel gas proportional β-detectors for ^{14}C (Table 1).

The samples were Soxhlet-extracted successively with methanol and toluene/methanol (3 : 7 v/v) for 100 h. The extract was separated into hexane-insoluble (asphaltenes) and hexane-soluble (lipid or bitumen) fractions. The latter was fractionated into aliphatic and aromatic hydrocarbons and resins by silica gel column chromatography[4]. Samples S313 and S267 had asphaltenes and S267 also had traces of elemental sulphur (Table 1). Sample S283 had no asphaltenes, but a considerable amount of elemental sulphur and resinous material characteristic of wood. The fractions were analysed by gas chromatography (GC) and GC–mass spectrometry. Sample S313 was ^{14}C tested again after exhaustive extraction with toluene methanol (3 : 7 v/v) and methylene chloride. After rinsing with 1 l of acetone to remove other organic solvents, the material was analysed for ^{14}C measurements[2]. The ^{14}C age determined was not significantly different from that found previously for the unextracted sample (Table 1).

The gravimetric (Table 1) and GC analyses revealed that the greater the discrepancy in age, the larger is the content of asphaltenes and hydrocarbons. The alkane profile of the control sample (S283) with correct ^{14}C age was very different from those of the other two samples (Fig. 1, S267 not shown).

The normal alkanes in sample S283 ranged from C_{15} to C_{31} overlying a broad unresolved complex mixture (Fig. 1). Pristane and phytane are almost equally abundant. The carbon preference index (CPI) is ~2.0, indicative of immature hydrocarbons derived from higher plant waxes[5]. Triterpanes are present in minor amounts and are mainly 17α(H), 21β(H)-hopanes. The lipids in this charcoal sample appear to be of mixed secondary origin from biogenic sources and traces of petroleum-like products seem to have been leached into the area by water over thousands of years. The presence of a few pyrolytic arenes[6] is consistent with such an input. The alkanes in samples S313 and S267 are predominantly cyclic triterpanes with minor amounts of steranes. Normal alkanes are found only in trace amounts (much less than in crude oils). The triterpanes consist mainly of a homologous series of 17α(H), 21β(H)-hopanes and the extended hopanes ($\geq C_{31}$) occur as their two diastereomers (*R* and *S* at position 22) in approximately equal abundance[7]. In fact, the ratio of the first eluting epimer (22*S*) to the second eluting epimer (22*R*) in the C_{31}–C_{35} hopane series is ~1.4 (measured with baseline GC resolution), consistent with mature ancient bitumen[8]. The aromatic fraction exhibits an unresolved hump over the entire boiling range, indicating heavy weathering of the lipid fraction. The low *n*-alkane content, such as that found in sample S283, could be masked in the other two samples which contain relatively higher concentrations of triterpanes from the presumed (fossil fuel) contamination.

Possible sources of oil contamination in the area are crankcase oil from motor vehicles, although the samples were retrieved from a depth of 2 m below the surface of an area with little or no

0028–0836/82/060517—03$01.00

Table 1 Organic geochemical results for archaeological samples from Terqa, Syria

Sample	Conventional ^{14}C age (BP)	Elemental sulphur* (μg per g)	Asphaltenes* (μg per g)	Hexane -soluble lipids* (μg per g)	Aliphatic fraction* (μg per g)	Aromatic fraction* (μg per g)	Asphaltenes H/C	Asphaltenes $\delta^{13}C$ (‰ PDB)	Asphaltenes $\delta^{18}O$ PDB	Asphaltenes δD (‰ SMOW)
Charcoal S283	4,110±70	~15	—	144	41	53	—	—	—	—
Charcoal S267	5,700±100	Trace	900	1,440	260	86	1.27	−27.61	−15.58	−60.9
Charcoal S313	28,700±1,100 28,200±1,300†	—	5,300	14,560	2,790	1,820	1.03	−27.61	−15.88	Lost
Asphalt from goblet	—	—	104,000	43,000	4,860	2,410	1.23	−27.95	−15.58	−60.0

1σ statistical counting errors are given for the conventional BP dates. The calibrated dates in centuries can be obtained using the table in ref 3. The age of the charcoal samples expected from stratigraphy is 3000 BC. PDB, Peedee belemnite. SMOW, standard mean ocean water. La Jolla Laboratory numbers in sequence of increasing ^{14}C are: LJ 5052, LJ 4823 and LJ 5031.

* Gravimetric determination. † After exhaustive extraction with organic solvents.

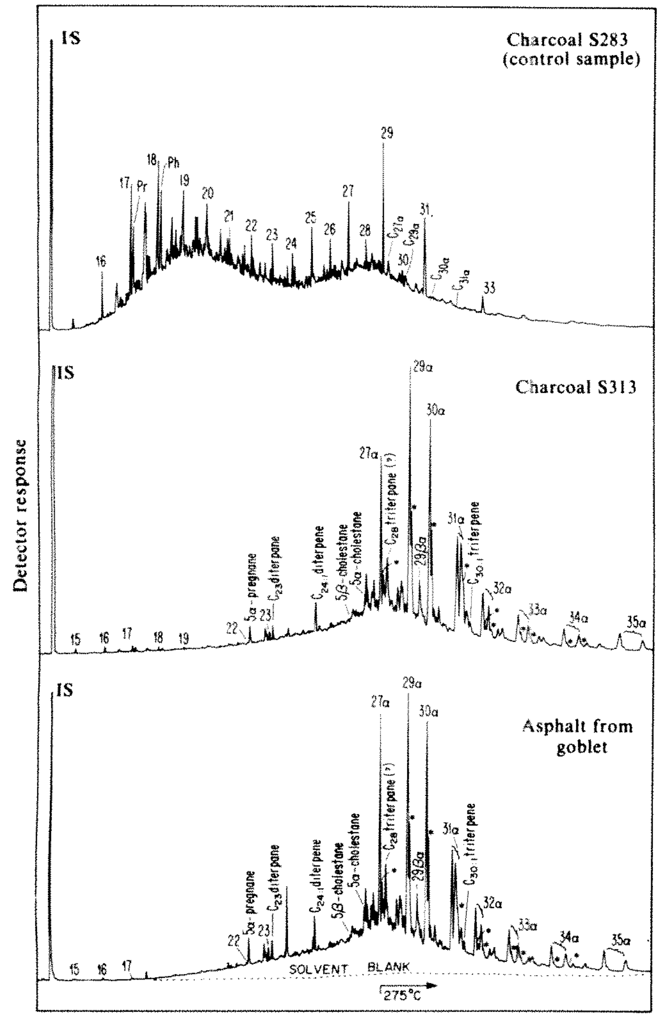

Fig. 1 Gas chromatograms of aliphatic fraction from charcoal and asphalt samples from Terqa, Syria. A Hewlett-Packard 5840A gas chromatograph equipped with a fused silica capillary column (SP-2100, 25 m, 0.2 mm i.d.) was used. The column was temperature-programmed for 35–275 $°C_{iso}$ at 4 °C per min. A 30 m, SE-54 (J&W) column of the same specifications was used for GC–MS analysis on a Finnigan model 4000 quadrupole mass spectrometer interfaced with a Finnigan Model 9610 gas chromatograph. The mass spectra data were processed with a Finnigan Incos Model 2300 data system. *n*-Alkanes were identified by their retention times. Di- and triterpenoids were identified from m/z 191 mass chromatograms. Triterpanes $\geq C_{31}$ occur as *R* and *S* diastereomers. IS, internal standard (hexamethylbenzene); numbers (except when followed by α or β) refer to *n*-alkanes; Pr, pristane; 27α, 29α, and so on refer to 17α(H), 21β(H)-hopanes with the designated carbon numbers; 29βα is a C_{29} moretane (17β(H), 21α(H)). * Refers to the homologous series of methylated hopanes. Charcoal sample S267 had the same GC profile as S313 and therefore is not shown here.

traffic until a few years ago, and ancient asphalt. The area on the Euphrates in Syria contains asphalt[9].

We analysed the hydrocarbon fractions of fresh hydraulic fluid and crankcase oil, fresh and weathered for ~1 month to 2 yr. The crankcase oil was collected from underneath impounded cars and the period of weathering of the spilled oil from the cars is documented. The GC profiles of the hydrocarbons in the oils (Fig. 2) have a major unresolved hump at C_{20}–C_{30} with a homologous series of *n*-alkanes and branched and cyclic hydrocarbons, in contrast to the contaminated charcoal samples which are depleted in *n*-alkanes. If the contaminant were crankcase oil weathered only since cars began operating in this region (20–40 yr), then almost total degradation of *n*-alkanes would be impossible. This can be surmised if we compare the fresh oil to the one weathered over two years (also heated to a certain extent in the car). The maximum temperature to which crankcase oil is normally heated is ~205 °C (250 °C in diesel engines, D. Godfrey, personal communication), which may not be high enough to pyrolyse all the *n*-alkanes[10,11] in the time during which the oil is heated in the car. Also, the stratigraphy at the sample locations showed no streaks of spilled oil from the surface to the 2 m depth of the samples. These observations preclude automobile oil from being the contaminant.

The only other possible source seems to be ancient, indigenous asphalt. Modern asphalt seems an unlikely candidate as there were no paved roads near the excavation site. An asphalt sample from a goblet in the area had the same *n*-alkane (trace amounts) and triterpenoidal distributions as did the two contaminated samples (Fig. 1). The H/C ratio and $\delta^{13}C$ data of the asphaltenes from the samples (Table 1) are typical of data reported for asphalts[12–14]. The close agreement in the stable isotopic data (of carbon, oxygen and hydrogen obtained according to ref. 15) of the asphaltenes also suggests a common source of asphalt in the contaminated samples and the asphalt from the goblet, that is, indigenous asphalt.

The nonextractable residue, after exhaustive solvent extraction, gave almost the same ^{14}C age as the original sample (Table 1), suggesting that the unusually old age is largely due to the insoluble pyrobitumen[16] that could have originated from the asphalt. (Modern motor oil would probably be completely extracted by organic solvents used on sample S313, in which case the residue should have given a comparable age to that of other syngenetic samples in the area.)

In the third millennium in Syria, the asphalt used for sealing cracks in ceramic vessels[17] and fastening tool heads onto wooden handles[9] was probably melted by heating[18,19]. Frequent reheating, coupled with weathering, might have altered most of the asphalt into pyrobitumen. The residual asphalt which did not undergo complete thermal alteration could contain a triterpenoidal profile similar to the one reported here. At elevated temperatures (~375 °C) straight-chain alkanes decompose[10], whereas tricyclic diterpanes and pentacyclic triterpanes survive[20]. Indeed, the triterpenoidal distribution in the contaminated samples and asphalt are very similar to those of pyrolysates from kerogen matrices[20]. These pyrolysates have lesser amounts of steranes and moretanes compared with triterpanes and the $C_{29}\alpha$ hopane is more abundant than the $C_{30}\alpha$ homologue, as is observed here (Fig. 1). A minor series with m/z 205, analogous to the major hopane series, is also present, indicating an extra methyl group in the A or B ring. 3-Methylhopanes have been detected in bacteria[21] and the presence of the methylated hopanes implies microbial residues probably involved in the synthesis of petroleum hopanes[22]. Water washing and biodegradation of crude oil in reservoirs also could remove n-alkanes and isoprenoids and lead to a similar distribution of triterpenoids in the resultant asphalt[23] as these compounds do not seem to be significantly affected by bacterial degradation[23,24]. It is not surprising, therefore, to see the biomarker steranes and di- and triterpanes (derived from the thermally altered and probably biodegraded indigenous asphalt) in the charcoal samples.

A broken storage pot of asphalt dumped in refuse could easily have contaminated some of the charcoal samples excavated from the ancient dumpsite. It is also feasible, that some of the native asphalt might have undergone thermal alteration by its proximity to the fireplace from which the charcoal samples could have originated. It is not known whether the asphalt was used as a fuel.

According to the ^{14}C data, pyrobitumen from ancient asphalt has contributed as much as 95.5% and 18% to the total carbon in samples S313 and S267 respectively. This large amount explains why, after removing the solvent solubles, a younger ^{14}C age was not observed for S313. The extractable material was much lower in concentration relative to the non-extractables.

This is the first organic geochemical study to verify contamination in ^{14}C dated archaeological samples, which could account for much older apparent ages than expected. Chronologies based on ^{14}C dates of archaeological materials containing fossil organic carbon in the absence of confirmatory molecular analysis should be accepted with caution. Similar organic geochemical analyses of a few samples (^{14}C dated) from Jericho and Jarmo (northern Iraq) where traces of asphalt have been found on ancient stone tools[18] are in progress.

We thank I. R. Kaplan for encouragment and advice, B. R. T. Simoneit, R. Eganhouse and I. R. Kaplan for reviewing the manuscript, E. Ruth for GC–MS analyses and D. Winter for helping in the stable isotope analyses. H.E.S. greatly appreciates the opportunity to spend the winter quarter (1981) with the IGPP at UCLA. Support for organic geochemical work (M.I.V.) was provided by NASA grant NGR-05-007-221. Excavations at Terqa were carried out with grants from the Ahmanson Foundation, the Ambassador International Cultural Foundation, the Samuel H. Kress Foundation and the Chancellor's Office at UCLA. This is contribution no. 2163 of the Institute of Geophysics and Planetary Physics, University of California, Los Angeles.

O-sulphated Leu-enkephalin in brain

C. D. Unsworth & John Hughes*

Department of Biochemistry, Imperial College of Science and Technology, London SW7 2AZ, UK

J. S. Morley

Pharmaceutical Division, ICI Ltd, Alderley Park, Cheshire, UK

The enkephalins appear to share a common precursor which is distinct from pro-opiocortin[1,2]. The adrenal proenkephalins have molecular weights (M_rs) in the range 5,000–30,000 with the largest species containing six copies of Met-enkephalin to one of Leu-enkephalin[3]. The brain proenkephalins appear to differ in that the molecular weights are in the range 5,000–90,000 and digestion of the largest protein with trypsin and carboxypeptidase B generates approximately equal proportions of Met- and Leu-enkephalin[4]. During our studies of brain proenkephalin we noted the generation of enkephalin-immunoreactive species that were chromatographically distinct from Met- and Leu-enkephalin. Here we identify one of these species as *O*-sulphated Leu-enkephalin and suggest possible roles for sulphation in the metabolism of opioid peptides.

Digestion of the striatal proenkephalin fraction ($M_r > 5{,}000$) with trypsin yielded a mixture of enkephalin-like immunoreactive and bioactive opioid species; these were separated by

high-voltage paper electrophoresis (HVPE) at *p*H 6.5 into basic, neutral and acidic species. The neutral peptides were analysed by reverse-phase HPLC using antisera directed against Met- and Leu-enkephalin, which showed that the two peptides were present in a ratio of 2 : 1. The precursor pool therefore contains extreme C-terminal enkephalin sequences with the Leu-enkephalin form predominating. Treatment of the basic peptide fraction with carboxypeptidase B yielded a further mixture of Met- and Leu-enkephalin with the former predominating although we were unable to determine an absolute ratio because of the presence of other unidentified immunoreactive species. Treatment of the acidic fraction with carboxypeptidase B resulted in an increase in Leu-enkephalin immunoreactivity but this activity still moved towards the anode at *p*H 6.5 and was found to possess a negative charge even at *p*H 1.9. Isoelectrophoretic analysis confirmed the presence of immunoreactive and bioactive opioid peptides with *p*I values of 3.5 to <2.5, that is, beyond the range of our ampholyte system. The peptides derived from trypsin and carboxypeptidase B digestion were subjected to HVPE both before and after treatment with neuraminidase, phosphatase and arylsulphatase. Treatment with the first two enzymes had no discernible effect on the mobility or immunoreactivity of the acidic fraction; however, arylsulphatase treatment caused a marked increase in Leu-enkephalin immunoreactivity which now co-migrated with marker enkephalin. When the acidic peptide fraction derived from trypsin digestion alone was reacted with arylsulphatase, the products were found to carry a positive charge at *p*H 6.5.

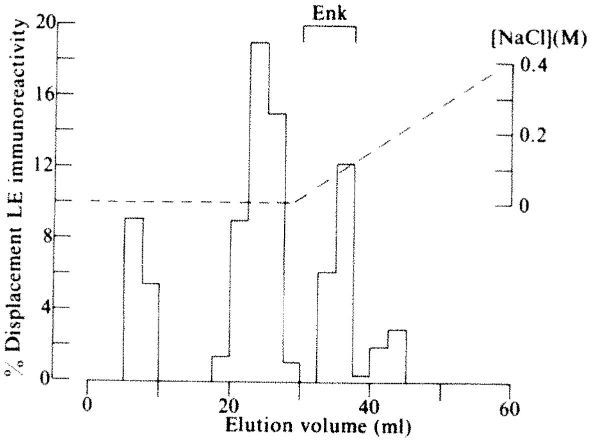

Fig. 1 Separation of tryptic opioid peptides by DEAE-ion-exchange chromatography. Mouse striatum was extracted with $10\ \mathrm{ml\ g^{-1}}$ of 1M acetic acid adjusted to *p*H 1.9 with HCl. The soluble proteins were passed through a Sephadex-G25 column and the excluded volume was collected and lyophilized. This protein fraction was dissolved in 50 mM Tris-HCl *p*H 8, incubated with trypsin (1 mg per 100 mg protein) for 4 h, then passed through a 400 mg Poropak-Q column and after a water wash the absorbed peptides were eluted with ethanol. The dried ethanol eluate was dissolved in 50 mM Tris-HCl, *p*H 9.25 and applied to a 20 × 0.7 cm DEAE-Sephadex (A-25) column. The column was first developed with 28 ml of 50 mM Tris-HCl *p*H 7.3, at which point a linear salt gradient was started. Aliquots of each 2.5-ml fraction, corresponding to 3 mg of starting tissue, were immunoassayed with both anti-Leu-enkephalin-antisera (LE1, 5% cross-reactivity with Met-enkephalin) and anti-Met-enkephalin-antisera (ME-T1, $<0.1\%$ cross-reactivity with Leu-enkephalin). The first two peaks, 0.6 and 1.2 pmol Met-enkephalin-equivalents, represent basic peptide fractions and only reacted with ME-T1. The third peak (0.33 pmol) corresponds to the elution position of authentic enkephalin and contained Leu- and Met-enkephalin in a 2 : 1 ratio. The fourth peak (0.11 pmol Leu-enkephalin (LE) equivalents) only reacted with LE1 and carried a negative charge at *p*H 6.5. Treatment of this peak with carboxypeptidase B gave a slight increase in immunoreactive material carrying a negative charge at *p*H 1.9. (Note that cross-reactivity of LE1 with Arg or Lys C-terminal-extended Leu-enkephalin is only slightly less than that of *O*-sulphated-Leu-enkephalin.)

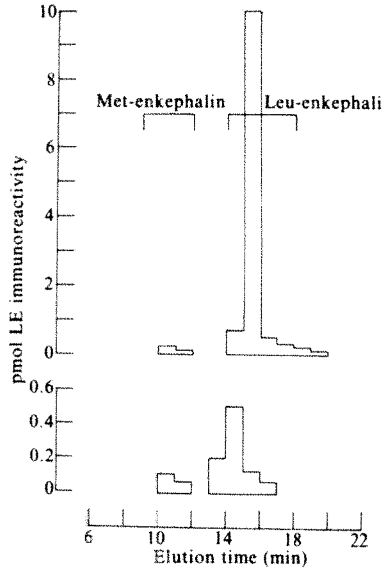

Fig. 2 Reverse-phase HPLC analysis of acidic Leu-enkephalin (LE)-immunoreactive peptide. Sheep striatum (70 mg protein) was extracted and treated with trypsin as in Fig. 1 and the acidic Leu-enkephalin-immunoreactive peak isolated by DEAE chromatography. This material was incubated at 37 °C for 2 h with 10 µg of carboxypeptidase B in 50 mM Tris-HCl, *p*H 8. One half of the sample was then incubated with arylsulphatase (0.5 unit) from *Patella vulgata* (200 mM sodium acetate, *p*H 5 for 2 h). The products of these digestions were absorbed on Poropak-Q and then chromatographed on a 250 × 4 mm Partisil-10-ODS-2 column in isocratic conditions (100 ethanol/250 water/3.5 acetic acid by vol) at $0.8\ \mathrm{ml\ min^{-1}}$. The lower panel shows the elution profile of LE1 immunoreactivity after trypsin and carboxypeptidase treatment, the upper panel after the additional arylsulphatase treatment.

Gradient elution of the tryptic digest on Sephadex-DEAE revealed the presence of four peaks of immunoreactivity (Fig. 1). Peaks 1 and 2 reacted strongly with anti-Met-enkephalin antibodies and were strongly basic. Peak 3 corresponded to the elution position of authentic Met- and Leu-enkephalin, the greater affinity for anti-Leu-enkephalin antisera reflecting the preponderance of Leu-enkephalin generation after trypsin digestion. Peak 4 corresponds to the acidic fraction detected by HVPE and showed a much greater affinity for anti-Leu- rather than for anti-Met-enkephalin antisera. Peak 4 was divided and one fraction treated with carboxypeptidase B, the other with carboxypeptidase B and arylsulphatase. These fractions were chromatographed on a Partisil-10-ODS (octadecyl silane) HPLC column (Fig. 2). Immunoassay of the effluent revealed the presence of a small Leu-enkephalin-immunoreactive peak in the carboxypeptidase B-treated fraction, this peak being close to, but not coincident with, an authentic Leu-enkephalin sample. The arylsulphatase-treated fraction yielded a much larger Leu-enkephalin-immunoreactive peak coincident with authentic Leu-enkephalin. Identical results were obtained with protein extracts of both mouse and sheep striatum.

These results indicated the presence in our protein fraction of a sulphated Leu-enkephalin sequence flanked by basic amino acids. Trypsin digestion alone should liberate a sulphated Leu-enkephalin sequence containing C-terminal Arg or Lys residues and carrying an overall negative charge due to the presence of *O*-sulphate. Treatment with arylsulphatase should change the overall charge to +1 due to the loss of sulphate while treatment with carboxypeptidase B and arylsulphatase yields a Leu-enkephalin-like peptide having no overall charge at *p*H 6.5. We cannot exclude the possibility that some sulphated Leu-enkephalin sequences might exist at the extreme C-terminal of proenkephalin but the above evidence supports an internal location for most of the material.

In view of the small amounts of natural material available, the *O*-sulphate ester of Leu-enkephalin (LES) was prepared and its properties compared with those of the material derived from enzymatic digestion of striatal proenkephalin. LES was prepared by coupling *N-t*-butoxycarbonyl-l-tyrosine-*O*-sulphate barium salt with glycylglycyl-l-phenylalanyl-l-leucine *t*-butyl ester. The final purified product was homogeneous in five TLC and two HPLC systems and gave amino acid ratios, after aminopeptidase M digestion, of Tyr(SO_3H) (1): Gly (1.99): Phe (0.97): Leu (1): Tyr (0), (J.S.M. and C. F. Hayward in preparation). LES caused a dose-dependent, naloxone-reversible inhibition of both the mouse vas deferens and guinea pig ileum but had only 0.0001 times the activity of Leu-enkephalin in these assays. Its cross-reactivity with our anti-Met- and anti-Leu-enkephalin antisera was <0.1% and 5% respectively. LES has no intrinsic opiate receptor activity as a small proportion can undergo desulphation during bioassay. Incubation of LES with arylsulphatase for 2–4 h caused a maximal conversion of 20–30% of the material to Leu-enkephalin within 2 h. An alternative method of desulphation was developed based on the observation that exposure of LES to anhydrous trifluoroacetic acid (TFA) during its synthesis causes a rapid loss of the sulphate moiety. Incubation of dried samples of LES with anhydrous TFA (50 μg LES in 500 μl TFA) at 37 °C resulted in complete conversion to Leu-enkephalin within 80 min as judged by HPLC. No other product was detected by HPLC nor was there any alteration of Leu-enkephalin activity.

Synthetic LES and our acidic Leu-enkephalin-immunoreactive fraction had identical mobilities in several chromatographic systems including silica-gel TLC, Partisil-10–anion-exchange HPLC and reverse-phase HPLC. Synthetic LES eluted between Met- and Leu-enkephalin on the Partisil-10–ODS system with overlap between Leu-enkephalin and LES. This was consistent with the result obtained before the synthetic material was available (Fig. 2). Complete separation of LES from the enkephalins was achieved by gradient elution on a μ-Bondepak C18 column (Fig. 3). Several peaks of immunoreactivity were observed in this separation but only those fractions co-eluting with authentic LES showed a marked increase in immunoreactivity after treatment with TFA or arylsulphatase (Fig. 3).

LES was also detected in the free form as part of the endogenous peptide pool in brain extracts. Material having the chromatographic properties of LES was detected by immunoassay or by bioassay after TFA treatment in several systems including silica-gel TLC, reverse-phase and cation- and anion-exchange HPLC. In Fig. 4*a*, material eluting at the position of synthetic LES was bioassayed before and after TFA treatment of the eluate fractions. Naloxone-reversible activity (~45 pmol) was detected in one fraction before TFA treatment. However, ~200 pmol of activity were detected in the same fraction after TFA treatment. As LES is only bioactive at nanomolar concentrations it was unlikely that the activity detected before TFA treatment was due to LES. Support for the existence of both LES and another intrinsically active opioid in this sample was obtained by chromatography of an identical sample on the same column after treatment with TFA. There were two peaks of activity, one (~120 pmol) corresponding to Leu-enkephalin arising from the desulphation of LES and the other, earlier peak (~40 pmol) eluting close to but slightly later than marker LES (Fig. 4*b*). The bioactivity detected in Fig. 4*a* before desulphation was quantitatively the same as that detected in Fig. 4*b* close to the LES elution point; the increase in bioactivity (Fig. 4*a*) after TFA was also quantitatively similar to the amount of Leu-enkephalin detected in Fig. 4*b*.

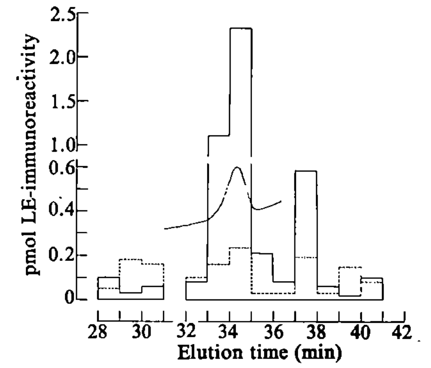

Fig. 3 Identification of the sulphate ester of Leu-enkephalin from mouse striated protein. The acidic fraction of a tryptic digest was isolated as described in Fig. 1 legend and then treated with carboxypeptidase B. The final digested sample was chromatographed on a μ-Bondepak C18 reverse-phase column (0.78 × 30 cm). The initial conditions were 5% acetic acid/propranol (90/10 v/v) with a 30-min concave gradient to give final proportions of 60/40 (v/v) and this was continued for a further 15 min. Fractions (1 ml) were collected and aliquots divided, one half being immunoassayed directly with LE1 antisera (dotted lines), and the other half treated with TFA before immunoassay (solid lines). The values correspond to 20 mg wet weight of mouse striatum. Several small peaks of Leu-enkephalin immunoreactivity were detected before TFA treatment, but only fractions 33–34, corresponding to the elution position of LES (superimposed UV absorption trace), showed a marked increase after TFA. A threefold increase in immunoreactivity was also seen with fraction 37.

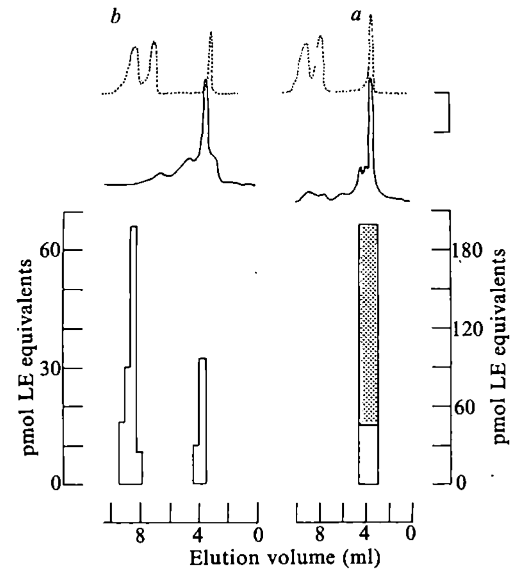

Fig. 4 Detection of endogenous acidic opioid peptides. Mouse striata were extracted as described in Fig. 1 legend and the peptide fraction separated from protein on Sephadex G-25. Acidic peptides were isolated by DEAE–Sephadex chromatography. The acidic peptides were chromatographed on a 250 × 4 mm Partisil-10–SCX column in isocratic conditions (10 mM NaH_2PO_4/H_3PO_4 *p*H 2.4; 0.5 and 0.4 ml min^{-1} for traces *a* and *b* respectively). Samples equivalent to 480 mg of starting tissue were used. *a*, Elution profile of an untreated sample. *b*, Chromatogram obtained for a sample that had been incubated with TFA for 80 min. In *a*, 2 min samples were collected and divided, one half being bioassayed directly on the mouse vas deferens for naloxone-reversible activity and the other half being treated with TFA before bioassay (shaded column). One fraction in *a* contained 45 pmol of intrinsic activity; treatment of this sample with TFA increased the activity to 198 pmol. In contrast, the other fractions contained no activity either before or after TFA treatment. In *b*, 1 min fractions were collected and bioassayed directly; opiate activity was detected in a peak emerging just after the position of authentic LES and coincident with authentic Leu-enkephalin. Activity is expressed in pmol Leu-enkephalin (LE) equivalents. The upper traces are the 206 nm absorption traces for the tissue samples and the broken traces those of marker peptides. Order of elution (right to left): LES, Met- and Leu-enkephalin.

The intrinsically active acid opioid peptide fraction, LES, the enkephalins and more basic endogenous opioid peptides were also separated and detected by isoelectrophoresis (Table 1). We demonstrated the existence of basic opioids which migrated to the cathode (*p*I >7.5), the enkephalins (*p*I 5.0–5.5) and a more acidic fraction (*p*I 2.9–3.1). None of the fractions showed any

Table 1 Isoelectrophoretic separation of rat brain opioid peptides

*p*I	Leu-enkephalin equivalent activity (pmol) Untreated eluate	 TFA-treated eluate
>7.5	110	120
4.9–5.5	460	425
2.9–3.2	60	48
<2.5	0	80

Three whole rat brains were homogenized in 5% TCA (10 ml per g tissue) and the solubilized peptides were absorbed on 200 mg of Poropak-Q; after a water wash the peptides were eluted with 5 ml of methanol. The methanol eluate was divided and dried. Isoelectric focusing was carried out on horizontal slab gels of Ultradex (prepared as recommended by LKB). Two runs were made with *p*H gradients of 5–8 and 2.5–4.0 respectively (2% Ampholines (LKB); 8 W constant power at 10 °C for 12 h). At the end of each run the gels were sliced and the peptides eluted with 2 ml distilled water. The samples were then absorbed on to Poropak-Q which was washed thoroughly with water to remove ampholines, then eluted with methanol. The dried methanol eluates were bioassayed directly on the mouse vas deferens and after TFA treatment. Trace amounts of ^{3}H-labelled enkephalins added to the original samples were also used to establish the isoelectric points of these peptides: Leu-enkephalin = 5.4 (5.2–5.5); Met-enkephalin = 5.2 (4.9–5.3).

enhancement of activity after TFA treatment except material from the anode where LES would be expected to migrate with a *p*I of <2.0.

We have detected the presence of protein-incorporated LES in sheep, mouse and guinea pig striatum. The free peptide, which is also present in these species and the rat, appears to constitute 10–20% of the total free pool of Leu-enkephalin. The proportion of LES in the proenkephalin fraction may be much higher, initial studies indicating that as much as 50% of protein-incorporated Leu-enkephalin may be sulphated. We have also detected LES in the high-molecular weight proenkephalin[4] and thus sulphation may occur early in peptide biogenesis, possibly at the nascent peptide stage. The sulphate ester of Met-enkephalin has not been detected although we cannot exclude completely its occurrence.

The significance of these findings is unknown. Sulphation may represent an inactivation mechanism, a signal for selective precursor cleavage or a means for conferring novel non-opiate activities on opioid peptides. The brain contains several endogenous enkephalin-related peptides including α-neo-endorphin[5], dynorphin[6], Met^5-enkephalinylarginylphenylalanine[7] as well as Met- and Leu-enkephalin[8]. At present we do not know if they share common biosynthetic pathways but it will be of considerable interest to determine whether any of these other peptides undergo sulphation. In the pro-opiomelanocortin system, *N*-acetylation[9] can lead to the activation of melanotropin and inactivation of β-endorphin, thus providing a flexible system for determining the nature of active products generated by a common precursor. It remains to be determined whether sulphation has a similar role in the proenkephalin system.

We thank Professor H. R. Morris, Dr G. Taylor, Dr C. F. Hayward, Mr A. Etienne, Ava Singh and Miss B. Birchmore for their help and advice. This work was supported by grants from the MRC and Nuffield Trust to J.H. C.D.U. is an MRC scholar.

Molecular size of benzodiazepine receptor in rat brain *in situ*: evidence for a functional dimer?

A. Doble & L. L. Iversen

MRC Neurochemical Pharmacology Unit, MRC Centre, Medical School, Hills Road, Cambridge CB2 2QH, UK

Benzodiazepine tranquillizers such as diazepam and chlordiazepoxide interact with high-affinity binding sites in nervous tissue[1,2]. The correlation between the affinities of various benzodiazepines for these sites with their clinical potencies and activity in behavioural and electrophysiological tests in animals suggests that the sites represent the functional 'receptor' whereby benzodiazepines exert their effects[3]. The intimate involvement of benzodiazepines with γ-aminobutyric acid (GABA) and chloride channels raised the possibility that the benzodiazepine binding site (BDZ-R) may be a protein in the GABA receptor–effector complex[4,5]. GABA agonists enhance the affinity of BDZ-R for benzodiazepines[6], although BDZ-R is distinct from the GABA receptor itself[3]. However, electrophysiological evidence suggests that the action of benzodiazepines is chloride channel, rather than receptor, directed[7–10]. Several attempts have been made to measure the molecular weight (M_r) of BDZ-R after solubilization from brain membranes: treatment with 1% Triton X-100 followed by assay of binding activity in solute fractions separated according to molecular weight suggested[11] a value of ~200,000, photoaffinity labelling of BDZ-R with ^{3}H-flunitrazepam (^{3}H-FNZ) followed by more rigorous solubilization and gel chromatography indicated[12,13] an apparent M_r of ~55,000 and a third approach[14] a value of ~100,000. The measured molecular weight seems to depend critically on the solubilization procedure used. Chang *et al.*[15] recently described the use of radiation inactivation to determine the size of BDZ-R *in situ* in calf brain membranes, and estimated a M_r of 216,000. We have also used this approach; the results reported here indicate a M_r of between 90,000 and 100,000, but this is reduced to 60,000–63,000 in membranes pretreated with GABA, suggesting the disaggregation of a normally dimeric form.

Radiation inactivation has been widely used to obtain the molecular weights of enzymes and other soluble macromolecules, and the technique has also been applied to membrane-bound proteins such as the (Na$^+$ + K$^+$)ATPase in erythrocytes, the tetrodotoxin binding site in neuronal membranes and the glucagon-stimulated adenlyate cyclase in hepatocytes[16]. The method has the great attraction of allowing size determinations to be made on functionally defined membrane proteins *in situ*. High-energy particles can inactivate biological macromolecules according to classical target theory: thus, if inactivation is considered an all-or-none event, the relationship between degree of inactivation and radiation dose will be an exponential one, whose decay constant will be solely a function of molecular size. This can be computed from the dose of radiation in megarads required to reduce biological activity by a factor of $1/e$ (the D_{37}) using a conversion constant which has been derived both theoretically and empirically[17]

$$M_r = 6.4 \times 10^5 / D_{37}$$

The radiation dose delivered was independently monitored by assaying an endogenous membrane marker of known molecular weight (acetylcholinesterase); the measurements indicated a M_r of 65,000 for the enzyme, in good agreement with previously determined values[17].

In the present study we irradiated *in vacuo* lyophilized neuronal membranes from rat brain with electrons accelerated through 16 MeV by the linear accelerator at Addenbrooke's Hospital, Cambridge for various times at a rate of 2 Mrad min^{-1}.

0028-0836/82/060522—02$01.00

Table 1 Affinity (K_D) and capacity (B_{max}) of ^{3}H-FNZ binding sites determined by Scatchard analysis

	K_d (nM)	B_{max} (pmol per g protein)	
Fresh membranes	2.5±0.3	282±11	($n = 3$)
Lyophilized membranes	2.3	270	
Irradiated membranes	2.0	90	

Values are compared in freshly prepared membranes, lyophilized and reconstituted membranes, and lyophilized membranes irradiated with 10 Mrad high-energy electrons before reconstitution. Each determination used data from triplicate determinations of specific binding at eight ^{3}H-FNZ concentrations between 0.1 and 10 nM. For K_d values, regression analysis of the slopes of Scatchard plots revealed no significant difference between experimental groups.

The residual BDZ-R activity was measured using a conventional ^{3}H-FNZ radiolabelling assay and compared with non-irradiated controls. The binding properties of lyophilized membranes were not significantly different from freshly prepared membranes (Table 1); by contrast the increase in GABA receptor affinity on freezing is well documented[18].

Figure 1 demonstrates that electron bombardment inactivated BDZ-R and the linear nature of the logarithmic transform suggests loss of a single component of homogeneous size; further experiments show that this linearity is preserved up to doses inactivating >90% of BDZ-R activity. Irradiation produced no change in the nonspecific ^{3}H-FNZ binding. Scatchard analysis shows that loss of activity reflected a loss of binding sites rather than a change in binding characteristics—as might be expected if the inactivation were not all-or-none (Table 1). The radiation-sensitive M_r calculated from these data is 89,000±15,000.

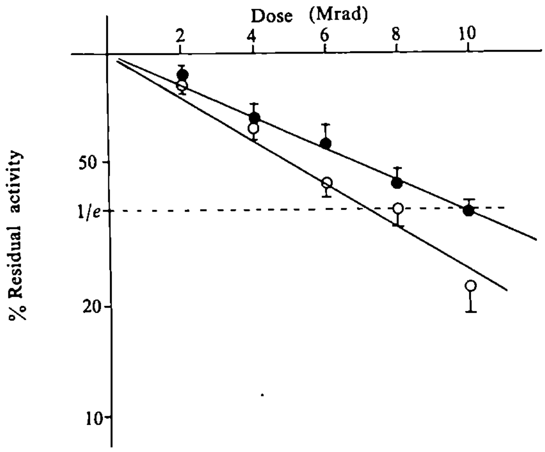

Fig. 1 Inactivation of ^{3}H-FNZ binding sites in rat neuronal membranes by high-energy electrons in the absence (○) and presence (●) of GABA. Membranes were prepared by homogenization of whole brain tissue 1:40 (w/v) in 50 mM Tris-citrate buffer *p*H 7.1, followed by 20 min centrifugation at 50,000*g*. The pellet obtained was resuspended and centrifuged a further four times before use. Pellets were suspended in distilled water with or without 10^{-4}M GABA and aliquots lyophilized in 5 ml glass centrifuge tubes. The tubes were evacuated and irradiated at 2 Mrad min^{-1}; during irradiation they were cooled by a stream of air that had passed through dry ice to maintain the temperature below 60 °C; this heating had no effect on the binding properties. Following irradiation, the samples were suspended in Tris-citrate buffer at a concentration of ~3 mg protein per ml, and the amount of ^{3}H-FNZ binding assessed: 500-μl aliquots were incubated at 4 °C for 30 min with 0.5 nM ^{3}H-FNZ and the binding terminated by filtration. 'Specific' binding was defined as the component displaceable by excess (2 μM) FNZ, and represents ~95% of total binding in control samples. Each sample was assayed in triplicate, and the data represent mean±s.e.m. of six independent experiments. Residual ^{3}H-FNZ binding is expressed as the percentage of that seen in non-irradiated controls. In these controls, specific binding represented 18.8±0.7 pmol per g protein, which was significantly increased ($P < 0.05$) in the presence of 10^{-4}M GABA to 22.4±1.5 pmol per g protein. The data were plotted as a semi-log transform, and the exponential decay lines of best fit computed by linear regression analysis. Intercept values (1/*e*) were 7.2 (5.8–8.6; 95% confidence limits) Mrad and 10.1 (9.1–11.1) Mrad, without and with GABA respectively. The dose of irradiation was monitored by measuring current flow to Earth from a Faraday cup before which the samples were mounted. The current flux was regularly calibrated by reference to absorbance change in clear Perspex HX mounted in place of the samples[22]. The dosimetry was independently confirmed by monitoring the acetylcholinesterase activity in aliquots of the brain membranes by the colorimetric method of Ellman *et al.*[23].

We also studied the molecular size of the BDZ-R in membranes treated before lyophilization with 10^{-4}M GABA, a concentration sufficient to cause a maximum increase in BDZ-R binding affinity[6]. In these membranes, the radiation-sensitive size was significantly ($P < 0.05$) decreased to 63,000±7,000. Values obtained from a further series of five experiments were 102,000 and 60,000 without and with GABA respectively; these values are not significantly different from the original values. The simplest explanation of this effect of GABA is that BDZ-R may exist as a dimer whose disaggregation is triggered by GABA receptor activation. If, as discussed above, BDZ-R is related to the chloride ion channel, then it is possible that GABA receptor activation causes the separation of two transmembrane proteins, thus opening a chloride ion channel; the open channel (BDZ-R monomer) would have a higher affinity for the benzodiazepines than the closed channel (BDZ-R dimer). A similar model of protein transformation in a receptor–ionophore complex has been postulated for GABA on physicochemical grounds[19], and parallels current models for the nicotinic acetylcholine receptor[20].

The apparent molecular size reported here for BDZ-R, between 90,000 and 100,000, is not significantly different from the value obtained by Braestrup *et al.*[14]. The more rigorous purification of photoaffinity-labelled BDZ-R which yields a weight of 55,000 may produce the 'monomeric' BDZ-R we have postulated above. The 200,000-M_r moiety labelled after solubilization[11] is still sensitive to GABA[21] and co-chromatographs with ^{3}H-labelled receptors[11], thus may represent the GABA receptor–ionophore complex, rather than independent BDZ-R. It is not clear why Chang *et al.*[15] found a value of ~200,000, using a similar radiation inactivation technique. However, they used a different species (ox) and treated the brain membranes with Triton X-100, which may affect the state of aggregation of membrane proteins.

The present study demonstrates the feasibility of using radiation inactivation not only to measure the size of membrane-bound receptors, but also to analyse physicochemically the effects of interactions between transmitters, receptors and effectors on their molecular properties.

We thank Dr J. C. Ellory for useful discussion, Mr R. Gouldstone and his staff in the Radiotherapeutics Department, Addenbrooke's Hospital, Cambridge for operating the linear accelerator and Mrs I. Anderson for typing assistance. A. D. is a MRC scholar.

Use of carboxyfluorescein diacetate to study formation of permeable channels between mouse blastomeres

H. Goodall & M. H. Johnson

Department of Anatomy, Downing Street, Cambridge
CB2 3DY, UK

The transmission of signals between cells of the early preimplantation embryo may be important in the recognition of relative cell position, thereby influencing the direction of cell differentiation[1-5]. Gap junctional (water-permeable) channels may provide one route for such signal transmission[6]. A previous report[7], in which intact, zona-free mouse embryos were impaled by microelectrodes, demonstrated that gap junction-mediated dye transfer and electrical continuity were absent between blastomeres of two- and four-cell embryos but appeared during the eight-cell stage. It is at the eight-cell stage that compaction occurs, during which cells polarize[3], flatten on each other[3,8] and show the first morphological evidence of intercellular junctions[9,10]. We report here the use of a simple, non-iontophoretic method to detect the passage of a low-molecular-weight dye between aggregated blastomeres of the early preimplantation mouse embryo. Cells are incubated in the nonfluorescent, non-polar reagent, 6-carboxyfluorescein diacetate (CFDA)[11,12], which enters the cell freely, where it becomes entrapped following enzymatic conversion[13] to the hydrophilic fluorophore 6-carboxyfluorescein (CF; molecular weight 370). The labelled cells may then be aggregated with unlabelled cells and the formation of communicating channels between cells is revealed by the passage of dye from labelled to unlabelled blastomeres. CFDA provides better results than previously used fluorescein esters[14,15], which hydrolyse to a much less hydrophilic fluorophore that leaks from the cell relatively quickly[11,15]. Using CFDA we have confirmed that the capacity to form channels is lacking at all stages from the mature oocyte to the four-cell embryo but appears during the first 6 h of the eight-cell stage, preceding the fully compacted state.

In preliminary experiments, it was established that CFDA (derived from a 10 mg ml^{-1} stock solution in acetone) at concentrations of 4–40 μg ml^{-1} in phosphate-buffered medium (PB1)[16] labelled cells brightly, with no detectable effects on viability or subsequent division. The dye was distributed evenly throughout the cytoplasm (Fig. 1), leaked only slowly from two-, four- or eight-cell blastomeres, as reported for the lymphocyte[11], although somewhat faster from unfertilized or fertilized eggs, and was not taken up in detectable quantity by unlabelled blastomeres co-cultured with labelled blastomeres. Free transfer of dye was detected only between aggregated blastomeres from the eight-cell embryo (Figs 1, 2).

The first sign of dye transmission was the appearance of a weak fluorescence in the unlabelled blastomeres, which subsequently increased, concomitant with a decline in the fluorescence of the labelled blastomeres, until all blastomeres fluoresced with similar intensity (Fig. 1). No dye was transferred between aggregated pairs of unfertilized eggs (Fig. 3*a*, *b*; 43 pairs observed at 15–17 h following injection of human chorionic gonadotropin [hCG]), consistent with earlier studies[17], or between one-cell embryos (18 pairs observed at 20 h post-hCG). Blastomeres from two- and four-cell embryos were not able to transmit dye (68 and 20 pairs examined respectively), even when cultured for up to 5 h (Figs 2, 3). A similar result was obtained from all pairings between cells of different embryonic stages from mature oocyte to eight-cell embryo (229 aggregates examined in various combinations), even when one cell of the aggregated pair was from a population proved capable of transmitting dye within itself (Fig. 3).

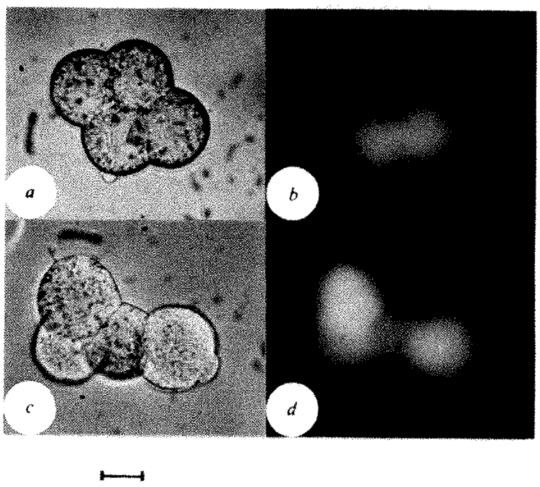

Fig. 1 Passage of CF between blastomeres derived from eight-cell mouse embryos. Female CFLP mice (Hacking and Churchill) were superovulated by intraperitoneal injection of 5 IU (international units) pregnant mare serum (PMS; Folligon) and 5 IU human chorionic gonadotropin (hCG) (Chorulon) 44–48 h later. Mice were mated, and compacted eight-cell embryos (~70 h post-hCG) were recovered, their zonae pellucidae removed and they were then disaggregated to either single cells (1/8) or pairs of cells, according to established procedures[3]. Blastomeres were then taken through four changes of CFDA (4 μg ml^{-1}) in phosphate-buffered medium (PB1)[16] without protein, and incubated in suspension in the final change of labelling medium for 2 min and then rinsed three times in PB1 containing 4 mg m^{-1} bovine serum albumin (BSA). Labelled cells were then aggregated to unlabelled cells using phytohaemagglutinin (Gibco Biocult) (5% v/v of stock solution in Ca^{2+}-deficient medium 16 + 6 mg ml^{-1} BSA), shown previously to have no obvious effect on development[3,19], rinsed in PB1 + BSA and cultured as described previously[3] in drops of medium 16 + 4 mg ml^{-1} BSA at 37 °C in 5% CO_2 in air, under oil in plastic cell culture dishes (Sterilin). After 3 h, the aggregates were mounted in PB1 + BSA on a tissue typing plate (Baird and Tatlock) and viewed with a Zeiss photomicroscope (filter set 48 77 09 with incident source HBO 200 for epifluorescence [*b*, *d*] and transmission optics for brightfield [*a*, *c*]). Photographs were taken on Kodak Tri-X 35 mm film. Fluorescence exposures were of 2 min duration. *a*, *b*, No transfer of CF between a labelled and unlabelled pair of blastomeres has yet occurred. *c*, *d*, Complete exchange of dye has occurred between the labelled pair and the unlabelled pair. Scale bar, 10 μm.

To measure the time taken to establish water-permeable channels between cells with an existing capability to transfer, individual blastomeres from compacted, late eight-cell embryos were labelled and aggregated with similar, unlabelled cells. Couplets were analysed at various times after aggregation for evidence of dye transmission (Fig. 2, left-hand curve). Four hours elapsed before all the pairs showed complete dye transmission, although this had occurred in some pairs within the first hour. Whether these early transmitting pairs resulted from assembly of pre-existing proteins or the synthesis *de novo* of gap-junctional proteins is not known, although in Cl-1d cells the minimum time required for synthesis and construction of permeable channels has been estimated to be 4–6 h (ref. 18).

To determine the time at which an eight-cell blastomere first develops the capacity to transmit dye, labelled 2/8 pairs were aggregated at a known time after their formation by division of 1/4 blastomeres, with unlabelled 2/8 pairs of the same age, and cultured for 3 h before analysis. The results are shown in the right-hand curve of Fig. 2; the slope of the curve is similar to that on the left, and presumably reflects the variability in time required to assemble functional junctions and transmit dye. However, the whole curve is shifted to the right by 2–3 h; it seems that ~2–3 h must elapse before a newly formed 1/8 blastomere becomes competent to assemble channels and transmit the dye. Junction formation, therefore, is a relatively early event in the life of the eight-cell embryo, coinciding with the induction of polarity[19] and preceding cell flattening[3].

This conclusion is further supported by experiments in which complete eight-cell embryos were aggregated and assayed for transfer of CF (Fig. 4). Transmission of dye occurred when both embryos were in a precompact state at the time of aggregation

0028-0836/82/060524—03$01.00

(Fig. 4*a*, *b*), suggesting that the competence to form water-permeable channels must precede complete cell flattening. However, when both embryos were compacted at aggregation, no transfer occurred (Fig. 4*c*, *d*), despite the proven ability of individual blastomeres isolated from compacted embryos to transmit the dye (Fig. 4*e*, *f*). Presumably, in compact embryos, the completely microvillous outer surfaces[20–22] of the cells either lacked gap-junctional proteins or were unable to assemble them in the time available to form functional channels.

The use of CFDA provides a simple technique for studying gap-junctional communication between small groups of cells. Moreover, many observations can be made within a short period. The results reported here confirm and extend previous observations using conventional iontophoretic techniques[7]. Thus the capacity to assemble functional gap-junctional channels does not develop until the early eight-cell stage when they form rapidly, due either to the insertion of gap-junctional proteins or to reorganization of existing gap-junctional proteins within the membrane[23]. It will be important to establish whether gap junction formation is required for the coordination of events resulting in polarization and cell flattening and if so, whether such coordination depends on the evening out of metabolic potential[24] or the passage of specific signalling molecules[6] between cells. The available evidence does not suggest that gap junctions are involved in the induction of polarity because two- and four-cell blastomeres can induce polarity in eight-cell blastomeres[19], yet cannot transmit to them. It remains to be determined, however, to what degree junctions are involved in subsequent events of early mouse development.

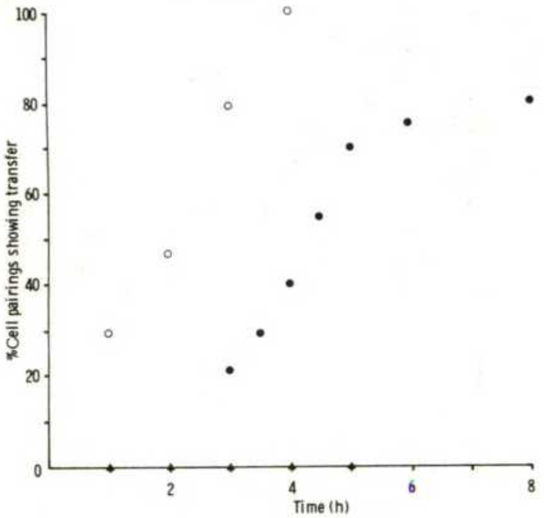

Fig. 2 Capacity of blastomeres to transmit CF. ○, Compact eight-cell embryos were disaggregated to single cells, some of which were labelled with CF and reaggregated with unlabelled cells. Couplets were examined for dye transfer at 1, 2, 3 or 4 h (67 couplets examined). For comparison, results with blastomeres derived from two-cell embryos (41 h post-hCG) and treated similarly are shown (Δ; 68 couplets examined). The horizontal axis represents time (in h) after aggregation at which aggregates were examined for dye transmission. ●, Four-cell embryos were disaggregated to 1/4 blastomeres, which were cultured *in vitro* and examined at 1/2 h intervals. Any cells dividing to 2/8 were collected[3], and the couplets were cultured for 0–5 h. At 0, 0.5, 1, 1.5, 2, 3 and 5 h, some couplets were labelled and aggregated to unlabelled couplets of the same age post-division. The aggregates were then cultured for 3 h and analysed for dye transmission as described in Fig. 1 legend. Fifty-nine pairs of couplets were examined in total. The horizontal axis represents total time (in h) elapsed since division to 2/8 had occurred and includes in each case the 3 h between labelling plus aggregation and examination for dye transmission. In all cases controls were prepared consisting of co-incubated, but unpaired, labelled and unlabelled cells that had been subjected to otherwise identical experimental conditions to the paired cells. The failure of 100% of paired cells to transmit merely reflects the choice of a 3-h transfer period (see the left-hand curve in which only 80% of pairs showed transmission after 3 h).

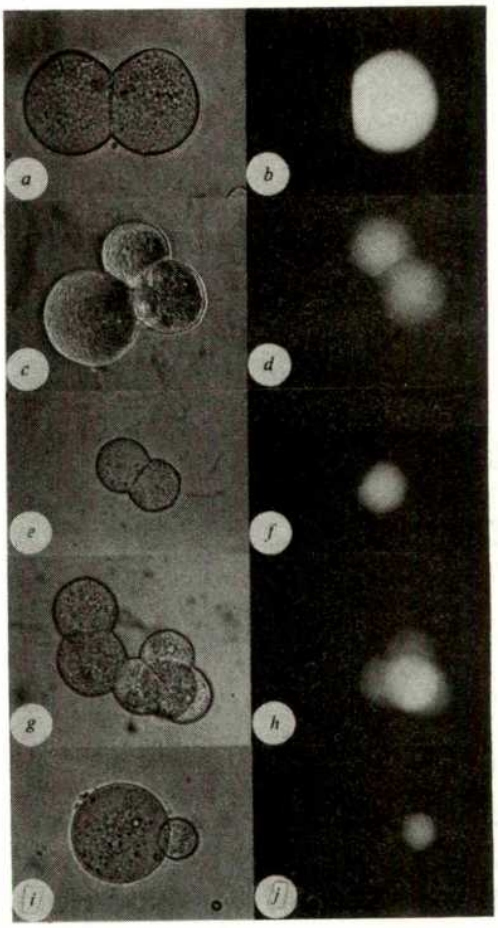

Fig. 3 Failure of CF to pass between cells taken from embryos at different stages of early development. Individual blastomeres were labelled with CF, incubated and photographed as described in Fig. 1 legend, whilst whole embryos were labelled within their zonae for 10 min, their zonae removed and then similarly treated. All aggregates were cultured for at least 3 h before examination. Phase-contrast (*a*, *c*, *e*, *g*, *i*) and fluorescence (*b*, *d*, *f*, *h*, *j*) images of the following couplets are shown: *a*, *b*, unfertilized egg + unfertilized egg; *c*, *d*, fertilized egg + two-cell embryo; *e*, *f*, 1/4 + 1/4 blastomeres; *g*, *h*, two-cell + four-cell embryos; and *i*, *j*, unfertilized egg + 1/8 blastomere. (No transfer was apparent even when the egg was labelled; thus failure to detect transfer did not result from dilution of CF.) Scale bar, 50 μm.

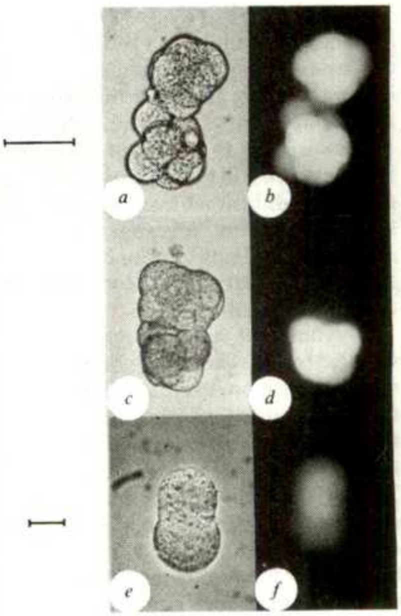

Fig. 4 CF transfer between intact eight-cell embryos after 3 h incubation. Late two-cell embryos were recovered and incubated *in vitro* for 16 h (ref. 3), by which time some had become precompact eight-cells. Some of these were labelled with CF and aggregated with unlabelled precompact eight-cell embryos immediately, whilst others were cultured further until compaction was complete and then were either similarly treated or disaggregated into 1/8 cells and then assayed for dye transfer. Phase-contrast (*a*, *c*, *e*) and fluorescence (*b*, *d*, *f*) images are shown. *a*, *b*, The transmission of CF between embryos that were precompact at time of labelling and aggregation. *c*, *d*, No transmission of CF between embryos that were compacted at labelling and aggregation. *e*, *f*, For comparison, the transmission of dye between 1/8 cells isolated from compacted eight-cell embryos. Scale bar: *a*–*d*, 50 μm; *e*, *f*, 10 μm.

The carboxyfluorescein diacetate was a gift from Dr J. W. Bruning via Dr A. J. Munro. It is now available from Molecular Probes Inc., Texas. We acknowledge the advice and criticism of Alan Munro, who suggested this new approach, and thank Hilary MacQueen, Carol Ziomek, Hester Pratt and John Reeve for criticism of the manuscript; Gin Flach, Ian Edgar, Mike Parr and John Bashford for help; and Tim Crane for preparation of photographic material. The work was supported by grants to M.H.J. from Cancer Research Campaign, MRC and Ford Foundation.

Crystal structure of a polyfunctional macrocyclic K^+ complex provides a solid-state model of a K^+ channel

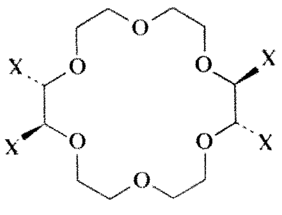
Jean-Paul Behr & Jean-Marie Lehn

Institut Le Bel, Université Louis Pasteur, 4 rue Blaise Pascal,
67000 Strasbourg, France

Ann-Catherine Dock & Dino Moras

IBMC du CNRS, 15 rue Descartes, 67084 Strasbourg Cédex, France

Molecular channels are thought to be important in ion exchange processes across membranes, and biophysical and physiological data point to the existence of ion-specific Na^+ and K^+ pores (see, for example, refs 1, 2). The nature and structure of these entities, as well as the molecular mechanism of ion flow through channels, are still largely unknown, whereas cation transport via facilitated diffusion by natural or synthetic carrier molecules has been extensively investigated in both natural and model membrane systems[3–5]. The formation of transmembrane cation channels has been studied mainly with linear peptides (gramicidin A, alamethicin; refs 3, 7, and refs 6, 8 and refs therein). The cylindrical macrotricyclic molecules are suitable model species for investigating both the synthetic construction of molecular channel subunits and their cation binding properties as they form cation inclusion complexes of cryptate type and undergo intramolecular cation jump processes[9–11]. We report here the crystal structure of the potassium complex (1, 1.5 KBr, 3.5 H_2O) of the chiral macrocyclic tetracarboxamide 1, a member of a group of functionalized macrocyclic polyethers[12,13] which strongly bind alkali and ammonium cations[14]. This structure presents a solid-state model of a molecular channel, in which the macrocyclic units are organized in a polymolecular stack and the K^+ cations are located alternatively inside and on top of successive macrocycles, as in a frozen picture of potassium ion propagation through the stack.



1 X = CONMe$_2$

Figure 1 shows the molecular crystal packing of the above complex along the [110] axis. The structure contains a polymolecular organic unit resulting from the repetition of a stacked dimeric asymmetric unit $[(\mathbf{1}, K)_2(H_2O)_3]^{2+}$, and is stabilized by hydrogen bonding of the water molecules with each other (O···O length 2.63 Å) and with six amide carbonyl groups (O···O length 2.50–2.95 Å), as well as by one ion dipole interaction (K_2^+···O 2.83 Å). The counterions are located in a polymeric chain $[KBr_3(H_2O)_4]^{2-}$ parallel to the organic one, made of alternating water-bridged KBr and BrBr fragments (Br···O 3.3–3.45 Å). The stability of the crystal packing is completed by Br···CH_3 van der Waals' interactions (3.68–3.76 Å) between the cationic and anionic chains.

The organic part of this structure has many attractive features. (1) The solid-state stacking of the macrocyclic units builds up an intermolecular arrangement clearly suggestive of a channel structure. The mean planes of the macrocycles are parallel to

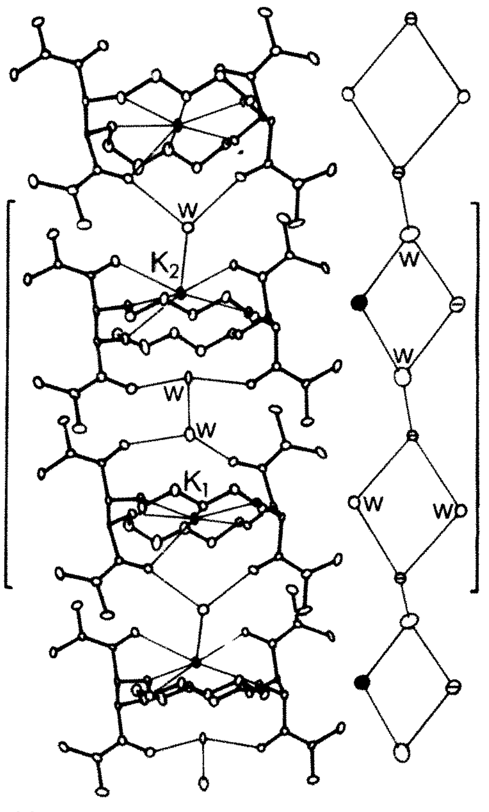


Fig. 1 Molecular packing of the complex $[(\mathbf{1}, K)_2, 3H_2O]^{2+} \cdot [KBr_3, 4H_2O]^{2-}$ down the [110] vector. Intermolecular contacts between the oxygen atoms of water molecules (W), and K^+ (●) or Br^- (⊖) ions are visualized by thin lines. Crystals belonging to the triclinic space group P1 were obtained by slow evaporation of an equimolecular solution of **1** and KBr in $CHCl_3/MeOH/H_2O$ ($a = 10.73$ Å, $b = 11.27$ Å, $c = 15.78$ Å; $\alpha = 109.85°$, $\beta = 99.35°$, $\gamma = 92.18°$). The crystal used had a size of $(0.4)^3$ mm^3. 6669 significant ($I > \sigma(I)$) reflections were collected up to $2\theta = 140°$ on an automated Nonius CAD4 diffractometer, using nickel-filtered Cu Kα radiation. The structure was solved by the standard heavy atom method followed by Fourier syntheses; final refinement by full-matrix least squares with anisotropic temperature factors for all non-hydrogen atoms led to an R factor of 0.096 for 799 variables. Atomic coordinates are available on request and will be deposited in the Cambridge Crystallographic Data Centre.

0028-0836/82/060526—02$01.00

each other and two neighbouring units are slightly shifted in a staircase-like fashion, due to steric hindrance between the lateral appendages.

(2) Both the macrocycles composing the asymmetric unit are in a relaxed conformation, similar to that found in other 18-crown-6-type complexes[15,16].

(3) The side chains $-CON(CH_3)_2$ are in an axial conformation, on both sides of the macrocyclic ring and direct their polar amide carbonyl groups into the internal space of the ligand.

(4) As a result of features (2) and (3) all apolar groups (methyl and methylene) of the macrocyclic units are on the outside. The previously determined structures of related compounds having secondary amide residues as lateral branches ($X = CONHR$ in **1**)[15] had already shown a *trans*-diaxial arrangement of the branches, but the carbonyl groups were directed outwards, with formation of an intramolecular $N-H\cdots O$ hydrogen bond between the CONH residues and the nearest ring ether oxygen atom. Consequently, the simple interconversion between secondary and tertiary amide functions allows a conformational control of the orientation of the polar groups towards the exterior or the interior of the structure respectively. This feature is of considerable interest for designing receptor molecules built on the basic macrocyclic unit **1**.

(5) There are two distinct K^+-binding schemes. In one complex of the asymmetric unit, the cation (K_1^+, Fig. 1) is located inside the macrocyclic ring, 0.25 Å from its mean plane; the receptor site includes all six ether oxygen atoms ($K_1^+\cdots O$ length 2.80 Å; $\sigma = 0.05$) and one carbonyl group ($K_1^+\cdots O{=}C$ length 2.76 Å). The other potassium ion (K_2^+, Fig. 1) is located on top of the macrocycle, at 1.13 Å from its mean plane; it is bound to only three ring oxygen atoms ($K_2^+\cdots O$ length 2.85 Å; $\sigma = 0.06$), to two amide carbonyl groups ($K_2^+\cdots O{=}C$ lengths 2.69, 2.89 Å) and to the oxygen of a water molecule ($K_2^+\cdots O$ 2.83 Å). These two modes of K^+ binding may be considered as two steps in a hopping mechanism of cation flow through the pore-like structure. Enniatins form sandwich complexes[17] like the RbNCS complex of enniatin B, in which every Rb^+ ion is bound to carbonyl oxygens of two ligand molecules[18].

(6) The polar interior of this solid-state channel contains three water molecules per asymmetric unit. They solvate the K^+ and amide groups, and provide H-bonding links between successive macrocyclic units.

In conclusion, the present structure possesses three main features which are expected to have a role in ion flow through membrane protein channels: a chain of cation binding units; polar inside/apolar outside orientation of residues; and mixed-site cation binding. It may therefore be considered a solid-state model of a molecular channel with cation propagation through the channel from one binding site to the next. The stepwise connection of macrocyclic units (Fig. 1) by their lateral appendages would allow the construction of a true artificial molecular channel, whose properties depend on the choice of the basic unit and of the linking branches. Synthetic work along these lines is in progress.

Transient nature of early haematopoietic spleen colonies

M. C. Magli*, N. N. Iscove† & N. Odartchenko*

* Swiss Cancer Research Institute, Épalinges-sur-Lausanne CH-1066, Switzerland
† Basel Institute for Immunology, Basel CH-4005, Switzerland

Certain cells (CFU-S) in the haematopoietic tissues of mice are able to form macroscopic nodules in the spleen 7–14 days after injection in heavily irradiated recipient mice[1]. At 7–9 days, most of the spleen colonies contain recognizable cells of one predominant haematopoietic lineage[2], and do not contain cells capable of spleen colony formation on injection in secondary hosts[3]. However, by 14 days most of the spleen colonies do contain cells of more than one line of haematopoietic differentiation[2], as well as precursor cells capable of again generating similar multilineal spleen colonies on retransplantation[3]. These observations have led to the widely accepted conclusion that most spleen colonies are derived from pluripotential 'stem' cells[3], and to the suggestion that the apparent transformation in character of spleen colonies from unilineal at early times to mixed later on reflects the local operation of 'instructive' differentiative signals in the splenic environment[2]. The reasoning behind these suggestions implicitly assumed that late colonies simply represented a further stage in the development of the same colonies observable at earlier times. Here, we present direct evidence against this assumption. Our data indicate that most spleen colonies identified as surface nodules at days 7–8 are neither multipotential nor self-maintaining, but rather are destined to disappear from the spleen within 72 h. The observations set limits on the validity of the spleen colony method as an assay for self-maintaining pluripotential progenitor cells, and give cause for reassessment of the data on which widely accepted views concerning the regulation of such cells are based.

Initial experiments compared individual spleen colonies at early and late times in their development in terms of their content of cells capable of growth in culture. Such data would provide two kinds of information concerning the character of a spleen colony. First, the presence or absence of 'primitive' haematopoietic precursors capable of extended proliferation in culture would indicate the potential of the spleen colony for further growth. Second, the number of different kinds of cells growing in the cultures would supply information on the differentiative potential of the original spleen colony-forming cell.

Adult mouse bone marrow cells were injected into heavily γ-irradiated syngeneic recipients, and after varying time intervals, the recipient spleens were excised and examined at ×11 magnification for surface colonies. A total of 156 consecutively identified colonies were dissected out from spleens containing 9 or fewer surface nodules. Particular care was taken to exclude the occasional colonies whose geometry suggested possible confluence of more than one colony. Single cell suspensions were prepared from each colony. Most of the cells were plated in methylcellulose cultures to assay for haematopoietic precursor cells, and the remaining cells were centrifuged onto glass slides for morphological evaluation. From the culture results, spleen colonies were classified as P^+ or P^- according to whether or not they contained any relatively 'primitive' precursor cells, defined as cells capable of forming mixed myeloid/erythroid clones in culture containing at least 1,000 cells, or clones containing at least 50 mononuclear or granulocytic cells, or at least 200 erythroid cells. Almost all spleen colonies which contained *in vitro* clonable mononuclear or granulocytic precursors also contained erythroid precursors. The proportion of each colony plated was such that the absence of growth in culture signified

0028–0836/82/060527—03$01.00

the presence within the spleen colony of fewer than eight clonable precursors in the case of large spleen colonies, and fewer than one or two in the case of spleen colonies consisting of $\leq$200,000 cells.

Figure 1*a* shows the results for 7–8-day spleen colonies. Most colonies consisted predominantly of recognizable erythroblasts and contained no 'primitive' precursors. Although devoid of primitive cells clonable *in vitro*, these P^- colonies did contain high numbers (up to 25% of the cells) of relatively mature erythroid precursors (CFU-E) capable of forming small clones of 8–60 erythroblasts in culture. Few spleen colonies contained >20% of morphologically unrecognizable cells. The frequency of such cells correlated neither with the predominant morphological type nor with the presence of primitive precursors.

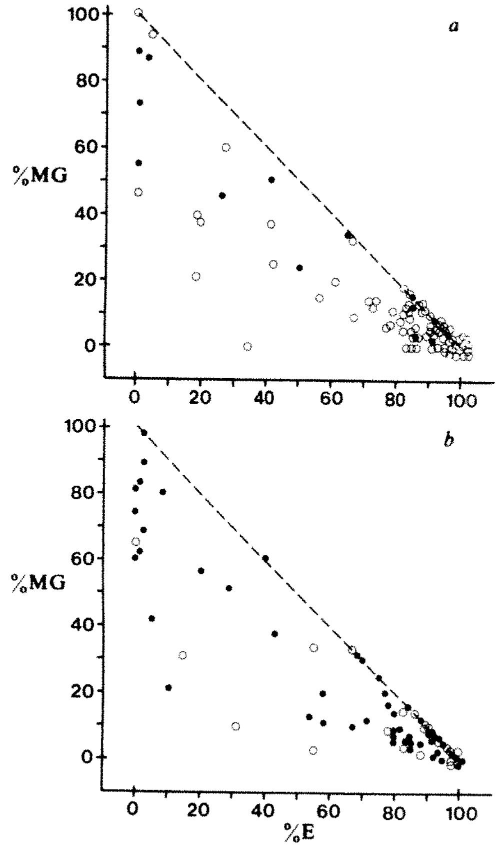

Fig. 1 Distribution of spleen colonies according to the character of their constituent cells. Each point represents one spleen colony, indicating presence (●) or absence (○) of primitive precursors capable of proliferating in culture, and the percentage of the cells identifiable morphologically as erythroid (E) or mononuclear/granulocytic (MG). *a*, Composition of spleen colonies after 7–8 days of growth in the spleen; *b*, after 9–12 days. Total numbers of spleen colonies examined were 37, 49, 14, 30, 17 and 9 on days 7–12, respectively. Female 8–12-week old BALB/c mice were γ-irradiated (800 R, ^{137}Cs) and injected intravenously with 1 or 3×10^4 nucleated syngeneic bone marrow cells suspended in IMDM[8] with 5% fetal calf serum (FCS). Controls injected with cell-free suspending medium had <1 colony per 20 spleens. Spleen colonies were dissected out and gently dispersed into single cell suspensions in IMDM containing 50% FCS. Some of the cells were cytocentrifuged onto glass slides, fixed in methanol and stained with Gurr's Giemsa. Cells were assigned to erythroid, mononuclear, granulocytic or megakaryocytic lineages on the basis of nuclear size, form, degree of condensation and presence of nucleoli, nuclear/cytoplasmic ratio, and cytoplasmic basophilia and granulation, according to classical morphological criteria. Cells were cultured at a maximum density of 10^5 per ml in IMDM containing α-thioglycerol, methylcellulose, bovine serum albumin, 15% FCS, iron-saturated transferrin, lecithin, oleic acid, cholesterol, 1 IU ml^{-1} human urinary erythropoietin (all as detailed elsewhere[8]) and 10% conditioned medium from WEHI-3 cells[9] as a source of erythroid burst-promoting activity[5] and of granulocyte/macrophage colony-stimulating activity. Small erythroid colonies from CFU-E were counted after 2 days of culture, and larger erythroid or mixed myeloid/erythroid bursts and granulocyte/macrophage colonies were counted on days 7, 10 and 14.

Figure 1*b* shows pooled results from spleen colonies analysed at later times of development (days 9–12). Three-quarters of the colonies now contained primitive precursors, a proportion consistent with earlier observations[3] on CFU-S in later spleen colonies but higher than that reported by Gregory and Henkelman in 11–12-day spleen colonies[4], possibly because of the addition to our cultures of a controlled concentration of 'burst-promoting activity'[5]. Half of our P^+ colonies showed mixed differentiation morphologically. Most P^- colonies again consisted predominantly of recognizable erythroblasts.

The relationship between early and late spleen colonies was then examined directly as follows. On days 7 or 8 after irradiation and marrow injection, recipient mice were anaesthetized and a small abdominal incision was made over the spleen. Each spleen was carefully inspected at ×11 magnification without excision and a topographical sketch made. The incision was then closed and splenic colony development permitted to continue for an additional 2 to 5 days before the mice were killed, and their spleens excised and again mapped topographically. Control experiments using irradiated mice which had not received bone marrow indicated that the surgical procedure did not itself induce the appearance of endogenous spleen colonies. The accuracy of the topographical sketches was confirmed in most cases by direct photography of the spleens. Figure 2 shows a typical result. Two of five colonies present on the spleen at day 8 are no longer visible at day 10, while, conversely, two of five colonies visible on day 10 were not visible at day 8. The aggregate results of the mapping experiments are presented in Table 1. Of the surface colonies visible on days 7 or 8, only half were still visible on day 10, whereas only one-third of colonies visible on day 10 had visible antecedents on days 7 or 8. In a separate experiment on a smaller scale, 80% of colonies visible at day 7 had vanished by day 12.

These results show spleen colonies to be divisible into two major categories. The first colony type (P^-) grows rapidly to achieve macroscopic dimensions at the spleen surface within 7–8 days and typically consists almost entirely of erythroid cells. Devoid of primitive cells capable of sustaining their growth, the P^- colonies soon vanish from the spleen, presumably as their cells differentiate terminally into erythrocytes and enter the circulation. A second colony type (P^+) grows more slowly in the first week, and at 7 days few can be indentified grossly at the spleen surface. Because their growth is sustained well beyond day 9 by the continuous presence of primitive cells, these P^+ colonies gradually become the predominant colony type as the P^- colonies recede and disappear.

These findings provide a fresh context for interpreting the significance of the 'transient endogenous erythroid spleen colonies' reported earlier[6,10,11]. Our observations and interpretations are also consistent with those of Hodgson and Bradley[7] on late-appearing spleen colony formation by fluorouracil-resistant precursors. Our results imply that the spleen colony method provides a measure of pluripotential cells

Table 1 Number of surface spleen colonies visible at ×11 magnification

	Days 7–8	Day 10
Transient	51	0
Persistent	50	50
Delayed in appearance	0	97
Total	101	147
	Day 7	Day 12
Transient	19	0
Persistent	5	5
Delayed in appearance	0	44
Total	24	49

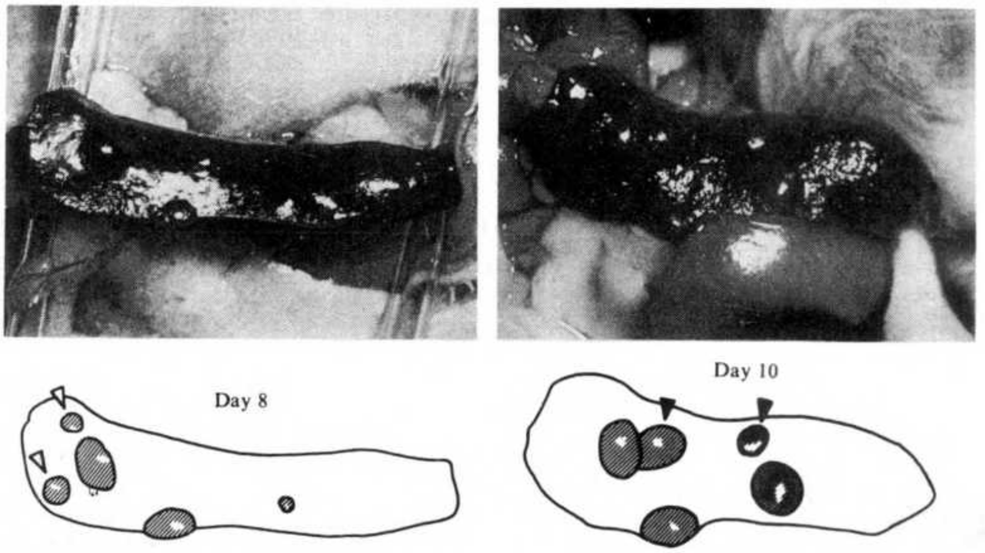

Fig. 2 The same spleen photographed after 8 (left) and 10 (right) days of spleen colony development. Drawings indicate the locations of the colonies. Colonies marked ▽ disappeared in this time interval; those marked ▼ were delayed in appearance.

capable of extensive proliferation only where macroscopic colonies are scored at 11 days or later. When spleen colonies are scored earlier than this, as has been done in almost the entire literature on the subject, the method appears to detect a population of cells more closely akin to the cells (BFU-E) which form large erythroid colonies after a similar length of time in semi-solid tissue culture[4,5]. Finally, our observations show that late multilineal P^+ spleen colonies are not derived from the unilineal P^- colonies visible at earlier times, and therefore remove a key supporting element from earlier arguments for 'instructive' local environmental control of self-renewal and determination at the level of multipotential progenitors.

We thank P. Barba and M. Bonzon for technical assistance, and N. Williams and C. Paige for critical readings of the manuscript. Isolation of membrane components associated with human red cell antigens Rh(D), (c̄), (E) and $\mathrm{Fy^a}$

Stephen Moore, Christina F. Woodrow
& D. Brian L. McClelland

South-east Scotland Regional Blood Transfusion Service,
The Royal Infirmary, Edinburgh EH3 9HB, UK

The isolation of human red cell membrane components associated with Rhesus (Rh) and Duffy (Fy) blood group antigen expression has been largely frustrated due to the small quantities in the membrane[1–5] and their probable integral membrane nature requiring lipid for optimum antigen expression[6–10]. The disadvantage of reported immunoaffinity techniques for investigating Rh(D) has been non-specific adsorption which complicates identification of antigen-associated components[11,12]. Thus, Rh(D) has been attributed to a 7,000 molecular weight (MW) fraction[11] and a subpopulation of band 3 (ref. 13; MW ~90,000)[12]. We report here a technique, with negligible non-specific adsorption, for the isolation of blood group antigen–antibody complexes and their analysis by SDS-polyacrylamide gel electrophoresis (PAGE). Radiolabelling techniques facilitated identification of antigen-associated membrane components. We found that expression of Rh(D), (c̄) and (E) was associated with a component(s) of 28,500 apparent MW, with additional 50,000- and 68,000-MW components associated with Rh(D). In contrast, $\mathrm{Fy^a}$ is associated with 39,500- (possibly PAS 2), 64,000- and 88,000-MW components, the latter having a similar mobility in SDS-PAGE to band 3.

The demonstration of stable Rh(D)–^{14}C-anti-Rh(D) complexes in detergent solution[10] together with the known affinity of protein A for the Fc region of IgG[14] suggested a rapid and generally applicable technique for the isolation of detergent-solubilized immune complexes of blood group antigen with the corresponding IgG antibody by adsorption to protein A–Sepharose (Pharmacia). The observation[10] that the optimum expression of Rh(D) occurs only in the native membrane environment suggested that it was advisable to form immune complexes by incubating antibody with the intact red cell.

^{125}I surface-labelled red cells were incubated (sensitized) with an appropriate IgG antibody and, following solubilization of the membrane in non-ionic detergent, the immune complexes isolated by adsorption to protein A–Sepharose. The complexes were eluted with SDS and analysed, in reducing conditions, by SDS-PAGE. The presence of ^{125}I label which indicated membrane components exposed on the outer surface of the red cell, a prerequisite for implication in expression of blood group antigen activity, was detected by autoradiography of the dried SDS-PAGE gels.

The total radioactivity present in complexes isolated from cells sensitized with anti-Rh(D), anti-Rh(c̄), anti-Rh(E) and anti-$\mathrm{Fy^a}$ antibodies is shown in Table 1. When compared with the negative controls, all complexes contained significant levels of ^{125}I, indicating the presence of surface exposed membrane components. The results obtained with anti-Rh(D) show, in particular, the effect of antigen dosage. The rare cells of genotype *-D-/-D-* ('super D') have ~2.5–5 times the amount of surface-exposed Rh(D) antigen compared with cells homozygous for Rh(D), such as $\bar{c}DE/\bar{c}DE$ (R_2R_2) cells[3]. The increased levels of ^{125}I in complexes from super D cells is consistent with this observation and is evidence for the specific association of the labelled component with Rh(D) antigen.

c̄DE/c̄DE	anti-Rh(E) (1:128, 25 ml)	23,656	1,604	22,052 (*e*)
CDe/CDe	anti-Rh(E) (1:128, 25 ml)	5,083	571	4,512 (*f*)
Fy(a + b−)†	anti-Fy^a (1:128, 25 ml)	23,912	1,530	22,382 (*g*)
Fy(a − b+)†	anti-Fy^a (1:128, 25 ml)	4,060	1,258	2,802 (*h*)

Washed human erythrocytes were surface-labelled with ^{125}I using the procedure of Reichstein and Blostein[18]: packed cells (1 ml) were incubated (37 °C, 90 min) with 20 ml of incubation buffer and washed (2 × 20 ml) with phosphate-buffered saline (PBS), *p*H 7.4. Packed cells were incubated (37 °C, 15 min) with 0.7 ml PBS, lactoperoxidase (EC1.11.1.7; Calbiochem grade B; 13 µl, 2.5 mg ml^{-1} in PBS), *β*-D-glucose oxidase (EC1.1.3.4; Sigma type V; 40 µl of 1:100 dilution in PBS), Na^{125}I (100 mCi ml^{-1}; Amersham; 10 µl (100 µCi) of 1:10 dilution in 0.01 M NaOH) and *α*-D-glucose (0.22 ml, 18 mg ml^{-1} in PBS prepared 24 h before use to allow mutarotation to occur), and washed with PBS (4 × 20 ml). The use of fresh batches of ^{125}I was critical to the success of the procedure. Old batches of ^{125}I did not significantly label Rhesus antigen-associated components, possibly due to oxidation of iodide by admitted air during storage. Packed, labelled (~30 µCi per ml packed cells) cells were incubated (37 °C, 60 min) with blood group antibody (whole human serum containing IgG blood group antibody of known specificity was obtained from volunteer donors and the titre determined by manual indirect antiglobulin test[19]), washed with PBS (3 × 20 ml) and the ghosts isolated[22] (1 ml of packed cells plus 40 ml of 5 mM NaH_2PO_4/Na_2HPO_4, *p*H 7.4 (4 °C), mix, centrifuge (48,000*g*, 15 min, 4 °C) repeat wash). Ghosts were incubated (15 min, room temperature) with 6 ml of PBS-Triton (PBS containing 1% (w/v) Triton X-100; BDH, scintillation grade), centrifuged (48,000*g*, 15 min, 4 °C) and the supernatant carefully aspirated. Immune complexes were adsorbed from the PBS-Triton extract (contained in a 10 ml, conical, plastic centrifuge tube) with 0.5 ml of a 10% (v/v) suspension of protein A–Sepharose in PBS-Triton and the mixture incubated (30 min, room temperature) with continuous roller mixing. The protein A–Sepharose beads were washed (4 × 10 ml) with PBS-Triton, counted for ^{125}I, washed with distilled H_2O (10 ml) and the packed beads resuspended in 1% SDS (1 ml) and incubated at 37 °C for 30 min. The supernatant was lyophilized by vacuum centrifugation[23] and reconstituted in 0.15 ml of electrophoresis sample buffer (0.0625 M Tris-HCl, *p*H 6.8, 8 M urea, 0.5 mM EDTA, 0.001% (w/v) Bromophenol blue, 5% (v/v) 2-mercaptoethanol) and stored at −40 °C. *a–h*, *n* Cross-refer to Fig. 1.

* Values for antibody titres and the volume used are given in parentheses.

† 2 ml packed cells used.

Figure 1 shows the results of SDS-PAGE analysis. In preliminary experiments (not shown) we could not obtain discrete electrophoretic separation of ^{125}I-labelled bands using the standard Laemmli sample buffer because the labelled material did not penetrate the stacking gel. Inclusion of 8 M urea in the sample buffer was essential to obtain discrete separation, thus suggesting the hydrophobic nature of these components.

Figure 1 shows that non-specific binding in negative controls (Fig. 1*b*, *d*, *f*, *h*) was not a problem in our procedure. The ^{125}I activity detected in negative controls (Table 1) was not detected by autoradiography and presumably represents low molecular weight, non-specifically adsorbed material not retained in the gel during fixation as autoradiography readily detects this level of activity[15,16]. The complexes isolated from cells sensitized with anti-Rh(D), anti-Rh(c̄) and anti-Rh(E) antibodies gave similar patterns of Coomassie brilliant blue (CBB) staining. In addition to IgG heavy (H) and light (L) chains, all contained CBB-stained components migrating in the band 3 region. This is of interest because recent reports suggest that band 3 is associated with the expression of Rh(D) activity[12,17]. However we did not detect any radioactivity in these components, suggesting that either these are not of band 3 origin (it is known that band 3 is labelled by the procedure used in this work[18]) or they are composed of an unlabelled band 3 subpopulation. We cannot completely exclude the possibility that these bands are derived from IgG.

Marked differences were observed in the radiolabelled components present in the various immune complexes which we isolated; for example compare the anti-Rh(D) complex pattern with that of anti-Fy^a complex (Fig. 1*j* and *i* respectively), and the patterns of the anti-Rh(c̄) and anti-Rh(E) complexes (Fig. 1*c* and *e* respectively). Differences were also observed in the Rhesus system; thus anti-Rh(D) complexes contained in addition to the 28,500-MW component (A28 in Fig. 1) common to all Rhesus complexes, bands of 50,000 and 68,000 MW which together accounted for ~20% of the radioactivity in the anti-Rh(D) complex. The presence of these extra bands was not influenced by sample loading (compare Fig. 1*a* with *j*). The possibility of qualitative differences between Rh(D)-associated components on *-D-/-D-* and *c̄DE/c̄DE* cells was investigated. Anti-Rh(D) complexes from these cells were qualitatively identical (Fig. 1*n*, *o*). However, we observed an increase in a component with similar mobility to A28 when comparing Triton extracts of *-D-/-D-* (Fig. 1*k*) and *c̄DE/c̄DE* (Fig. 1*l*) cells. This component is probably A28 because there is increased expression of Rh(D) on *-D-/-D-* cells. The A28 bands were the most prominent feature in the three Rhesus complexes tested and therefore most likely to carry the majority of the antigen sites on the cell surface. The ratio of ^{125}I activity to observed CBB staining intensity for A28 was much higher in anti-Rh(D) complexes. There are two possible explanations: (1) Rh(D) may be associated with a different population of A28 molecules which contain a higher number of iodination sites, and (2) the increased ratio of label to CBB stain may reflect a greater exposure on the red cell surface. The latter possibility is intriguing because it is well documented that Rh(D) is by far the most immunogenic of the Rhesus antigens[19,20].

The lower quantity of IgG H and L chains observed in anti-Fy^a complexes (Fig. 1*g*) may reflect the smaller number of Fy^a sites per cell compared with Rhesus antigens[5]. We concluded from Fig. 1*g*, *m* that expression of Fy^a activity is associated with a radiolabelled band of 39,500 MW showing similar mobility to PAS 2 (compare Fig. 1*l* with *m*). Labelled bands of 64,000 and 88,000 MW were also seen with counterparts in Triton extracts of labelled membranes (Fig. 1*k*, *l*, *p*). The 88,000-MW component had a similar mobility to PAS 1 and band 3. The possibility that Fy^a is carried by a fraction of the major red cell membrane sialoglycoprotein and band 3 requires further investigation. The 50,000-MW component (Fig. 1*i*) with an apparent similarity to the 50,000-MW component associated with Rh(D) (Fig. 1*j*) was not always observed in anti-Fy^a complexes (see Fig. 1*m*). The identity of this component is therefore obscure.

The molecular composition of the Rhesus and Duffy native antigens remains unclear. Folkerd *et al.*[21] have measured a value of 174,000 ± 10,000 for the *in situ* molecular weight of Rh(D) by radiation inactivation, which suggests that A28 is a subunit of a larger molecule or that degradation has occurred during immune complex isolation. Degradation due to radiolabelling or proteolysis was not detected in our procedure. Identical CBB staining of Rh complexes isolated from labelled and unlabelled cells was seen in SDS-PAGE. Identical CBB staining and autoradiographic profile were also seen when 1 mM phenyl-

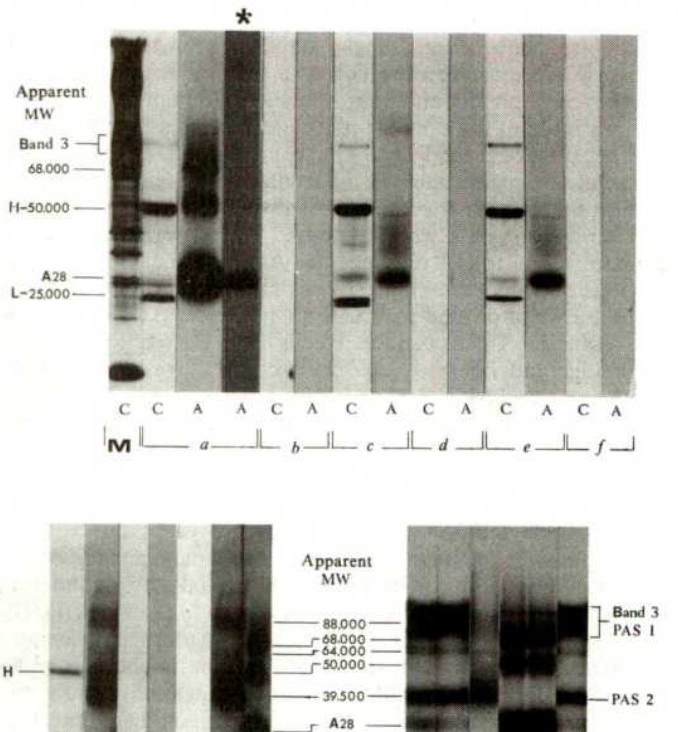

Fig. 1 SDS-PAGE of immune complexes eluted from protein A-Sepharose (see Table 1). Electrophoresis was performed at 35 mA (stacking) and 100 mA (running) on 7.5–15% polyacrylamide gradient gels ($180\times140\times0.27$ cm; Pharmacia GE2/4LS vertical apparatus) with a 5% polyacrylamide stacking gel using the discontinuous system of Laemmli[24]. Gels were stained with CBB and autoradiography of dried gels performed at −75 °C using Kodak XS-1 X-ray film and Cronex Lighting Plus intensifying screens[15,16]. Films were developed and fixed with Kodak DX-80 and FX-40 respectively, according to the manufacturers instructions. Samples were incubated overnight at 37 °C before electrophoresis. Samples *a–h* (see Table 1) were applied to gels in their entirety. *i*, *j*, Comparison of autoradiographs of anti-Fy^a (*i*) and anti-Rh(D) (*j*) immune complexes, 20,000 c.p.m. per sample. *k–p*, Autoradiographic comparison of anti-Rh(D) complexes from *-D-/-D-* (*n*) and *c̄DE/c̄DE* (*o*) cells with anti-Fy^a complexes (*m*; separate experiments to *g*, *i*), and with Triton-soluble membrane fractions sampled before protein A-Sepharose addition and diluted with 9 vol of electrophoresis sample buffer plus 5% SDS; *k*, *-D-/-D-* cells; *l*, *p*, *c̄DE/c̄DE*, Fy(a+) cells. 50,000 c.p.m. were applied for samples *k*, *l*, *n–p*; 16,000 c.p.m. for *m*. Average c.p.m. for total Triton soluble fraction (7 ml) $\approx 4\times10^7$. Autoradiograph exposure times: *a–j*, *m*, 60 h; *k*, *l*, *n–p*, 3.6 h. H, L, H and L chains of IgG; A, autoradiograph; C, CBB stained. *, Short exposure of Kodak XR-1 film to demonstrate the centre of the radiolabelled band. M, red cell ghosts solubilized in sample buffer plus 5% SDS.

methylsulphonyl fluoride, 2 mM *N*-ethylmaleimide and 0.5 mM EDTA were included in cell lysis and membrane solubilization buffers to inhibit proteolysis. The possibility that A28 and the 68,000-MW component in Rh(D) complexes (Fig. 1*a*, *j*, *n*, *o*) are the band 3 degradation products reported to bind IgG non-specifically[12] can be discounted as these were absent in Fy^a complexes (Fig. 1*i*, *m*).

In conclusion, the advantages of our procedure are its simplicity, lack of non-specific interference and the ease with which membrane components exposed on the outer surface of the red cell can be identified. Coupled with the potential for preparative isolation of immune complexes we consider this technique to be of value for future work on the structure of red cell antigens.

This work was supported by grant K/MRS/50/206 from the Biomedical Research Committee of the Scottish Home and Health Department. We thank Mr A. McGowan and Mr G. Neill for supplying the necessary antisera and the South London Blood Transfusion Service for the gift of *-D-/-D-* cells.

Absence of *Ir* gene control of T cells recognizing foreign antigen in the context of allogeneic MHC molecules

Norihisa Ishii*, Zoltan A. Nagy & Jan Klein

Max-Planck-Institut für Biologie, Abteilung Immungenetik,
Corrensstrasse 42, 7400 Tübingen, FRG

The major histocompatibility complex (MHC)-linked immune response (*Ir*) genes confer high responsiveness on some MHC haplotypes and low or no responsiveness to certain antigens on other haplotypes (for review see ref. 1). The cause of nonresponsiveness is thought to be a failure of T cells to be stimulated by a given combination of antigen and MHC molecules, which can, in principle, arise in two ways: either the antigen-presenting cells (APCs or macrophages) of the nonresponder haplotypes are incapable of presenting the foreign antigen to T cells in an immunogenic form[2,3] or the T-cell repertoire of nonresponder haplotypes lacks clones recognizing the antigen in the context of a given MHC[4]. We have recently shown that APCs from nonresponder strains can in fact present antigen to allogeneic responder T cells, depleted of alloreactivity against the APCs themselves[5], which indicates that the mechanism of nonresponsiveness is not a failure of APC function. Using the same experimental system, we show here that responses of T cells to antigen presented on allogeneic APCs do not depend on the Ir phenotype of either the T cell or the APC: *Ir* gene control is completely absent from these responses. The results strongly suggest that *Ir* gene-controlled nonresponsiveness is associated with the adjustment of the T-cell repertoire to self-MHC antigens.

Recently we have developed an assay system for measuring the proliferative response of T cells to antigens presented by allogeneic APCs[5]. T cells were prepared by nylon wool-column separation of nucleated spleen cells from unprimed mice, and adherent cells obtained from peritoneal washing served as APCs. The T cells were first cultured with allogeneic APCs and alloreactive T cells were removed by treatment with 5-bromo-2′-deoxyuridine (BUdR) and light on day 3 (ref. 6). The surviving T cells were then primed *in vitro* using fresh allogeneic APCs and an antigen, the response to which is under *Ir* gene control. After an additional 7 days in culture, T cells were collected, distributed into flat-bottomed microtitre plates and tested for

Proliferation of *in vitro* primed T cells (1×10^5) in the presence of 1×10^5 APCs and 40 μg ml^{-1} GA was measured by ^{3}H-thymidine incorporation[7]. The results are expressed as Δ c.p.m., that is, c.p.m. in cultures with GA and APC −c.p.m. in cultures with APC and without GA; and stimulation index (SI), that is, c.p.m. in cultures with GA and APC divided by c.p.m. in cultures with APC but without GA. The background c.p.m. in cultures without antigen were in the range 167–3,224. The culture and assay conditions were identical (including preculturing of T cells with APCs alone, followed by BUdR and light treatment) to those used for allogeneic T cell–APC combinations[5]. R, responder; NR, nonresponder.

secondary proliferative response to the priming antigen and fresh APCs in a 3-day assay[7]. In this system, allogeneic APCs alone did not induce appreciable specific T-cell proliferation. Using the antigens poly($Glu^{40}Ala^{60}$) (GA), poly($Glu^{51}Lys^{34}Tyr^{15}$) (GLT) and lactate dehydrogenase B (LDH-B), secondary T-cell proliferation was induced only by the priming antigen presented on the priming allogeneic APC. Furthermore, proliferation was inhibited by monoclonal antibodies raised against Ia antigens on the APCs, but was not affected by antibodies to Ia antigens present on the T cells (ref. 5 and N.I., unpublished results). Thus, the secondary proliferation *in vitro* of T cells is antigen specific, and is restricted by Ia antigens of the allogeneic APCs.

This study was undertaken to determine the possible influence of the Ir phenotype of T cells and APCs on the secondary response *in vitro*. We used GA as a test antigen because the number of responder and nonresponder *H–2* haplotypes to this antigen is about the same[7]; this allowed us to assemble a large number of allogeneic T cell–APC combinations with strains of different responder status. To ascertain that our *in vitro* system is subject to the same *Ir* gene control as the *in vitro* response of T cells primed *in vivo*, we first studied the responses of T cells primed *in vitro* to GA on syngeneic APCs. The data in Table 1 demonstrate that responder T cells can mount a proliferative response when primed with GA on syngeneic APCs, whereas nonresponder T cells cannot. T cells from F_1 hybrids between responder and nonresponder mice can only respond to GA when presented by F_1 APCs, or APCs of the responder parent. Thus we conclude that the *Ir* gene control of the *in vitro* secondary T-cell response is identical to that observed after priming *in vivo*[7,8]. We then tested the anti-GA response in a large number of allogeneic T cell–APC combinations. The combinations fell into four groups: (1) responder T cell–responder APC, (2) nonresponder T cell–nonresponder APC, (3) nonresponder T cell–responder APC, and (4) responder T cell–nonresponder APC. The results (Table 2) show that T-cell proliferation to GA was readily induced in all four types of strain combination. The rate of success of our experiments was 83% (for a total of 108 tests), and the occasional negative results were never reproducible. The data therefore establish that the response of T cells to antigen presented by fully allogeneic APCs is not under *Ir* gene control.

However, note that we did observe nonresponsiveness in partially allogeneic T cell–APC combinations. For example, of several strain combinations where the genetic difference between the T cells and APCs consisted of non-expression as opposed to expression of the I-E molecule (such as B10.A(4R)–B10.A(2R) and B10.S(7R)–(B10.S(9R)), some combinations were consistently found to respond, whereas others were nonresponders, to the antigen GLT. The detailed results of these experiments and their interpretation will be published elsewhere (N.I., Z.A.N. and J.K., in preparation).

The assay conditions and calculations of Δ c.p.m. and SI were as described in Table 1 legend. Background c.p.m. (cultures with allogeneic APCs but without GA) were in the range 445–4,263.

The lack of *Ir* gene control in allogeneic T cell–APC interactions is best explained by assuming that the T-cell repertoire of each individual consists of (at least) two different compartments: one that recognizes foreign antigen in the context of self-MHC antigens[9–13], and another that uses all allogeneic MHC antigens of the species for antigen recognition. The self-restricted part of the repertoire is incomplete, that is, it exhibits *Ir* gene-controlled nonresponsiveness, whereas the allogeneic MHC-restricted part appears to be complete. Nonresponsiveness probably arises by functional or physical elimination of autoaggressive T-cell clones from the self-restricted repertoire[14]. This elimination process should not affect the allogeneic MHC-restricted part of the repertoire. The physiological significance of T cells restricted by allogeneic MHC is unclear. There are two possible explanations: either these cells are irrelevant for the individual or allogeneic restriction represents cross-reactivity of T cells normally recognizing another foreign antigen together with self-MHC molecules.

tRNA precursor transcribed from a mutant human gene inserted into a SV40 vector is processed incorrectly

Michael Zasloff*, Tomas Santos* & Dean H. Hamer†

* Genetics and Biochemistry Branch, National Institute of Arthritis, Diabetes, Digestive and Kidney Diseases, and † Laboratory of Biochemistry, National Cancer Institute, National Institutes of Health, Bethesda, Maryland 20205, USA

We have identified 12 initiator methionine tRNA ($\mathrm{tRNA}_i^{\mathrm{Met}}$) genes in the haploid human genome[1]. One gene, cloned from a recombinant phage library of human fetal liver DNA, contained a base substitution at position 56 in the mature eukaryotic initiator tRNA sequence. The substitution, a G replaced by a T, should generate a tRNA species having a U at a sequence position not observed in any of 178 sequenced prokaryotic and eukaryotic tRNAs[2]. Recently, we have demonstrated[3] that this variant tRNA gene is efficiently transcribed in an homologous *in vitro* system derived from KB cells. However, the precursor RNA species of the variant gene, unlike that of the normal one, is not fully processed to a mature sequence in these cell-free extracts. Although the three nucleotides of the 5′ leader sequence are efficiently trimmed, the 13-nucleotide 3′ trailer is not processed, resulting in the accumulation of an 87-nucleotide precursor. In this report we assay the functional properties of the human variant initiator tRNA gene within an intact cell by studying its transcription from a simian virus 40 (SV40) recombinant during lytic infection of African green monkey kidney (AGMK) cells. We demonstrate that the variant gene is efficiently transcribed when inserted in the SV40 chromosome but, as *in vitro*, the precursor tRNA is not processed to a mature tRNA species.

The SV40 vector used for this study has been described in detail elsewhere[4]. The structure of the SV40–$\mathrm{tRNA}_i^{\mathrm{Met}}$ recombinant (SVtm) is shown in Fig. 1. It contains a 1.15-kilobase (kb) fragment of human genomic DNA harbouring a single $\mathrm{tRNA}_i^{\mathrm{Met}}$ gene. This fragment is inserted in an SV40 vector that contains the origin of replication, the entire viral early region, and the extreme 5′ and 3′ termini of the viral late region. The $\mathrm{tRNA}_i^{\mathrm{Met}}$ gene is oriented such that its polarity of transcription is opposed to that of the viral late promoters. AGMK cells were infected with a mixture of SVtm DNA and the temperature-sensitive helper, SV40tsA239 (ref. 5), and the resulting viral stocks were used in the following studies.

Confluent flasks of AGMK cells were infected with an innoculum of the viral stock prepared as described above, or with a control preparation consisting of a SV40 recombinant containing murine α-fetoprotein DNA sequences[6]. After 60 h of infection at 39.5 °C, the cells were placed in low phosphate medium containing 100 μCi ml^{-1} of ^{32}P$_i$, and cultured for an additional 6 h. Restriction analysis of the DNA recovered from one such infection showed that SVtm represented ~60% of the viral molecules and SV40tsA239 the remainder.

Total cytoplasmic and nuclear RNA were recovered from the infected cells and analysed by electrophoresis in 10% polyacrylamide gels in 7 M urea[7]. An autoradiograph of one such product analysis is shown in Fig. 2. Both the cytoplasmic and nuclear fractions from SVtm-infected cells contain a single low-molecular weight species, absent from the control samples, that is ~89 nucleotides long, compared with the 90-nucleotide primary transcript observed *in vitro*[3]. This RNA species represents ~30% of the newly synthesized tRNA species resolved on the gel. The relative intensities of the other low-molecular weight RNA species observed do not appreciably differ between the SVtm and control infections. For example, with respect to the intensity of the 5S RNA species, the amounts of labelled 4.5S and total tRNA do not differ between the SVtm- and control-infected cells.

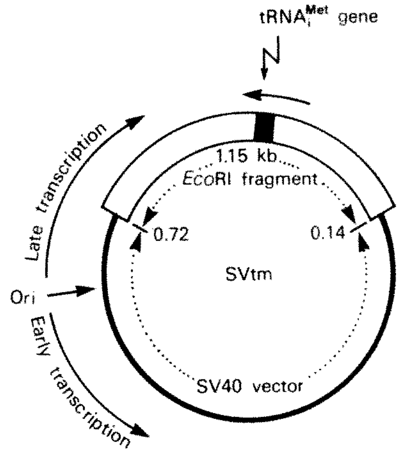

Fig. 1 SV40 recombinant containing the 1.15-kb fragment of human DNA bearing the variant $\mathrm{tRNA}_i^{\mathrm{Met}}$ gene. A 3.1-kb fragment of SV40 DNA, extending from 0.72 to 0.14 on the circular map and containing the early region, was cloned in pBR322 at the *Eco*RI site as described previously[4]. The pBR322–SV40 vector was linearized by partial *Eco*RI digestion and recovered after agarose gel electrophoresis. The linear vector was ligated to the 1.15-kb fragment bearing the variant $\mathrm{tRNA}_i^{\mathrm{Met}}$ gene[1], and the ligation mixture used to transform *Escherichia coli* strain LE392 (ref. 18). Clones bearing the 1.15-kb insert were identified by colony hybridization[19], and one containing the $\mathrm{tRNA}_i^{\mathrm{Met}}$ in an orientation opposite to that of the late viral promoter was propagated. Plasmid DNA from this clone was isolated[20] and digested partially with *Eco*RI, releasing a 4.25-kb fragment consisting of the 3.1-kb viral sequence and the 1.15-kb fragment. Following purification by gel electrophoresis, the fragment was recovered and circularized with T4 DNA ligase[4]. Ori, origin of viral replication; ■, schematic location of the $\mathrm{tRNA}_i^{\mathrm{Met}}$ gene within the chromosomal insert, with arrow above indicating direction of transcription from the tRNA promoter.

0028–0836/82/060533—03$01.00

The RNA species accumulating in the SVtm infection was recovered from the gel and analysed by classical fingerprinting techniques[8,9]. A fingerprint of a T1 digest of this RNA is shown in Fig. 3 and the complete sequence is presented in Fig. 4. The numbered spots were identified by secondary complete pancreatic RNase digestion and product analysis. Absolute identification was aided by knowledge of the sequence and previous fingerprint analysis of *in vitro* transcripts of this gene[3]. The point critical to this discussion is that the transcript is clearly a precursor of the variant tRNA$_{\mathrm{i}}^{\mathrm{Met}}$. The base substitution at position 56 eliminates an AUCG oligonucleotide and results in the appearance of the long oligonucleotide AUCUAAACCAUCCUCUG (spots 12, 13), representing the loop 4 region of the tRNA. The 3'-terminal sequence CUUU is present, along with the oligonucleotide CUAAAG, which lies within the 3' trailer. Digestion of the precursor with T1 generates a pUUAG arising from position −2 in the DNA sequence. Analysis of a total T2 digest by two-dimensional TLC fails to reveal any pppGp.

We have performed only a preliminary analysis of base modification within the precursor. 1-Methylation of adenosine at position 57, adjacent to the base substitution at 56, occurs in ~70% of the precursor. The adenosine at position 36, adjacent to the anticodon, and normally modified in tRNA$_{\mathrm{i}}^{\mathrm{Met}}$ to N^6-(threoninocarbonyl)adenosine is unmodified in the precursor (data not shown). Analysis of total modified nucleosides by the TLC methods of Nishimura[10] demonstrated some 5,6-dihydrouridine, 5-methylcytidine (position 47) and G-methylation, but the full extent of these, and specific positions, have not been determined.

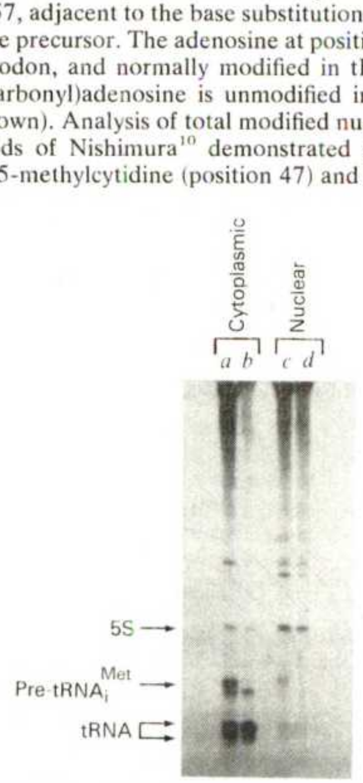

Fig. 2 Electrophoretic analysis of ^{32}P-labelled RNA isolated from AGMK cells during late phase of SVtm infection. SVtm, described in Fig. 1, was encapsidated by transfection of AGMK cells with 0.5 μg of SVtm DNA and 0.2 μg SV40 tsA239 helper DNA, as described elsewhere[4]; 2.5 ml of the resulting lysate was added to a monolayer of 2×10^7 AGMK cells and incubated at 39.5 °C for 64 h. Media was replaced with minimal essential medium without phosphate but containing 5% dialysed fetal calf serum. Carrier-free ^{32}P (New England Nuclear) was added to 100 μCi ml^{-1}, and the cells were incubated at 39.5 °C for an additional 6 h. The flasks were washed several times with Dulbecco's phosphate-buffered saline (PBS) (without added magnesium and calcium) and then scraped free with a rubber policeman. After several washes with PBS the cells were washed once in TKM buffer containing 50 mM Tris-HCl *p*H 7.6, 80mM KCl, 5mM magnesium chloride, collected by centrifugation, and lysed by suspension in 1 ml of TKM containing 0.2% NP-40. Nuclei were removed by centrifugation at 10,000*g* for 10 min. The post-nuclear supernatant was collected, made 0.2% in SDS and extracted twice with 1 vol of phenol, 1/2 vol chloroform/isoamyl alcohol (24:1). Nuclear RNA was extracted by the hot acid-phenol method[21]. A control infection, using the identical SV40 vector ligated to a 2.5-kb fragment containing the murine α-fetoprotein gene sequences[6] was carried through all corresponding steps. Samples of RNA were loaded onto a 1 mm-thick, 25 cm-long 10% acrylamide gel in TBE buffer[7] containing 7M urea and electrophoresed at 700 V for 4 h. The gels were autoradiographed against Kodak XR2 film at −20 °C for 20 min. Lanes *a*, *c*, ^{32}P-RNA from cells infected with SVtm; lanes *b*, *d*, RNA from cells infected with SV40 vector containing murine α-fetoprotein genomic insert. Arrows indicate mobilities of 5S RNA, tRNA and tRNA$_{\mathrm{i}}^{\mathrm{Met}}$ precursor.

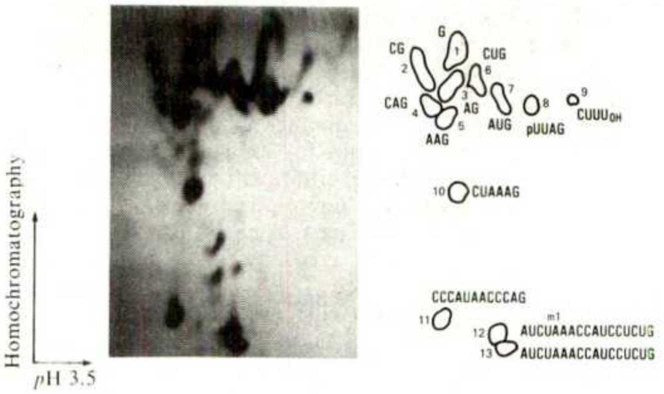

Fig. 3 Fingerprint analysis of the 89-nucleotide RNA accumulating during late infection with SVtm. The major species migrating in the pre-tRNA region, as shown in Fig. 2*a*, was recovered from the gel[22] (10^5 d.p.m.), digested to completion with T1 RNase and fingerprinted as described elsewhere[8,9] using iontophoresis on cellulose acetate at *p*H 3.5 in the first dimension; and homochromatography on DEAE-cellulose TLC plates in the second dimension. Secondary digestions of selected oligonucleotides were done using pancreatic RNase, followed by electrophoresis on DEAE-cellulose paper, to confirm oligonucleotide assignment. 1-Methyladenosine was identified by secondary digestion of oligonucleotide 12 with RNase T2, followed by two-dimensional TLC[10].

As the precursor represents ~30% of the total newly synthesized RNA in the tRNA population, we would expect that efficient processing of this species should result in the accumulation of tRNA$_{\mathrm{i}}^{\mathrm{Met}}$ as a major RNA species in the cell. However, hybridization of equal amounts of gel-purified tRNA from SVtm and control infections to filter-bound tRNA$_{\mathrm{i}}^{\mathrm{Met}}$ DNA occurred at approximately equal rates and reached a maximum level of hybridization of ~1% of the input radioactivity in each case (data not shown). We conclude that conversion of the mutant precursor to mature tRNA does not occur with any significant efficiency.

Conclusions concerning the *in vivo* activity of the human variant tRNA$_{\mathrm{i}}^{\mathrm{Met}}$ gene are based on the assumption that transcription of the gene occurs from the tRNA$_{\mathrm{i}}^{\mathrm{Met}}$ promoter. Several observations lead us to believe that this is the case. The tRNA$_{\mathrm{i}}^{\mathrm{Met}}$ is most likely transcribed from the recombinant SV40 chromosome by RNA polymerase III, based on the 3'-terminal sequence of the tRNA$_{\mathrm{i}}^{\mathrm{Met}}$ precursor, GCUUU. The polymerase responsible appears to have recognized accurately the termination signal of the gene, GCTTTTT . . . , a property, as far as we know, unique to RNA polymerase III[11]. Although the major intermediate lacks a 5'-terminal triphosphate, and thus is not an intact initial transcript, it is shorter by only one nucleotide than the primary transcript observed during transcription *in vitro* of the variant tRNA$_{\mathrm{i}}^{\mathrm{Met}}$ gene. We presume that some nibbling of the 5' end has occurred in the system, similar to that observed during the biosynthesis of tRNA$^{\mathrm{Tyr}}$ following injection of the gene into the intact *Xenopus laevis* oocyte[12]. Although it is possible that the 89-nucleotide intermediate represents the product of previous cleavage of a longer RNA species initiated upstream, we believe there is no strong evidence to support this possibility. No RNA polymerase III promoter has been demonstrated on the 1.15-kb chromosomal fragment inserted in SV40, except for the tRNA$_{\mathrm{i}}^{\mathrm{Met}}$ gene, in *in vitro* systems using KB cells and *X. laevis* ovarian extracts[3]. Initiation from within a viral sequence is unlikely as no functional RNA polymerase III transcription unit having activity comparable with that observed on the SVtm recombinant has been identified on SV40[13]. Furthermore, the level of expression is much higher than would be expected from the viral early promoter, which is oriented in the same polarity as the tRNA gene, representing no more than 0.01% of total RNA synthesized late in lytic infections[14].

Although the variant human tRNA$_{\mathrm{i}}^{\mathrm{Met}}$ gene is transcribed *in*

Fig. 4 Sequence of the variant tRNA$_i^{Met}$ transcript and the corresponding gene. Arrow denotes the base transversion at position 56 in the tRNA$_i^{Met}$ sequence. Brackets indicate mature termini of the tRNA. Numbered oligonucleotides correspond to those noted in Fig. 3. The sequence of the gene and flanking regions was determined previously[1].

vitro to about the same extent as the normal gene, the significance of this is rather clouded in that the template is not, in conditions of cell-free transcription, organized into chromatin, the structure it assumes physiologically. By using the SV40 vector, however, we can demonstrate that the mutant tRNA gene is indeed functional when present in the nucleus as a supercoiled, chromatin-packaged structure.

Our finding that the variant human tRNA$_i^{Met}$ gene is transcribed in an intact cell but that the precursor is not efficiently processed to a mature tRNA suggests that mutations within eukaryotic tRNA genes may be more prevalent than assumed from the limited sequence variation observed in mature tRNA species. We suggest that nucleolytic processing of tRNA precursors, which in the case of the human tRNA$_i^{Met}$ gene transcript involves excision of a 5′ leader and 3′ trailer, provides a 'proof-reading' function resulting from stringent sequence or structural requirements of cellular processing endonucleases. Note that the absence of any significant conversion of the variant precursor to mature tRNA$_i^{Met}$ also argues against the presence of an activity in the intact cell, such as a purine 'insertase'[15], which might efficiently correct mutations at a post-transcriptional step.

Although it is clear that the variant tRNA$_i^{Met}$ gene is expressed on the SV40 vector, it does not necessarily follow that the gene is active in the human genome. Foreign genes inserted into SV40 are generally expressed regardless of the state of transcriptional activity of the gene in the infected cell[16]. We do not yet know the functional state of the variant tRNA$_i^{Met}$ locus in human somatic cells, although several studies probing the nuclease sensitivity[17] of the locus are in progress.

We thank Dr Schumperli for help with the RNA sequence analysis and Mrs Joan Glass for helping to prepare the manuscript.

Stereochemistry of iron in deoxyhaemoglobin

M. F. Perutz*, S. Samar Hasnain†, P. J. Duke†, J. L. Sessler‡ & J. E. Hahn‡

* MRC Laboratory of Molecular Biology, Cambridge CB2 2QH, UK

X-ray crystallography has shown that in deoxyhaemoglobin the iron atoms are displaced by 0.56±0.03 Å from the mean porphyrin plane, whereas in liganded haemoglobins they lie either in or close to that plane[1,2]. Perutz[3] proposed this shift as one principal factor responsible for haem–haem interaction. Eisenberger *et al.* used extended X-ray absorption fine structure (EXAFS) to measure the Fe–N distance in deoxyhaemoglobin and concluded that the irons lie only 0.2 $^{+0.1}_{-0.2}$ Å from the plane of the porphyrin nitrogens and that the mechanism of Perutz is therefore invalid[4]. We have now compared the EXAFS of deoxyhaemoglobin with that of the ferrous 'picket fence' 2-methylimidazole complex in which the displacement of the iron from the plane of the porphyrin nitrogens is known to be 0.399±0.004 and 0.426±0.004 Å from the mean porphyrin plane (ref. 5). The two EXAFS spectra are very similar, consistent with similar displacements of the irons. We find the same Fe–N distance of 2.06±0.01 Å in deoxyhaemoglobin as Eisenberger *et al.*, but show that the displacement of the iron cannot be calculated from that distance.

The samples were prepared as follows. A 15 mM solution of human deoxyhaemoglobin was prepared from a red cell lysate by pressure dialysis followed by deoxygenation and addition of neutral $Na_2S_2O_4$ in an oxygen-free glove box. A drop of this solution was mounted in a hole 5 mm wide in a 1 mm-thick copper strip, sealed between thin mylar films and kept under nitrogen before use. The crystalline picket fence complex (2-methylimidazole-*meso*-tetra(*α*,*α*,*α*,*α*-*O*-pivamidophenyl)porphyrinatoiron-(II)-ethanol [Fe^{2+}(T piv PP)-(2-MeIm).EtOH] was prepared in oxygen-free conditions as described in ref. 5. In the first of the two independent EXAFS experiments, 2 mm-wide thin-walled glass capillaries were filled with the sample and sealed with bees' wax. In the second, the complex was diluted by mixing with boron nitride (~1 : 1 by wt) and then formed into a pellet 0.4 mm thick by pressing between two Mylar sheets separated by an aluminium spacer. After the EXAFS experiment, the sample was extracted from the pellet with toluene and checked spectrophotometrically to ensure that neither oxygenation nor oxidation has occurred.

EXAFS associated with the Fe K-edge was recorded both in fluorescence and transmission modes at the Stanford Radiation Laboratory. Five spectra of deoxyhaemoglobin collected at 10K (three scans), 44K (one scan) and 110K (one scan) were averaged to give a good-quality spectrum. For the first picket fence sample a single spectrum was recorded at 100K; for the second sample three spectra were recorded at 300K. No appreciable difference was found between these spectra at $E < 150$ eV. The spectrum analysed in detail at Daresbury was that recorded at 100K; those recorded at 300K were analysed at Stanford.

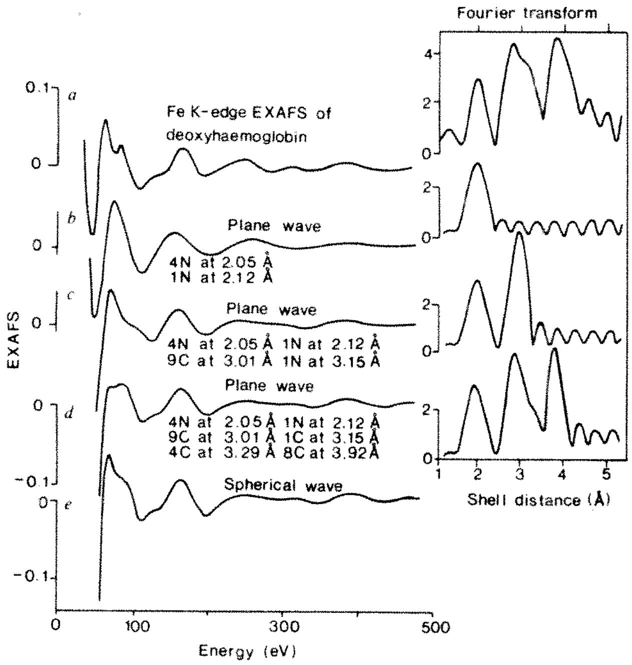

Fig. 1 EXAFS and Fourier transforms of human deoxyhaemoglobin. *a*, Experimental curve and transform derived from it. *b*, Calculated curves taking into account scattering from nearest neighbours only (first shell); *c*, same for first and second shell; *d*, same for first three shells; *b*–*d* were calculated using the plane wave method. *e*, EXAFS curve calculated for first three shells using spherical wave method. Best-fitting distances of carbon and nitrogen atoms from the iron are listed in Table 1. Fourier transforms have been multiplied by R^2 to obtain the radial intensity distributions of the atoms surrounding the iron.

We have used the atomic coordinates of the picket fence model[5] to calculate the distances of carbon and nitrogen atoms up to 4 Å from the Fe atom. For data manipulation and the calculation of theoretical spectra at the Daresbury Laboratory we used the procedures and programs described in refs 6 and 7 and for our interpretation we relied on Lee and Pendry's theoretical approach[8,9].

Phase shifts were calculated using the MUFPOT program, by constructing a complex muffin-tin potential following the standard Matheiss prescription, and making use of the Clementi–Roetti wave functions for carbon and nitrogen atoms in the neutral state. The excited iron atom was approximated by the wave functions of the Co atom with one electron from the 1 s orbital removed. The EXAFS spectra of deoxyhaemoglobin and the picket fence are shown in Figs 1–3. They show a close resemblance: each contains several beat regions at 40–90, 100–180 and 200–300 eV, indicating similarities in the distances and nature of the atoms surrounding the Fe atom. The large number of beats suggests that the complex EXAFS profile arises from the interference of several back-reflected waves. This is evident from the Fourier transforms which show strong contributions from scattering distances of up to 4 Å.

The theoretical and experimental EXAFS spectra were converted into k space defined by $k = \sqrt{2(E - E_0)}$ where E is the energy of the incident beam and E_0 the energy of the beam at the absorption edge of iron. Fourier transforms were then calculated with respect to $\exp(-i2kR)$ where R is the radial distance of an atom from the Fe atom. The problems of secondary maxima and changes in peak positions induced by phase shifts were dealt with by correcting the spectrum for the back-scattering factor of the nearest shell and by multiplying the EXAFS spectrum with a gaussian function, $\exp[-0.1(k - k_0)]$ with k_0 at the centre of the available range. Instead of using a Fourier filtering technique and isolating individual shells (peaks) we preferred to identify the contribution of individual shells to the EXAFS spectrum and to the Fourier transforms. This approach has recently been applied successfully to Cu-Zn superoxide dismutase and its various substituents[7]. EXAFS simulations were performed with both the raw and the splined data.

The following parameters were used to calculate the EXAFS: (1) the distances of the shells from the central Fe atom; (2) the kinds and numbers of atoms in each shell; (3) their thermal and structural disorder; and (4) the shift in energy of the X-ray absorption edge (E_0). Parameters (1) and (2) determine the phase and amplitude over the whole energy range; (3) influences the amplitude at energies >200 eV; and (4) linearly shifts the experimental spectrum. Parameters (2) are known. The crystallographic distances in the picket fence[5] were used as the starting distances for both deoxyhaemoglobin and the picket fence. Parameters (1) and (3) were optimized individually for each shell by visual inspection of (*a*) the agreement between the experimental and theoretical EXAFS; (*b*) the agreement between their respective Fourier transforms; (*c*) by considering the major features of the Fourier transform of the difference between the experimental and theoretical EXAFS; and (*d*) by monitoring the difference function $[0.15(\chi_{exp} - \chi_{theo})]^2$. Once the theoretical EXAFS resembled the experimental one, an edge shift of 15 eV was applied and then parameters (1) and (3) were further refined, again using criteria (*a*)–(*d*).

Figure 1 shows the uniqueness of the EXAFS spectrum and its Fourier transform with the contributions to them by the individual shells of atoms. The three beat regions could be simulated only by including all the atoms lying within 4 Å of the Fe atom. Figure 2 shows two theoretical spectra and two theoretical transforms, one set calculated with the optimized Fe–$N_{porphyrin}$ distance of 2.05 Å and the other with a distance of 2.07 Å. The longer distance makes the theoretical curve in the first beat region narrower than the experimental curve and makes the first shell peak of the Fourier transform appear at a longer distance than the experimental one. Figure 3 shows the EXAFS spectrum of the picket fence and its theoretical simulation together with their respective transforms. Table 1 lists the distances and Debye–Waller terms used for the simulations. The most important parameter is the distance from the Fe atom to the porphyrin nitrogens, Fe–$N_{porphyrin}$. That distance measured by EXAFS at ≤110K is 2.05 (±0.01) Å for deoxyhaemoglobin and 2.06±0.02 Å for the picket fence; at 300K a distance of 2.10±0.04 Å was measured for the picket fence: also at 300K a

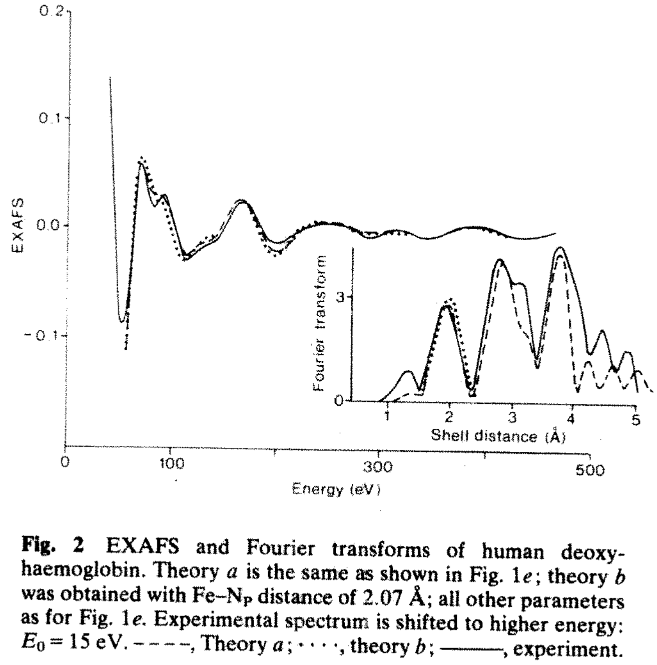

Fig. 2 EXAFS and Fourier transforms of human deoxyhaemoglobin. Theory *a* is the same as shown in Fig. 1*e*; theory *b* was obtained with Fe–N_P distance of 2.07 Å; all other parameters as for Fig. 1*e*. Experimental spectrum is shifted to higher energy: $E_0 = 15$ eV. ----, Theory *a*; ····, theory *b*; ——, experiment.

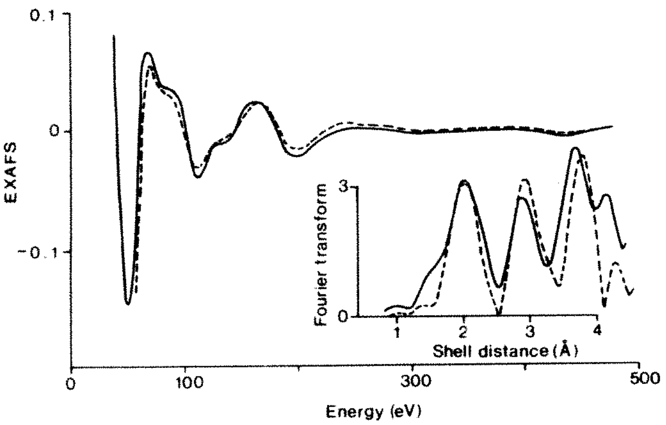

Fig. 3 EXAFS and Fourier transform of oxygen-free picket fence complex (first samples, 100K). Curves were calculated by the spherical wave method. Experimental spectrum is shifted to higher energy: $E_0 = 15$ eV.

distance of 2.072 ± 0.005 Å was found by single crystal X-ray analysis[5]. Thermal expansion between 100K and 300K would lengthen the Fe–N bond by ~0.01 Å. All the values therefore agree within the error limits. For the next three shells the agreement between the picket fence EXAFS and crystallographic data is also good, but for the distant shells 4C (3.45 Å) and 8C (4.3 Å), EXAFS gives shorter distances than the crystallographic analysis. A similar apparent shortening of distances was found in the Cu–Zn superoxide dismutase for both the enzyme systems and the well characterized chemical system $Cu(imid)_4(NO_3)_2$ (ref. 7). The reasons for this discrepancy were not well understood, but multiple scattering and shadowing effects may become important for distances >3.2 Å. The application of EXAFS to this well characterized model of deoxyhaemoglobin provides confidence that the theory can be used reliably for determining the distances of atoms within 3.2 Å from the Fe atom; beyond this EXAFS may underestimate them.

Before comparing the EXAFS results with the crystallographic data for deoxyhaemoglobin[1] and the picket-fence model[5], we must consider the powers and limitations inherent in the different methods of structural analysis. EXAFS gives the distances of atoms from a central metal atom with a standard error of ≤0.02 Å, but no data on the distribution of these atoms in space. Refinement of X-ray data obtained from single crystals of the picket fence at high resolution using Mo K_α radiation gives the positions of the central Fe atom with a standard error of 0.001 Å and of the carbon and nitrogen atoms with a standard error of 0.01 Å. The distance of the Fe from the plane of the porphyrin nitrogens can be determined with a standard error of 0.004 Å (ref. 5). The electron density maps of human deoxyhaemoglobin at 2.5 Å resolution obtained by multiple isomorphous replacement, allow the positions of the Fe atoms to be determined with a standard error of 0.05 Å. By fitting a planar model of protoporphyrin IX to the map, the positions of the porphyrin nitrogens and carbons in that plane can be determined with a standard error of 0.14 Å and the distance of the Fe from the porphyrin plane with a standard error of 0.03 Å (refs 1 and 10). All three analyses rely on computer algorithms that render the results fairly free from human bias.

Table 1 Parameters used to simulate the EXAFS associated with the Fe K-edge of deoxyhaemoglobin and deoxy picket fence complex

	Deoxyhaemoglobin		Deoxy 'picket fence'		Single crystal X-ray analysis[5]
Atom	σ^2 (Å^2)	R (Å)	σ^2 (Å^2)	R (Å)	
4N	0.004	2.05	0.006	2.06	2.07
1N	0.006	2.12	0.006	2.11	2.10
9C	0.003	3.01	0.011	3.01	3.09
1C	0.003	3.15	0.003	3.15	3.14
4C*	0.003	3.29	0.008	3.34	3.45
8C*	0.003	3.92	0.006	3.89	4.30

R denotes the distance of the atom from the Fe atom. σ^2 is a Debye Waller factor and is equivalent to ΔR^2. $E_0 = 15$ eV. The difference in Debye Waller factors of the 9 carbon atoms is significant and derives from a difference of EXAFS at ~300 eV and of the amplitudes of the Fourier terms at ~3 Å (Figs 2, 3).

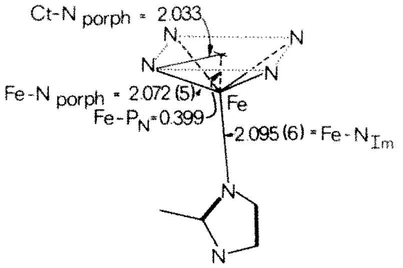

Fig. 4 Stereochemistry of iron coordination in the oxygen-free picket fence complex[5]. Distances in ångströms; numbers in parentheses give the standard error in 0.001 Å.

In the picket fence the four pyrrol rings are domed slightly towards the Fe which lies 0.399 Å from the plane of the porphyrin nitrogens and 0.426 Å from the mean plane of the 24 porphyrin nitrogens and carbons (Fig. 4). In deoxyhaemoglobin the resolution is insufficient to determine whether the pyrrol rings are domed. The distance of the Fe from the planar skeleton of 32 nitrogens and carbons that Fermi fitted to the electron density was 0.56 Å in both the α and β subunits[1]. Our EXAFS results are consistent with Fermi's finding as they show that the distances from the Fe atom to the nitrogens and carbons are similar in the picket fence and in deoxyhaemoglobin. Our EXAFS spectrum and $Fe–N_{porph}$ distances agree with those of Eisenberger *et al.*[4]; we wondered, therefore, what led them to conclude that the iron in deoxyhaemoglobin was only 0.2 Å from the porphyrin plane.

Eisenberger *et al.* obtained this value by triangulation. They used their EXAFS distance of 2.055 Å from the Fe to the porphyrin nitrogens ($Fe–N_{porph}$) in deoxyhaemoglobin as the base of a right-angled triangle; for one of its sides they used the distance of 2.045 Å of the porphyrin nitrogens from the centre of the porphyrin ring ($Ct–N_{porph}$) found in a single crystal study of model compound $Fe^{2+}(TPP)(2\text{-}MeIm).EtOH$ (D. A. Buckingham, quoted in ref. 14). This makes the other side of the triangle $Fe–P_N = \sqrt{(2.055)^2 - (2.045)^2} = 0.2$ Å. Eisenberger *et al.* also compared the EXAFS of deoxyhaemoglobin with that of a deoxygenated picket fence complex having a water molecule weakly coordinated to the sixth position at the Fe atom. This has $Fe–N_{porph} = 2.068 \pm 0.014$ Å, the same as the picket fence we have used, but due to the sixth ligand the displacement of the Fe from the plane of the porphyrin nitrogens is reduced to 0.28 Å (ref. 12).

Table 2 Parameters of five-coordinated high-spin iron porphyrins from single crystal X-ray analyses

Complex	Fe–P_N (Å)	Fe–N_{porph} (Å)	Ct–N_{porph}	Δ	Fe–P_{CN}
O[Fe^{3+}(diMeOEP)]$_2$	0.512	2.065	1.995	0.018	0.535
O[Fe^{3+}(TPP)]$_2$	0.496	2.087	2.027	0.044	0.532
Fe^{3+}(TPP)(Br)	0.489	2.069	1.992	0.070	0.539
Fe^{3+}(TPP)(NCS)	0.485	2.065	2.007	0.068	0.541
Fe^{3+}(TPP)(I)	0.480	2.066	1.996	0.068	0.537
Fe^{3+}(Protoporph)Cl	0.474	2.062	2.007	0.080	0.541
Fe^{3+}(Meso-DME)(OCH_3)	0.456	2.073	2.022	0.034	0.484
Fe^{3+}(Proto-DME)(SR)	0.434	2.064	2.015	0.015	0.446
Fe^{2+}(TPP)(2-MeIm)	0.418	2.086	2.043	0.134	0.530
Fe^{2+}(Tpiv PP)(2-MeIm)	0.399	2.072	2.033	0.027	0.505
Fe^{3+}(TPP)Cl	0.404	2.063	2.023	−0.015	0.392
Mean	0.457	2.070	2.015	0.052	0.507

P_N, mean plane of porphyrin nitrogens; P_C, mean plane of conjugated carbons; P_{CN}, mean plane of nitrogens and carbons. Δ is the doming parameter, giving the difference between the plane of the nitrogens and carbons ($=P_C-P_N$). For details of these structures see ref. 15, except Fe^{2+}(TpivPP)(2-MeIm) EtOH which is described in ref. 5.

Table 2 summarizes structural parameters for various high-spin iron porphyrins determined by X-ray analysis of single crystals at high resolution. In no case is Fe–$P_N < 0.4$ Å. If the displacement in deoxyhaemoglobin were only 0.2 Å, as Eisenberger *et al.* proposed, then its stereochemistry would be unique among five-coordinated high-spin iron porphyrins. The triangulation of Eisenberger *et al.* relies on taking the root of the difference of two squares of nearly equal value. A change in Fe–N_{porph} or Ct–N_{porph} of only 0.01 Å therefore changes Fe–P_N by ~0.05 Å. Eisenberger *et al.*'s value of Fe–P_N = 0.2 Å was derived by using Fe–N_{porph} and Ct–N_{porph} values from two different haem complexes. Because calculation shows that $\delta(\text{Fe–}P_N)/\delta(\text{Ct–}N_{porph}) = 5$, an accurate value of Fe–P_N could be obtained by this method only if Ct–N_{porph} distances were invariant among five-coordinated high-spin haems and a direct correlation therefore existed between Fe–N_{porph} and Fe–P_N; but this is not the case (Table 2 and Fig. 5). The structures of five-coordinated high-spin iron porphyrins determined by X-ray analysis of single crystals at high resolution show that the value of Fe–N_{porph} from one compound cannot be combined with that of Ct–N_{porph} from another to derive a reliable value for Fe–P_N, because the individual distances are too variable and there is no correlation between the two parameters. We conclude that it is impossible to infer from EXAFS the displacement of the iron from the porphyrin plane unless multiple scattering theory can be applied to the near-edge structure[13]; it has to be measured directly by single crystal X-ray analysis.

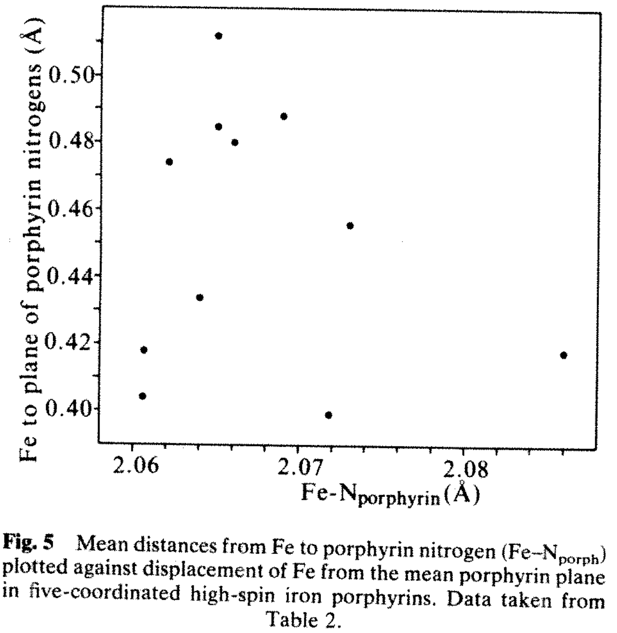

Fig. 5 Mean distances from Fe to porphyrin nitrogen (Fe–N_{porph}) plotted against displacement of Fe from the mean porphyrin plane in five-coordinated high-spin iron porphyrins. Data taken from Table 2.

When M.F.P. first proposed his stereochemical mechanism of haem–haem interaction, he believed the displacement of the Fe from the porphyrin plane in deoxyhaemoglobin to be due entirely to the increase in iron radius on going from its low-spin in oxyhaemoglobin to its high-spin form in deoxyhaemoglobin. Warshel[13] and Eisenberger *et al.*[4] have pointed out that this was an oversimplication. In reality, a mixture of electronic factors (repulsion of the occupied $d_{x^2-y^2}$ orbitals of the Fe by the π orbital of the porphyrin) and steric factors (van der Waals' repulsion of the proximal histidine by the porphyrin nitrogens) conspire to push the Fe out of the porphyrin plane and dome the pyrrols towards the Fe, so that the Fe atoms and the proximal histidines in deoxyhaemoglobin are further from the mean porphyrin planes than in liganded haemoglobins. However, from the mechanistic point of view, the causes of the displacements do not matter: what matters is that they do occur. Hopfield[14] predicted that the free energy of haem–haem interaction may be directly proportional to the sum of those displacements. Many other observations point to the crucial part played by the movement of the iron and the proximal histidine relative to the porphyrin and the general dominance of stereochemical factors in the mechanism of cooperativity.

ANNOUNCEMENTS

Awards

The National Academy of Sciences awards for 1982 include: James Murray Luck Prize to **Victor A. McKusick,** (The Johns Hopkins School of Medicine); Award in Chemical Sciences to **Gilbert Stork** (Columbia University); Award for Initiatives in Research to **Kerry E. Sieh** (California Institute of Technology); Public, Welfare Medal to **Paul G. Rogers** (formerly of the House Subcommittee on Health and the Environment); Gilbert Morgan Smith Medal to **Luigi Provasoli** (Yale University); Mary Clark Thompson Medal to **William A. Berggren** (Woods Hole Oceanographic Institution); US Steel Foundation Award in Molecular Biology to **Joan A. Steitz** (Yale University); Selman A. Waksman Award to **I.C. Gunsalus** (University of Illinois); Charles Doolittle Walcott Medal to **Martin F. Glaessner** (University of Adelaide); G.K. Warren Prize to **John T. Hack** (The Geroge Washington University); James Craign Watson Medal to **Stanton J. Peale** (University of California).

Dr Theodore Brewster Taylor (Appropriate Solar Technology Institute, Inc.) is the recipient of The Boris Pregel Award for Applied Science and Technology.

Professor William Trager (Rockefeller University) has been awarded the First Rameshwardas Birla Triennial International Award in tropical medicine by the Medical Research Centre of the Bombay Hospital Trust.

Nineteen Prize Fellow selected by D. and Catherine T. MacArthur Foundation will receive unrestricted awards of $24,000 to $60,000 annually for five years: **Dr Hugh John Cairns** (Cancer research; microbiology); **Joel E. Cohen** (Mathematics & demography; public health); **Richard P. Critchfield** (Journalism); **Howard E. Gardner** (Developmental psychology; clinician); **John P. Gaventa** (Political science; social activism); **David Hawkins** (Philosophy; education); **John P. Holdren** (Physics; energy and environment); **Ada Louise Huxtable** (Architecture criticism); **Robert W. Kates** (Geography; natural hazards research); **Dr Raphael C. Lee** (Surgery; biomedical engineering); **Cormac McCarthy** (Novels); **Richard C. Mulligan** (Cancer research; biochemistry); **Elaine H. Pagels** (History of religion); **David Pingree** (History of science); **Paul G. Richards** (Theoretical seismology); **Richard M. Rorty** (Philosophy); **Joseph H. Taylor** (Radio astronomy; astrophysics); **Michael Woodford** (Economics; legal theory); **George Zweig** (Physics; neurobiology). In addition Barbara McClintock, 79, a geneticist, has been selected as the Foundation's first Prize Fellow Laureate — assuring her of $60,000 annually.

Dr Nien-Chu C. Yang (University of Chicago) is the recipient of The Gregory and Freda Halpern Award in Photochemistry sponsored by the Polychrome Corporation.

The Institute of Physics Award for 1982 are: Charles Vernon Boys Prize to **Dr B.J. Isherwood** (GEC Hirst Research Centre); Duddell Medal and Prize to **S. van der Meer** (CERN); Glazebrook Medal and Prize to **Professor J.M.A. Lenihan** (West of Scotland Health Boards); Guthrie Medal and Prize to **Sir Charles Frank** (University of Bristol); Maxwell Medal and Prize to **Dr J.R. Ellis** (CERN); Rutherford Medal and Prize to **Dr D.M. Brink** (University of Oxford); Prizes for the 1981 Graduateship Examination of the Institute to **D.J. Pointer** and **T.J. Mays** (Bristol Polytechnic).

The Paul-Martini-Prize for promoting the development of scientific methods for the evaluation in the clinical pharmacological and therapeutical fields will be confered by the Paul-Martini-Foundation which is sponsored by the Medizinisch Pharmazeutische Studiengesellschaft (Mainz, FRG). Papers must be self-contained not older than two years. They should be sumbitted either in English or German with six copies to the Medizinisch Pharmazeutische Studiengesellschaft e.V., Bilhildisstraße 2, Postfach 3048, D-6500 Mainz, FRG before 30 April 1982.

An open competition in geometry for an award of $2,500 is being sponsored by Science Software Systems, Inc. The award will be presented to the competitor who submits the most complete solution to the problem: What geometrical properties of dissimilar inversion loci are consequences of the property of self-inversion of a basis curve at angles other than 0° or 180°? For further information send a stamped self-addressed envelope to Science Software Systems, Inc., 11899 W. Pico Boulevard, Los Angeles, California 90064, USA.

The Trustees of the Lady Tata Memorial Trust invite applications for Awards for personal support for research on leukaemia, in the Academic Year beginning 1 October 1982. Candidates with programmes of research on any aspect of malignant disease which may throw light on problems of leukaemia will be eligible for consideration. Awards are open to suitably qualified investigators of any nationality, working either in their own institutions or in other centres abroad. Further particulars from the Secretary of the (European) Scientific Advisory Committee, Lady Tata Memorial Trust, MRC Leukaemia Unit, Royal Postgraduate Medical School, Du Cane Road, London W12, UK.

The Eli Lilly Fellowship in diabetes in children has been established by the British Diabetic Association. It will be funded by Eli Lilly & Company. This fellowship will be for a doctor of registrar status and will last for two years. The research into diabetes in children will be carried out at the hospital of the successful candidate. Application forms from the assistant secretary, British Diabetic Association, 10 Queen Anne Street, London W1, UK.

The L.S.B. Leakey Trust is now able to award research grants to scholars in the fields of human palaeontology, archaeology and primate behaviour. Contact: Miss Anne Turner, The L.S.B. Leakey Trust, 10 St George's Mansions, Vauxhall Bridge Road, London SW1, UK.

Appointments

Mr J.W. Bundy (Agricultural General Manager of Birds Eye Foods Limited) has been elected by the Council of the National Institute of Agricultural Botany to be their Chairman for 1982–83.

Professor C.S. Holling (University of British Columbia in Vancouver) will be the new director of the International Institute for Applied Systems Analysis in Laxenburg near Vienna, Austria.

Meetings

1-4 March, **Mobility and Function in Proteins and Nucleic Acids,** London (The Ciba Foundation, 41 Portland Place, London W1, UK).

4 March, **Developments in Low-temperature Biochemistry and Biology,** London (The Royal Society, 6 Carlton House Terrace, London SW1, UK).

15-17 March, **Energy and Feedstocks for the European Chemical Industry,** Belgium (Society of Chemical Industry, 14-15 Belgrave Square, London SW1, UK).

15-23 March, **Introduction of Utramicrotomy,** Seefelder (Reichert-Jung UK, 820 Yeovil Rd, Slough, UK).

18 March, **The "Simple Surface"**, London (Conference Secretary, IEETE, 2 Savoy Hill, London WC2, UK).

19, March, **Wind and its Effects on Man,** Plants and Animals, Edinburgh (The Royal Society of Edinburgh, 29 Queen St, Edinburgh, UK).

22 March, **European Symposium on the CANDU Reactor,** London (Scientific and Technical Studies, Norwich House, Norwich St, London EC4, UK.

24 March, **Concrete for Durability,** London (The Concrete Society, Terminal House, Grosvenor Gardens, London SW1, UK).

CORRESPONDENCE

Continued from page 452

During a relatively short period, many of the above demands were introduced practically although not by law. In particular the presidium of the academy and the chancellors and deans in almost all universities were chosen in a truly democratic way.

It is significant that most of those elected were politically inactive before 1980 and of moderate views, and gained their authority solely on the basis of their scientific achievements. Thus the elected people can be seen as truly representative of a scientific community which is not heroic but truthful, which follows directives but recognizes that the political direction of science has damaging effects.

It can be argued that a similar attitude is typical of "normal" scientific communities. But the Polish one is not "normal". Its older members endured the Nazi holocaust or harsh life in remote Soviet provinces; their students started their careers during the period of the Stalin cult with its brainwashing machinery. This community suffered the wave of repressions and purges in 1968 followed by the liquidation of the remnants of academic freedoms. It was corrupted during the past ten years of mild but effective "sovietization". Thus it was encouraging to see that the old ideals of scientific freedom, so often declared to be outdated, are so deeply rooted in the bulk of this community and that it is ready to support democratic changes.

Surely the power of the reformers of the scientific establishment rested not only, and not even mainly, on the social forces in their own home but on the forces of an awakening society.

Perhaps much more could have been achieved. There were too many useless meetings, endless and inconclusive discussions about the new structure of science or about formulations of new constitutions. We were drunk after taking too large a draught of democracy and were not yet ready to use it effectively.

Most of the staff of the academy and universities joined Solidarity. But surprisingly, during 1980–81, students were less eager to follow this movement, although a large number of new student organizations appeared. Even the most influential of these, *Niezalezne Zrzeszenie Studentów* (NZS, Independent Student Association) was joined by fewer than 20 per cent of the students.

The main action of NZS was the proclamation in October 1981 of a general strike in protest at the halting of legislative procedures concerned with the new progressive law of higher education and in support of the protest of the Radom branch of NZS and Solidarity against the way the rector of Radom Polytechnic had been elected. This strike was joined by a most of the schools of higher education in the country. In spite of the efforts of Solidarity, the Church and the Council of Chancellors of the Polish Schools of Higher Education, this strike was continued after the strikers' first demand was conceded. A few days before martial law was declared the strike broke down. In January 1982 NZS was dissolved by the authorities.

The era of Solidarity — understood here not as a name of this particular organization with its achievements and follies but as synonymous with the greatest all-national movement in our history — is over. Solidarity is for the time being defeated. But it should be underlined that to the same or an even larger extent the communists who ruled the country for more than 35 years have also been defeated. The political regime proved itself to be not only ineffective and acting against the will of the people, but irreparable and wholly dependent on external powers. In a sense only the Russians won the battle, by finding a way of solving the problem without needing to use their own troops.

The battle is lost, the war is not. It is still the common belief that something very important happened which will influence our future, and perhaps not only ours. I have in mind not only economic and social changes but the changes of spirit of those who rule and those who are ruled — these changes are not as abstract as the word spirit suggests.

Just after the declaration of martial law there was a wave of protests. This wave did not bypass scientific institutions. As yet we do not have a full account of what happened, but we know about the strikes of a few institutes of the academy in the Staszic Palace in the centre of Warsaw which were terminated by force; about a letter of protest signed by more than 300 scientists in the Institute of Chemical Physics; about the strike in the Institute of Nuclear Research in Swierk near Warsaw followed by arrests and trials of several scientists.

The work of all schools of higher education was immediately suspended, but there was a protest of teachers and students in Wroclaw Technical University where several people including the vice-chancellor were badly beaten. We know about strikes in the Warsaw Agricultural Academy, the Mining Academy in Krakow, and the University of Lublin. The senate of the oldest Polish University, the Jagiellonian University in Kraków, sent a letter of protest with a demand for the release of the arrested people.

The number of students and staff arrested is not known. In the University of Warsaw more than 40 people were either interned or arrested. An overall estimate based on this figure might be misleading because the University of Warsaw has been under the special care of the authorities for many years.

Young people, those between 18 and 25, seem likely to be the main losers: they will lose if they decide to fight, because there is no chance of winning; they will lose if they decide to give up, because of the devastating effects of conformity. The generation gap between them and us, already felt during their strike, seems to be widening. The students prefer to follow the heroic pattern of the young generation duing World War II and do not want to give up the only experience they have gained by their own efforts, the experience of the past year.

As yet almost nothing of importance has been changed in scientific institutions by martial law. True, in all universities, as well as in all schools and in most institutes, there are military commissars who are acting not directly but through the existing administration.

But we are only at the beginning of the new road. It seems almost certain that many teachers at all levels will lose their jobs. In secondary schools and in all institutions of public administration the authorities have already demanded written declarations of loyalty, and those who refuse to sign are fired. A similar type of verification of staff and students is expected in the universities, and it will lead to the replacement of all elected bodies by nominees. Many scientists will probably lose the opportunity to continue their scientific work, as happened in Czechoslovakia.

The outlook is not optimistic. We may expect the worst members of the scientific community to move to the front of the scene. It is a well established tradition to ignore such people; but in the present situation this should not be followed. Scientists who try to abolish what has been achieved should be named and ostracized by the scientific community all over the world. And those who suffer for the defence of scientific freedom should feel the moral, and perhaps also material, support of all their friends and colleagues, first of all here in Poland, but also abroad. If we fail to condemn the former and to provide effective support for the latter our defeat may become a catastrophe.

Not the baron

SIR — Sir Peter Medawar asks in a book review (*Nature* 28 January, p.351) "was it not Cuvier who named a fossil ichthyosaurus *Homo diluvii testis* . . .?". It was not: the fossil (now on display in the Teyler Museum, Haarlem) was so called by J.J. Scheuchzer (1726)[1]. Scheuchzer also describes the fossil in a letter published in *Philosophical Transactions of the Royal Society of London*[2]. Baron Cuvier, visiting the Netherlands as a member of a commission sent by Napoleon, confirmed his own identification of the fossil as a giant salamander by carefully removing some of the matrix to reveal the forelimbs (illustrated in Cuvier, 1824)[3].

2. Scheuchzer, J.J. *Phil. Trans. R. Soc.* **24**, 38–39 (1726–27).
3. Cuvier, G. *Recherches sur les Ossemens Fossiles* 1st Edn, Vol. V, 431–434 and Plate XXVI (Paris, 1824).

US spoken

SIR — The editor's leftist leanings have been quite evident of late, but isn't the sentence (*Nature* 14 January, p.86), "*United States users* of the telephone will most immediately discover that it costs them more to use the local telephone service as if it were unmetered water" (italics mine), not only lacking in lucidity but also bending a bit too far left when it employs "United States" as a general adjective? We are Americans, by God!, not "United Statesers" — and the adjective is *American*! I and others proud of America deplore your emasculation of our rightful name, especially when it is to indulge the arrogance of leftists in Nicaragua, Mexico, or wherever, who never refer to themselves as "Americans", but at the same time, with a malevolent dog-in-the-manger attitude, wish to deny us that distinctive title.

EDWIN E. ROSENBLUM
New York, America

What universities should aim at

The die may not be finally cast on British university policy. The universities should quickly propose a reform of the system of student maintenance grants.

For the past several weeks, there has been a curious lull in the storm about the future of the British universities. The belief that the British government could not seriously intend the beastliness it first advertised fifteen months ago has in most places been dispelled, and universities have dutifully set about making the self-inflicted wounds that their reduced budgets require. Most of them have been spurred on by the knowledge that they may not be able to share in the £220 million with which the University Grants Committee has been provided to compensate redundant academics unless their claims are staked about now. Temporarily at least, however, the lull has now been unexpectedly broken by no less a person than Sir Keith Joseph, Secretary of State for Education and Science, in a long letter to the London *Times* last week. Inevitably, his intervention will tempt some to hope that all is not yet lost. Is there a chance that, even at this late stage, the British government might be persuaded to change its mind?

The circumstances which have provoked this public statement are significant. The minister had apparently been stung by the pointed criticism of Dr Robin Marris, professor of economics at Birkbeck College in London, whose complaints appear to have been all the more forceful because they acknowledged that there is an economic need for the British government to contain economic expenditure. This is a point that the universities should have conceded, more generously, at the outset of their long wrangle with the government. That would have enabled them more strenously now to complain that, as things have turned out, the university system is likely to become less and not more efficient.

The planned reduction of student numbers is likely to be proportionately less than the reduction of the teaching force, so that the ratios of students to teachers at many universities will be "improved". There is, however, a high chance that the teachers who will volunteer to leave their jobs in the next few months will include many of those whose departure can least be afforded. Similarly, as teaching departments shrink, teaching staffs will be less able to cover the ground expected of them, while buildings and other equipment will be less than fully used. One glimmer of hope in last week's public statement is the promise that the University Grants Committee will be allowed some room for manoeuvre. Moreover, Sir Keith has now agreed that if academics nationally agree to salary increases which are less than four per cent, the money thus saved could be used for other purposes, and that the University Grants Committee will similarly behave leniently towards individual universities. So far, however, there is no sign that the government will allow a relaxation of the principle from which the most absurd diseconomies spring — its insistence that the numbers of students taught at British universities should now decline.

The ceilings on the numbers of home students which have been set, nationally and for individual universities, are absurd for several reasons. They are diseconomies in the sense that they prevent the full utilization of a well developed university system. They are inequitable, and an arbitrary infringement of academic freedom and university autonomy, in that they limit the right of universities to decide for themselves what to teach, and to whom. The quotas are certain needlessly to deprive young men and women leaving British schools of a university education. So why should the government perversely persist with its support for student quotas (technically, it is true, devised by the University Grants Committee)? Sir Keith Joseph had two comments on this issue last week. Letting universities decide for themselves their responses to shrunken budgets is unacceptable because the universities depend on the public purse and because "planning" is necessary for universities as for the other sectors of higher education. Then, more to the point, student numbers entail a hidden cost to the public purse because of the government's commitment to reimburse local authorities required by legislation to pay maintenance grants to students following first degree courses anywhere in the system of higher education. For the past year, the government has been muttering that these arrangements provide the universities with a blank cheque on its resources. Student quotas conveniently give an upper limit to the annual bill.

The government's preoccupation with the supposed blank cheque is irrational. In 1979–80, local authorities in England and Wales spent £192 million on maintenance grants to university students, when the recurrent budget of the University Grants Committee (for the whole of the United Kingdom) was £801 million. In that year, the average cost of maintenance grants was just over £1,000 a student — less than the maximum amount because individual awards are means-tested on the basis of parental income. In the same year, local authorities paid university fees of £137 million on behalf of their students, an amount that will be reduced from next September by the simple device of reducing by a half the notional cost of university fees for students from the United Kingdom (thus penalizing universities that have taken in extra students in the past two years). In happier times, the social value of this system was not seriously questioned. The system has, for example, partially ensured that students are not discouraged from going on to higher education because of the economic circumstances of their families. But the system is also wasteful. British students make only the smallest contributions towards the cost of their maintenance, and are tempted by the system to seek university places far from their homes, increasing the cost of student housing on university campuses.

These circumstances offer the basis for a better deal between the government and the universities than that now being implemented. In impoverished Britain, the simple abolition of the system of maintenance grants would have the effect of putting university education beyond the reach of a large and important section of the school-leaving population. But why not substitute for the present system of mandatory awards a system of scholarships awarded on merit to some tens of thousands of potential students each year? One result would be that the government would know the extent of its commitment each year. Another is that, by a suitable choice of numbers, students would have an incentive to opt for the most economical education they could find. Finally, provided that university fees were not driven sky-high by government decree, universities would have an incentive to educate as many young people as their resources (determined by the University Grants Committee on the government's behalf) would allow. The result of that would be far-reaching and important. For in such a system, universities would find they had an incentive towards diversity — not, as at present, a common ambition to ape the Oxbridge model. Given last week's evidence, flimsy though it is, that Sir Keith Joseph's mind is not finally closed, the universities should seize the chance to advocate some such scheme.

Doves in false garb

The claim by the anti-nuclear movement of professional support is mostly a sham.

Professional societies have now lost most of the characteristics of the mediaeval guilds from which they sprang. A little like trades unions, from which they are often indistinguishable, they are naturally defensive of the interests of those who happen to belong to them. On many issues, they are often at odds with the communities in which they are embedded. So how, and in what circumstances, should professional organizations set out to influence events on a wider canvas than that with which they are professionally concerned? These are some of the questions provoked by last week's meeting in London (see page 544) at which a number of informal groups set out to stimulate professional interest in the problems of nuclear disarmament. It is important, not least for professional people themselves, that the questions should be answered clearly.

In modern circumstances, professional societies have become anachronisms. The days have long since gone when they could automatically assume responsibility for deciding which individuals should be licensed to carry out professional tasks. Even in Britain, only the two halves of the legal professional retain an absolute right to determine entry into a profession; the professional registration of physicians has long since been the responsibility of the General Medical Council, while the analogous functions of the engineering institutions are about to be transferred to a more public central body (as recommended by Finniston two years ago). Other professional organizations, the Royal Institute of British Architects for example, have found it convenient to offer the public service of a means by which disappointed clients may settle claims against professional people, often as an antidote for some restrictive practice such as the enforcement of minimum fees. Others have chosen to shoulder the public burden of defining technical standards of performance, as the Institute of Electrical and Electronics Engineers does for much of the electronic equipment introduced in the United States and thus, by extension, internationally. However truncated their roles, however, most professional organizations remain valuable as learned societies and also rightly function as legitimate and beneficial pressure groups. Physicians' organizations usually have something to say about public policy on smoking and fluoridation, for example. Science, it will be remarked, is for the most part too new to have been tarred with the mediaeval brush.

But if the professional societies have been liberated from most of their statutory functions of deciding who is and is not entitled to practise as a professional, is it not all the easier for them to speak out on wider issues, military policy for example? This was the implicit assumption of last week's conference in London. The simple answer is that the expectation is over-simple. Even as things are, professional organizations are needlessly indifferent to important public issues well within the spheres in which their professional competence would command respect. Physicians have been consistently indifferent to the quality of health care (in Britain) and its cost (in the United States). In the past thirty years, members of teachers' organizations in many places have officiated at the rapid transformation of teaching practice without drawing attention to the serious social consequences that may accompany the intended benefits. Yet these are questions on which the opinions of quasi-professional organizations might be influential, even welcome. And, in their absence, opinions on wider issues, even if they could be arrived at without violence to the views of dissenting members, would cut no ice.

This is why much of last week's discussion was misplaced. The claim that the professions as such have a responsibility to alert the general public to the great issues that confront society, inflation and unemployment just as much as nuclear armaments, is unwarranted and impractical. But there is a sense in which professional people, acting individually, may be held to shoulder an extra responsibility for giving wider currency to their conclusions about important issues on which they have some special knowledge. Professional people have in the past been too mealy-mouthed on many important questions. Even if the question is necessarily as contentious as a nation's defence policy, they should not be afraid to say so. But professional people are mistaken to suppose that the task can be done respectably under titles such as those paraded at last week's conference. What other justification is there for the Medical Campaign against Nuclear Weapons except that physicians prefer hobnobbing with other physicians than with the hoi polloi? Or can they waywardly suppose that they may be able to capture something of the now-vanished mediaeval mystique by pretending that they are part of such an organization? The truth is that they are not, and that their attempts to invest their legitimate causes with spurious authority are a deceit, and a counter-productive one at that. If architects, physicians, teachers and scientists claim a special right to speak for their professions on nuclear weapons, they should take their courage in their hands and join Lords Brockway and Noel Baker on the hustings.

Up and over the top

The United States seems not to appreciate the damage that will be done by last week's budget.

When the United States began in the 1960s to pay for the Vietnam war by printing dollar bills, several years went by before people elsewhere fully appreciated what was happening. The result was that inflation had firmly taken hold throughout the industrialized world before governments (including that of the United States) began to take remedial action — by which time the oil-producing states had devised their own way of penalizing fiscal self-indulgence. Now the shoe is on the other foot. Thanks to the tight coupling between the major industrial markets ironically engendered by institutions such as the Eurodollar market created during the last bout of inflation exported from the United States, economies other than the American are now, if possible, almost hypersensitive to what Washington is planning. That is the simple reason why administrations elsewhere are busily planning for the inevitable rise of interest rates in the coming year; their financial markets are discounting the consequences as quickly as their courage will allow.

Even those who sympathize with the Administration's present objectives are dismayed by what is happening. In round numbers, President Ronald Reagan has asked Congress for authority to spend something like $100,000 million more than his Administration will collect in taxes. While some of his more contentious demands may be moderated in the long months that lie ahead, he must know as well as the rest of the world that Congress will also declare itself strongly against some of the sharp curtailments of welfare expenditure now planned. So it is natural that people should already be anticipating with varying degrees of gloom the prospect of a United States deficit greater than the total revenue of any other government in the West.

But why should this matter? And how can the scientific enterprise be affected? Why should not honest researchers persist in the pursuit of understanding, confident that in the end some productive use will have been made of their findings? The snag is that it will not and cannot be so easy. The Administration must soon settle for some blend of the only two ways of dealing with the crisis it has wished upon itself — it can use higher interest rates to persuade citizens of the United States to lend their earnings to the Treasury rather than to spend them, in which case there will be a slump. Or it can print dollar bills to make up the difference between what it spends and what it collects, in which case there will certainly be high interest rates, but the slump may be avoided at the expense of established institutions — universities, foundations and the like. Mr Paul Volker at the Federal Reserve Board would prefer the first course. Most politicians would prefer the second. Other people, other institutions and the research enterprise as a whole will suffer either way.

Cancer Institute withholds grant

Straus denies fresh charges of impropriety

Washington

The running battle between the US National Cancer Institute (NCI) and research scientist Dr Mark Straus of the New York Medical College (NYMC) in Valhalla, New York State, entered a new round last week when the institute announced it was suspending part of Dr Straus's current grant because of failure to comply with federal rules on the use of human subjects in research.

Dr Vincent DeVita, the director of NCI, has also informed the medical college that the final part of the three-year, $910,000 grant is being withheld from the beginning of March on the basis of a site-visit team's report that there has been "minimal progress" in the research into the application of cell kinetics to chemotherapy.

Dr Straus has angrily denied both the charges. On the first, he argues that his work with human cancer patients has involved only conventional radiotherapy and chemotherapy, and is therefore not covered by federal research rules. On the second, he argues that the conclusions of the visiting team are at variance with reports prepared by three previous visiting teams which each claimed that progress in the research was satisfactory.

Four years ago, Dr Straus was relieved of his position as chief of the oncology department at Boston University after the discovery that patients' records had been falsified in part of a broad survey of cancer treatment, supported by NCI, for which he had been the principal investigator.

Dr Straus, who has denied allegations that he was responsible for the forged data, has since moved to NYMC where he is professor of medicine and chief of the department of oncology. In 1979 he was awarded a three-year grant, beginning in March 1980, to continue his research into cell kinetics following what Dr DeVita has described as a "very good" score by scientific reviewers of his grant application.

Disagreements between Dr Straus and NCI emerged last summer, when NCI was accused by members of the Senate's Labor and Human Resources Committee of failing to take stricter action against him in the light of the Boston allegations. Several senators were especially critical of the fact that Dr Straus had been awarded a new NCI grant even though his previous activities were under investigation.

Dr DeVita defended the grant on the basis of the high marks it had received from reviewers but said that support for the clinical trials proposed in the application had not been provided. After the Senate hearing, at which he received some harsh criticism from the committee's chairman, Senator Orrin Hatch of Utah, Dr DeVita received a strong public vote of confidence from the cancer research community.

The new disagreement between NCI and Dr Straus seems to focus on his treatment of cancer patients with a combination of radiation and the drug 5-fluorouracil (5-FU), which was approved by the Food and Drug Agency as an anti-cancer agent several years ago and is widely used by physicians and clinical oncologists.

NCI contends that even though it was not part of the NCI grant, Dr Straus's use of such treatment was experimental, and that a research protocol should therefore have been submitted to the medical college's institutional review board under new federal regulations.

Since this was not done, Dr DeVita said in a letter last month to NYMC president Dr John Connolly, the result has been a "material failure to comply with the terms of the grant". The clinical portion of the grant has therefore been suspended "until the matter is resolved to NCI's satisfaction or until the grant is terminated", as required by federal regulations.

Asked to explain how funding for the "clinical portions" of the grant could be suspended if Dr DeVita had previously assured the Senate committee that no clinical work was covered by the grant, NIH officials admitted last week that this had caused some unfortunate confusion. "The statement made last summer should have said that the approved grant did not involve therapeutic research, rather than

Amersham International floats

Amersham International, the supplier of radioactive chemicals being sold off this week by the British government, seems likely to cause a minor sensation on the London Stock Exchange. On Monday this week, the financial community was persuaded that the 50 million shares could have been successfully offered for sale at a higher price than £1.42 each, thus recouping a larger sum for British taxpayers and providing the company with a larger stock of working capital than the £5 million it now expects. As things are, the offer for sale was expected to be heavily oversubscribed.

The sale of Amersham has been on the cards for the past two years, and is broadly welcomed by the management of the company. Arrangements have been made to give each employee £50 worth of shares, and there are also arrangements whereby employees may buy further shares, now and in the future, which will be held in trust for them.

The argument that Amersham is being sold too cheaply derives from the company's rapid growth in recent years and from the relatively high profit (£8.0 million) before tax forecast for the current year. But some in the financial community point out that the offer price is 18.9 times the expected profit after tax, a largeish ratio for conventional businesses but by no means as great as the price of shares in other high-technology companies, electronics for example.

In such circumstances, shares are preferably sold by tender, with the highest bidders being given preference. On this occasion, however, the merchant banks handling the sale of shares appear to have persuaded the British Treasury that a sale by tender would have been too complicated for many would-be investors.

The Treasury seems also to have devised an ingenious device for assuring the future independence of the company. The government will retain a single "special rights preference share" that will allow it to prevent either a substantial disposal of the assets of the company or a significant change in the pattern of share ownership that might compromise independence.

That Amersham is attractive to investors at this point in its history is easily understood. The company's new plant at Cardiff has come into production within the past year, while the weakening of sterling in relation to the dollar within the past year has necessarily increased the profits of the company, which earns 80 per cent of its revenue outside the United Kingdom. (The prospectus estimates that a five per cent change in the value of sterling implies a ten per cent change in profit.)

Amersham's interest in genetic manipulation through its sale of labelled nucleotides and other materials used in genetic manipulation, at least at the research bench, seems not to have been widely appreciated by the financial press, which may moderate the embarrassment caused to the company's merchant banks by an even more heavily oversubscribed offer than that now in prospect.

The prospectus for the public sale of shares explains that Amersham International owes its existence to a business established in 1940 to refine radium used in the manufacture of self-luminous components for navigational aids. The company employs just over 2,000 people, three-quarters of them in the United Kingdom and most of the remainder in North America and West Germany. In recent years, Amersham has been spending seven per cent of its revenue on research and development. The City of London is impressed; others wonder whether it is enough.

0028-0836/82/070543-02$01.00

clinical research", an NIH spokesman said, adding that biopsy analysis had been included.

Describing the NCI charges as "outrageous", a research colleague of Dr Straus, Dr Jeffrey Ambinder, insisted last week that only conventional treatment had been used. He read a statement from Dr Straus, who was not available for comment, comparing NCI's claims to a situation in which, if a cancer patient is given an aspirin and then finds the cancer has gone away, "then it should have been submitted to a review board".

NYMC has already set up a subcommittee of its Institutional Review Board to investigate whether the treatment should have been submitted for its approval. Although the subcommittee was established before the site visit by the NCI team, it will now have to decide whether to concur with the visiting team's conclusion that the treatment should have been classified as experimental, or to accept Dr Straus's argument that prior approval was not required.

NCI itself has referred the matter to its Office of Protection from Research Risks to see if any further action should be taken. The institute's verdict on the progress of Dr Straus's research is also likely to generate controversy, since the decision to withhold the third year of the grant — amounting to about $300,000 — can be taken to appeal by Dr Straus and/or the medical college.

Explaining his actions in the letter to Dr Connolly, Dr DeVita says the decision to withhold the grant followed the visiting team's conclusion that "minimal progress had been made on both the pre-clinical and the clinical cytogenetic studies".

Dr Straus, described by Dr Ambinder as a "brilliant scientist" whose "ethics are beyond reproach", says in his statement that the criticism is incorrect, and that his group had not been supported to carry out the studies which the visiting team says should have been done. Dr Ambinder also defended the research group's use of tritiated thymine, to study the kinetics of cancer cells, which he says had been approved of by the three previous visiting teams but criticized by the last team which visited in November.

Dr Straus is already suing five of his former research colleagues at Boston University for $33 million, denying the allegations that he had been responsible for the falsified data in the earlier study. Last week he and his lawyer, Andrew Good, were taking depositions from witnesses to establish the basis for his charges of conspiracy.

A full report on the Boston incident is expected to be completed shortly by the Department of Health and Human Services. Meanwhile, staff members of the Senate Health Committee, which was strongly criticized for its treatment of Dr DeVita last summer, said last week that the committee had no further action planned, but was watching events. **David Dickson**

Polish students

Workers help

Help is urgently needed for Polish students penalized under the martial law regulations, according to a clandestine Solidarity bulletin from the Krakow region. The dissolution last month of the Independent Students' Association (NZS) has left the students without any organization to defend them, just when the new rules of conduct for the universities make such protection more necessary than ever. Several former NZS activists have already received prison sentences for allegedly organizing resistance to the military takeover; scores or hundreds more are in internment camps. Those who sign the necessary oath of loyalty and return to their studies face penalties ranging from compulsory "socially useful work" to expulsion and military service even for such minor infractions as cutting lectures or being on campus after hours.

The bulletin notes that the staff of the University of Warsaw have already organized a system of financial and legal aid for students, and are also trying to provide accommodation for those students who have been expelled from their hostels. A similar initiative seems to be under way in Poznan. There, on the declaration of martial law, the deans and deputy deans of the various faculties apparently resigned as a body, but had returned to their posts last week, apparently for the sake of the students, in advance of the riots at the end of the week.

The Krakow bulletin marks an important new development in the Polish democratic movement. Before 1976, there were protests by workers and by intellectuals (including students) but for different causes and on different occasions. After the food-price demonstrations of June 1976, however, intellectuals and students organized legal and material aid to those affected by the wave of police repressions, and were themselves frequently heavily penalized for doing so. This is the first time, however, that a workers' organization has spoken out in defence of intellectuals and students.

The bulletin, which describes the victimized students as "our best young people", coincides with a major propaganda offensive designed to break the ties between workers and intellectuals which developed after 1976 and which are consolidated by Solidarity. At the end of January, Michal Hebda, the rector of Radom Engineering College, whose "undemocratic" appointment triggered the nationwide student strikes last autumn, said on Warsaw radio that the combination of student and worker protests showed that it must have been organized from abroad. Many intellectuals in internment have been creamed off from the general camps and transferred to somewhat more comfortable accommodation.

Most surprising of all is the remark attributed to deputy prime minister Mieczyslaw Rakowski, editor in chief of the weekly *Polityka*, which is due to resume publication shortly. He is reported to have told a staff briefing conference that in his opinion the intellectuals in Solidarity were directly responsible for the imposition of martial law. What finally tipped the balance, he claimed, was the declaration by the Conference of University Rectors that its members should have the right to vote for the Minister of Science, Higher Education and Technology. **Vera Rich**

British anti-nuclear campaign

Pros not all con

The two British veterans of disarmament, Lords Brockway and Noel-Baker, gave their blessing last weekend to a campaign to mobilize British professional opinion against nuclear arms. But the conference at Imperial College, London on 12 February, planned by the World Disarmament Campaign, demonstrated that only the anti-nuclear profession is sure of where it stands.

The theme of the conference was that professional people and even professional organizations have a responsibility to inform the general population of the present danger from the accumulation of nuclear weapons, calculated by Dr Frank Barnaby, until recently director of the Stockholm International Peace Research Institute, as the equivalent of 3 tonnes of TNT per head of the world's population.

British professional organizations were not formally represented at the conference, although Mr Jack Chambers, president of the National Union of Teachers, claimed the backing of an organization with 250,000 members for his demand for a place in the school curriculum for the "teaching of peace". In passing, he protested at the complaints from newspapers that teachers were guilty of "political indoctrination" by telling their students of their "profound distaste for the present levels of armaments" and of the British government's "scandalous support for the United States government on El Salvador".

Dr John Dawson, head of the division responsible for professional questions at the British Medical Association, gave a more temperate account of the association's study of the effects of a nuclear attack on Britain, which should be complete in about a year. He explained that the association's objective was to enable members of the medical profession to make up their own minds. He provoked cries of "Shame!" from some among the audience by saying that the British Medical Association had "no policy" on nuclear weapons, and the ridicule of a psychiatrist from the north of England who asked what purpose could be served by a solemn study of the effects of nuclear weapons on the

0028-0836/82/070544-02$01.00

British water supply if the recent cold weather had caused water to be rationed in some places.

The association's study has in part been occasioned by a resolution passed at last year's annual representative conference. That circumstance is counted as a success for the Medical Campaign against Nuclear Weapons, which now claims 1,400 members, perhaps 2 per cent of registered physicians in Britain. Other professional anti-nuclear groups may follow this example.

Architects for Peace has similarly taken the initiative by asking the professional organization whether architects can ethically help with building missile sites or underground bunkers, while both the physicians and the Nursing Campaign against Nuclear Weapons intend to make fun of the plans worked out by central and local government for dealing with the consequences of a nuclear attack.

Mr Michael Walsh, chairman of the nurses' organization, produced a scathing criticism of the official British policy that medical personnel should be dispersed to rural areas if there should be advance warning of a nuclear attack, and that the urban population should rely on "self-help". One participant at the conference contributed the intelligence that a local authority plan for dealing with the aftermath of a nuclear attack on the north of England has prudently qualified the advice that the dean of the local medical school should be consulted with the phrase "or his representative".

"IT WAS DESIGNED BY ARCHITECTS FOR PEACE."
BIFF

The surprise of the conference was the declaration by General Michael Harbottle, now secretary-general of the World Disarmament Campaign, that there are now almost enough ex-military men like himself to form an organization called "Generals for Peace". More predictable was the steady undertone of criticism of the British and American governments, accused by Ms Norma Turner ("Journalists against Nuclear Extermination") of assailing the media with "anti-Soviet pro-nuclear propaganda". Several speakers considered that the meeting early in June of the NATO council that President Ronald Reagan will attend had been arranged to distract attention from the Second Special Assembly of the United Nations on disarmament, while General Harbottle thought it possible that Queen Elizabeth II's political independence had been compromised by her invitation to the president to dine at Windsor Castle on 10 June.

The conference was attended by 430 people, more than a third of them from the medical professions. About ten per cent of the participants were scientists, among whom Dr Tom Kibble, professor of physics at Imperial College and vice-chairman of "Scientists against Nuclear Arms", raised the provoking (and unanswered) question of how and when to raise with students, "very often the military technicians of tomorrow", the propriety of taking jobs in military research.

Rights on DNA

Brussels

A move to widen the scope of the European Human Rights Convention to include the dangers of genetic engineering provides further evidence of the unease which recombinant DNA work still arouses in Europe. A report adopted by the assembly of the Council of Europe in Strasbourg on 26 January included eight recommendations on the legal, ethical and social issues raised by the prospect of interference with human genetic inheritance. The rapporteurs, Lennart Petterson (Social Democrat, Sweden) and Bjorn Elmquist (Liberal, Denmark), based their recommendations on the findings of a public parliamentary hearing last May.

The right to a genetic inheritance free from any form of engineering should be included in the European Human Rights Convention, say the Strasbourg legislators. Exceptions include the treatment of genes to eliminate genetically transmitted diseases but this must only be done with the consent of those concerned or, for children or a fetus, the consent of the parents.

The recommendations also stress the need to monitor the harmonization of safety regulations applied to recombinant DNA research in Europe, and suggest that this should be done by the European Science Foundation. EEC's draft legislation on the registration of DNA research should also be examined to see whether it should be applied throughout Europe. Finally, the Council of Europe proposes to study how microorganisms which have been modified by recombinant DNA techniques can be patented.

Jasper Becker

Chemical warfare

Protest plans

Washington

Twenty-five religious, environmental and arms control groups have formed a coalition to lobby against the Reagan Administration's plans to resume the production of chemical weapons after a 13-year moratorium.

The coalition, being organized by the Washington-based Council for a Livable World, was announced last week, just after President Reagan had removed the last remaining legal barrier to resumed production by declaring that the production of nerve gas weapons was "essential" to the national security of the United States.

This in turn coincided with a request from the Reagan Administration for a budget of $705 million for chemical warfare activities conducted by the Department of Defense for the 1983 fiscal year, which begins on 1 October. $77 million is also being added to the budget for the current year, which will now total $532 million — and compares with the $111 million being spent only four years ago.

Included in the 1983 request, most of which will be spent on improving defensive equipment and apparatus, is $30 million which will be used to produce "binary weapons" at the Pine Bluff Arsenal in Arkansas. Congress has already agreed to spend $20 million to build the production facilities, which are now expected to be completed by mid-1983.

According to Defense Secretary Caspar Weinberger, two types of chemical weapons will be produced: 155 mm artillery shells and Big-Eye bombs. Both will be based on the binary concept, in which two non-lethal chemicals are stored separately.

President Reagan's announcement had been widely expected, following pressure from the US military to replace the existing stockpile of chemical weapons, and widespread claims about Soviet superiority in chemical weapons as well as the alleged use of "yellow rain" in South-East Asia. (*Nature* **293**, 327; 1981).

Two years ago, the Pentagon's Defense Science Board, chaired by Dr John Deutch of the Massachusetts Institute of Technology, recommended a start on the production of binary weapons and that the Department of Defense should prepare for a major increase in its chemical warfare programmes. The department is said to be planning to spend about $1,400 million in 1984, and even more later.

Supporters of the chemical weapons programme argue that it is necessary to persuade the Soviet Union to speed up the chemical disarmament treaty, which the United States and the Soviet Union have been discussing in Geneva since 1975.

In a letter to the leader of the House of Representatives, Mr Tip O'Neill, President Reagan argued that the resumption of production, which had been banned by

0028-0836/82/070545-02$01.00

President Nixon in 1969, would "provide strong leverage towards negotiating a verifiable agreement banning chemical weapons." He added: "Considering the current world situation, particularly the absence of a verifiable ban . . . the United States must also deter chemical warfare by denying a significant military advantage to any possible initiator."

Opposition to the Administration's plans is expected to focus on two main lines of argument. The first is the technical discussion about whether an increased chemical capability would, in fact, act as a deterrent to the Soviet Union, or whether — given some of the inherent limitations of binary weapons — it would make more sense to modernize existing stockpiles by more conventional means.

The second argument focuses on the opposition which is already developing in Western Europe, where the chemical weapons would have to be stored if, as expected, their main use was to be in a European theatre of war. According to critics of the Administration from both the left and the right, this opposition could lead to a destabilizing of the Atlantic Alliance which would, in itself, be an additional threat to national security.

Last year, the Administration's plans to build the production facility were approved by the Senate only by two votes in contrast in the House of Representatives there was a strong majority in favour of the new facility. This year the critics hope that the combination of a stringent budget outlook and forthcoming congressional elections will give them the votes needed to defeat the proposal to resume production; but with both the Defense Department and the White House apparently determined to push the proposal through, those trying to head it off recognize that they face a tough uphill task.

David Dickson

Deep-sea mining

Fairer shares

Brussels

A recent European Commission policy paper is urging that, when the world's developed and developing countries meet again in March at the International Conference on the Law of the Sea, to renew their fight over the mineral spoils of the deep seabeds, the EEC's member states should vote together in favour of a better deal for the mining consortia.

Europe, the Commission points out, is almost totally dependent on outside supplies of the minerals in question. Nearly all of Europe's cobalt, copper, manganese and nickel requirements are mined in the developing world, mostly in countries marked by political instability and a poor investment record.

Added to this are the national interests of the six consortia at present in the queue for mining licences. France is represented by the Association d'Etude et de Recherche des Nodules Polymetalliques (AFERNOD), which includes CNEXO (National Centre for the Exploration of the Oceans), the Le Nickel company and the atomic energy commissariat. Britain is represented by the Kennecott Copper Corporation, which is controlled by British Petroleum. Italy's ENI and Belgium's Union Minière Belge have interests in Ocean Mining Associates. Three German companies are partners in Ocean Management Incorporated and Holland's Bos Kalis is a member of the Ocean Mineral Company.

Although they have obvious interests in common, the member states have largely acted independently of one another. However, both the European Commission and the European Parliament would like the conference to decide on a joint EEC policy on raw materials. For the forthcoming round of negotiations the Commission recommends that the Ten should concentrate on ensuring that the mining consortia are not burdened to the point of non-profitability by restrictions and levies.

Mining permission by the proposed authority should be given impartially and there should, the Commission considers, be a way of appealing against decisions. However, the Commission rejects the idea that the authority should be funded by taxes levied in the mining consortia, pointing out that the financial risks of investing an estimated $1,000 or 1,500 million to mine a site of 3 million tonnes are well above those required to extract the same amount of metal in a developing country. To counterbalance this, the Commission wants the law to guarantee that production levels as well as access to the markets can be maintained for the duration of a licence.

The developing countries see the problem as ensuring that their own mineral resources are not cut out of the market by competition from seabed mining. In addition, they are pressing for a transfer of technology and joint ventures, and hence a share of mining profits. The Commission is doubtful about how this would work out in practice and wants developing countries to share more of the risks involved.

Sources at the Commission suggest that since the conference ended last March little has happened to alter the negotiating positions of the opposing camps of developed and developing countries which are likely to remain at loggerheads this coming March.

Jasper Becker

Small growth fund

The address of the Treasurer of the Association for Research into Restricted Growth was given incorrectly in *Nature* 11 February. The following is the correct address: Pam Worsfold, 8 Cotswold Avenue, Rayleigh, Essex.

German academics

Tenure vanishes

Hannover

Since its inception 10 years ago, the policy of *Berufsverbot*, the exclusion of "political activists" from employment in West Germany's civil service, has meant not so much the dismissal of persons considered "extremist" but rather the blocking of their entry into public employment. In academic circles, therefore, the principal victims were young graduates who had formerly been members of (quite legal) left-wing student societies, and found themselves barred from an academic career.

But the recent "Campaign against *Berufsverbot*" conference in Hannover met under the shadow of a new threat, which has arisen as a result of the case of post office official Hans Peter, sacked for his political views after 30 years of service. After a vociferous campaign Peter's appeal was finally dismissed by the federal court last October.

The significance of the Peter case is that this is the first time a tenured official (*Beamte*) has been dismissed for his political views. West German employment policy recognizes three categories of employed person: "worker", "employee" and "*Beamte*". In return for job tenure for life, *Beamte* employees are expected to swear an oath to uphold the constitution. Anti-*Berufsverbot* campaigners explain that those barred from state employment for being activists are fully prepared to uphold the constitution (which guarantees freedom of conscience and opinion). What they are not always willing to do is to equate their loyalty to the constitution with unqualified support of specific government policies.

During the past 10 years, the spectrum of victims of *Berufsverbot* (the campaign lists some 5,000 cases of exclusion throughout the Federal Republic) has gradually widened from communists to socialists, to liberals, to the peace movement and — most recently — to the ecology lobby.

The immediate threat of *Berufsverbot* policy to academics is indirect. Although the Peter case threatens any tenured position, during the past few years a tacit agreement has grown up in the universities that a scholar at risk would formally hold a non-tenured post, but would in other respects be treated as if fully tenured. However, recent cut-backs in university funding in West Germany have meant the abolition of a large number of non-tenured posts. Academics who have been at risk of *Berufsverbot* are thus being eliminated from the universities without the direct intervention of political considerations. With the scope of the screening process apparently becoming ever wider, and unemployment figures soaring, their prospect of finding other jobs seems bleak.

Vera Rich

0028-0836/82/070546-01$01.00

Scientific exchanges

DoD retreat

Washington

Following a series of protests from the academic community, the US State Department has backed away from its previous insistence that rigid restrictions be placed on the topics that a Soviet computer scientist will be allowed to discuss with American scientists during his visit to various research universities later this year.

Last month Stanford University told the State Department that it was not prepared to accept limitations on a visit to its department of mechanical engineering by Dr Nickolay V. Umnov, a robotics specialist. In particular, the university objected to the requirement that Dr Umnov should only be shown research results that have already appeared in the open literature, only discuss theoretical aspects of the research and not be shown details of robot control units or programming techniques.

Stanford's dean of research, Dr Gerald Liebermann, said the university was not prepared to police Dr Umnov's visit, either on or off the campus. He also expressed surprise that the State Department's restrictions had been forwarded without comment by the National Academy of Sciences (NAS), which is arranging Dr Umnov's visit as part of its conventional scientific exchange programme.

NAS president Dr Frank Press subsequently announced that the academy was suspending the automatic transmission of such instructions until the matter had been discussed in detail with the State Department. And last week, Stanford announced that the department had "clarified" its instructions, producing a revised form of the restrictions which the university would now be able to accept.

In particular, Dr Umnov would be able to discuss any research that either has been or is about to be published in scientific papers, and also be given access to details about the control units and programming techniques. In addition, Stanford would no longer be responsible for ensuring that he did not visit local industrial research facilities, another restriction included in the earlier letter.

After the State Department's clarification, the University of Wisconsin, which had previously withdrawn an invitation to Dr Umnov in the wake of Stanford's protest, also announced that it found the new conditions acceptable and Dr Umnov could now visit the university.

The softening of the State Department's line follows intense discussions involving both Stanford and the National Academy of Sciences. It also reflects a split within the Administration on the advantages to be gained from the strict control of university-based research, given the disruption of the free flow of scientific information that would result.

Critics in both Congress and the Administration have identified scientific exchange programmes as vehicles by which the Soviet Union is able to gain access to technical data which it is then able to use to bolster its own military efforts. In response, universities such as Stanford argue that this is a small price to pay for the advantages of open communication in the scientific community.

Dr Jay Keyworth, President Reagan's science adviser, said in an interview last week that he thought the tightening up of the restrictions applied to visiting Soviet scientists was more a reflection of the efforts by President Reagan to make access for the Soviet Union to US technology more difficult after recent events in Poland than a specific attempt to restrict the export of technical data on robotics.

Although Stanford has now said that it is prepared to accept Dr Umnov's visit under the revised restrictions from the State Department, the department itself has yet to give formal approval to the visit. The university has described the National Academy as acting as an "honest broker" between itself and the department.

The academy's position will be discussed at a meeting of its governing board and of the National Research Council which takes place in Washington next week. Academy officials are still hoping to set up a committee to examine the tensions between national security and academic freedom in greater depth. Meanwhile, Stanford president Dr Donald Kennedy, one of the public leaders of the academic community's campaign against excessive government restrictions on research, has agreed to act as chairman with Dr Richard DeLauer, Under-Secretary of Defense for research and development, of a committee being established by the Association of American Universities, to address the same topic.

David Dickson

Lister Institute

End of the road

At the end of May, the Lister Institute of Preventive Medicine will announce the results of applications for five newly created research fellowships thus marking the fundamental change in its status that has now been accomplished. Inflation and escalating costs over the past ten years have defeated the institute's struggle to support a research programme with its investments and production facilities. The laboratories at Elstree and Chelsea have been sold and the interest from the institute's capital of £6 million will now be used for the fellowships.

The Lister Institute was the first major medical research body in Britain, predating the Medical Research Council by 30 years, and in its early days ranked with institutes such as the Pasteur and the Rockefeller. When established in 1891, the institute had a dual function — the production of vaccines and antitoxins and medical research. In spite of passionate opposition from anti-vivisectionists, the institute enlisted the sympathy of the first Lord Iveagh, who after his stableman was bitten by a rabid dog and was sent to Pasteur in Paris because no treatment could be procured in England, gave it £250,000. (The stableman lived to the ripe old age of 89.) In its early decades, the Lister Institute flourished as a private research organization with endowments and income from the sale of biomedical products.

By 1952, the institute encompassed twelve departments. Research was concentrated at the Chelsea laboratory, which closed in 1975 and is now being developed as a hospital. The sale of biomedical products contributed greatly to the income of the institute but Elstree laboratories, the production centre, was finally sold in 1978. From 1896, when the first diphtheria antitoxin used in Britain was prepared, Elstree manufactured vaccines against tetanus, whooping cough, typhoid, plague and cholera and was the main British supplier of smallpox vaccine. Elstree also developed the dried smallpox vaccine widely used in the WHO smallpox eradication programme.

The fate of the institute reflects the difficulties of a privately funded research organization in times of inflation. The institute repeatedly failed to obtain government support, but its Blood Products Laboratory and Blood Group Reference Laboratory have been handed over to the North West Thames Regional Health Authority.

The institute has now been reduced to a small governing body under the chairmanship of Professor Albert Neuberger, a small secretariat and a Scientific Advisory Committee chaired by Professor Geoffrey Dawes, director of the Nuffield Institute for Medical Research at Oxford. The fellowships now to be offered are aimed at promising young scientists who, in the present economic climate, may find it difficult to obtain financial backing for their research. The institute is encouraged by the response to its first advertisement — "It takes only one to make a breakthrough, after all".

Jane Wynn

0028-0836/82/070547-01$01.00

CORRESPONDENCE

Aircraft evolution

SIR — Hoyle (*Nature*, 12 November 1981, p.105) was echoed by Wickramasinghe, as reported in newspapers on 17 December 1981 during the Arkansas trial, and is quoted by Sluyser (*Nature* 21 January, p.184), as saying that "for higher life forms to have evolved by chance is comparable with the chance that a tornado sweeping through a junkyard might assemble a Boeing 747 from the materials therein". The simile is glib, meretricious and deceptive. No evolutionist has suggested that higher life forms are assembled by chance from debris.

However, the inept comparison provokes memories of the actual evolution of the Boeing 747, starting a mere 80 years ago with primitive flying machines that indeed looked like products of junkyards. As in biology, but almost infinitely more rapidly, aeronautics proceeded from the simple to the complex. The inventions of the Wright brothers and Santos Dumont led to Blériot's 1909 monoplane and a host of larger aircraft within the next decade. Boeing planes started to cross the oceans in 1934 and the 74-passenger Boeing Clipper was in trans-Pacific service in 1937. Preceded by the British Comet, Boeing 707s brought in the jet age of travel in 1959. They were the evolutionary predecessors of the 747. The brief history of aircraft technology is filled with branching processes, phylogeny and extinctions that are a striking counterpart of three billion years of biological evolution.

Instead of misleading newspaper reporters with attacks on evolution and fables about 'flu bugs in comet tails, Hoyle and Wickramasinghe should note that protein molecules evolve by elongation of small polypeptides and that living organisms acquire ever-increasing complexity from gene duplication as now revealed in DNA sequences. Also, that wide-bodied jets evolved from small contraptions made in bicycle shops. Or in junkyards.

THOMAS H. JUKES

University of California,
Berkeley, California, USA

Brought to Book

SIR — Jon Marks's letter about Creationism (*Nature* 28 January, p.276) is obviously either a parody or a hoax. No other explanation is possible of such a farrago of perversity and farce.

The inerrancy of the Bible may well be a risible Aunt Sally, but even so it is not to be knocked down by the ineptly aimed brickbats lobbed at it by Mr Marks. His paraphrase of St Luke's account of Jesus and the repentant thief is inaccurate, and his comment upon it ludicrously, if not wilfully, naive; his gibe at *Leviticus*'s classification of bats with birds would strike home only if "bird" had always had the same narrow meaning as it has today, which, of course, is not the case. And as for Origen's mockery of the proposition that "the first three days existed without Sun, Moon and stars", I suspect that most modern cosmologists would prefer to side with *Genesis*! If one wishes to confute Fundamentalism, is it not best merely to point to the Bible's self-contradictions? These, after all, are many: for example, the discrepancy between the genealogies of Jesus offered in *Matthew* 1 and in *Luke* 3.

Fallible the Bible certainly is, but I cannot agree with Mr Marks that its myth has even more rivals, let alone any superiors. The wealth of the Bible's wisdom, the beauty of its story, the power of its images are vast, unexampled, seemingly inexhaustible: if proof were needed, the Bible is the source of some of the greatest works of some of our greatest artists — the *Divina Commedia*, the *St Matthew Passion*, the Sistine frescoes, *Paradise Lost*, the *Last Supper*, *Messiah*. Where are the fruits of the *Kalevala*, or the *Elder Edda*, or the *Odyssey*?

That the Bible is not "original", everyone admits: but that is far from being a failing: in literature, as in ethics, "originality" is the prerogative of cranks, and the "original" usually monstrous — and, like most monsters, sterile. No great story — be it the *Morte d'Arthur* or the tale of Noah's Flood — is *sui generis*. Indeed, to trace the resemblances between the biblical myth and those of other books is to play straight into the Christians' hands, for it is part of the Christian thesis that among the pagan legends there may be "good dreams" sent from Heaven: blurred, poetic visions of what, in the New Testament, became concrete, prosaic fact.

It is sad that Mr Marks thinks that a Creator of 750,000 species of insect would have to be a "cosmic bore", but the blame for boredom usually lies with the bored: Mr Marks's remark tells us more about Mr Marks than it does about God. Yawns are not admissible as philosophical arguments.

But Mr Marks is quite correct, I believe, when he says that the existence of God is "irrelevant" to evolution; perhaps one might broaden his observation, and say that the existence of God is irrelevant to science generally. The supernatural, if it exists, is by definition intrinsically unknowable to "natural" science (except in the very limited sense that Shakespeare is knowable to literary criticism). Worse still, even if the supernatural not only existed but also operated upon nature, science would certainly find those operations all but impossible to assimilate: for the price that science pays for relying ultimately upon repeatable experiments is that science finds it enormously difficult to incorporate irreproducible phenomena, especially when such phenomena do not seem to accord with current scientific theory. There is a perennial temptation to reject odd phenomena as "impossible". "Improbable" they may be, but "impossible" they most definitely are not. To label any observation, however bizarre, as "impossible", is profoundly to misunderstand the provisional nature of scientific law. Those who jeer at the Bible's reports of miracles commit precisely the same philosophical error as those old astronomers who, we recall, were frightfully amused by the quaint bucolic fantasy that stones sometimes fell from the sky.

In conclusion, then, Christian apologists should regard science neither with fear nor with hope: science is not, and never can be, an arbiter of theology: no experiment in any laboratory will ever verify or falsify the resurrection of Jesus Christ. Similarly scientists must have the honesty and the humility to concede that science's methods of inquiry are radically limited in scope. We cannot vivisect God.

Though, in our way, we tried.

Losers all

SIR — Your report that the Medical Research Council will not accept grant applications from British university departments inadequately equipped for the proposed research (*Nature* 19 November 1981, p.201) invites comparison with the analogous situation in the United States. In both countries, a system of "dual support" prevails for government-sponsored academic research. Government agencies, accepting that discipline-oriented university research yields fundamental findings of profound cultural value and of potential benefit for society, and the major — but by no means only — investors in these activities. As a condition of making limited grants to departments or individuals, the government expects the universities to supply the remaining research necessities. (In Britain, the university's resulting relative share is much higher than in the United States.)

Here, the two systems diverge in nature. The British university's general funds come from the same exchequer as do research grants. The same austerity mood that leads a research council to emphasize that it will withhold funding unless the laboratory involved is "well found" also leads to the tightening of general university support from which the university is expected to equip laboratories. Without other resources for this type of research, the institution makes painful choices to sustain part of the research "duet".

In the United States, the federal government pays less than total direct and total indirect costs of sponsored faculty projects (regardless of method of reimbursement). The universities receive no general federal support but must meet the balance of federal project costs by drawing on their own general funds for instruction and other activities. These come principally from state governments (for state universities) and student tuition and, to a lesser extent, from alumni, foundations, industry and endowment. Admittedly, American universities have a more diversified financial base than do most British institutions. Yet, non-federal sources of funds have their own views on research and are not eager to make up the difference on federal projects.

Here, some similarities can perhaps be suggested. In Britain, departments receiving inadequate university funding may be denied research council support. In the United States, the university may be forced to make up the balance, on federal projects, with funds it would otherwise use for promising research by graduate students or young faculty members. In this zero-sum situation, these faculty and graduates are not only the immediate losers but also involuntary co-sponsors of the public interest research that *does* receive their university's funds. Ultimately, as you observe, "the rest of us" are the losers.

Breaking the 600 metre barrier

from the Scientific Party, DSDP Leg 83

In the 12 years' existence of the *Glomar Challenger*, deep-sea drilling in more than 600 holes has repeatedly failed to penetrate deeper than 582 m into the pillow lava sequence at the top of the crust. A myth had thus arisen among geologists that deeper drilling in the oceanic basement is prohibited with current technology. Now the mythical 600 m barrier has been broken. Leg 83 of the Deep-Sea Drilling Project has deepened, by 514 m, Hole 504B in the 6.2 Myr crust on the southern flank of the Costa Rica Rift, and penetrated to 1,076 m of basalt. The hole penetrates almost twice as deep into the oceanic crust as any other and has been used for making an extensive set of geophysical experiments, utilizing the borehole as a natural 'window' into the crust.

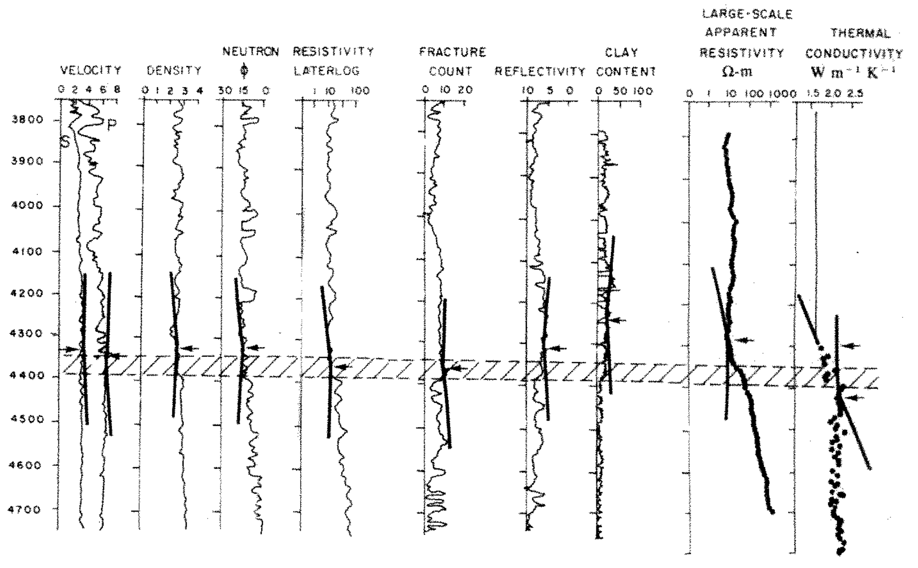
A consensus has steadily arisen over the past several years that the best model of the structure and composition of the oceanic crust is provided by ophiolites on land. An ophiolite is a layered tectonic sequence progressing, top to bottom, from marine deep-water sediments to pillow basalts, then to a sheeted, nearly vertical dike complex. Beneath the dikes are the cooled remains of what was once a magma chamber, gabbros and layered cumulates. Ultramafics lie beneath the gabbros across a transition thought to be the MOHO. With depth the entire sequence is altered to successively higher-temperature metamorphic rock: first zeolite facies in the pillows, then greenschist facies in the pillows and dikes, and finally amphibolite facies in the lower dikes and gabbros. Ophiolites are thought to represent old oceanic crust generated at a mid-ocean ridge spreading centre and somehow 'obducted' onto land during collisions of the gigantic plates moving over the Earth's surface.

Leg 83 goes a long way towards validating the ophiolite model, although it exposes a few inconsistencies that will require re-examination of the ophiolites. First, Leg 83 penetrated through the pillow lavas, and at about 700 m it broke through into a sheeted dike complex. The transition occurred sharply, over a depth range of about 50 m, in every geophysical log and experiment run in the hole. The figure shows that seismic velocity, density and thermal conductivity of samples, as well as *in situ* electrical resistivity, sonic velocity and reflectivity from a downhole sonic televiewer (showing rock hardness), all increased in a step-like fashion. By contrast the porosity, degree of fracturing, amount of alteration minerals, and magnetic intensity and susceptibility all fell while *in situ* permeability decreased by three orders of magnitude below the boundary.

Marine seismology has provided evidence of a layered structure of the oceanic crust in which surficial low-velocity pillows are referred to as layers 2A and 2B, a deeper dike layer as layer 2C and the deeper gabbros as layer 3. Leg 83 drilled into layer 2C and measured *in situ* 'layer 2C-type' seismic velocities in the sheeted dike sequence.

Above the dikes, Leg 83 found an extensively altered pillow and breccia layer, with a stockwork of iron, zinc and probably copper sulphides in hydrothermal silicate veins. In the ophiolites, massive sulphide ore bodies of economically important metals have been mined, whose 'feeders' are stockworks strikingly similar to that found in the Leg 83 drill hole. Above this layer, alteration dropped off in extent and grade, and a highly permeable layer 2A was found.

In 1979, Legs 69 and 70 had drilled 562 m into the same area of oceanic crust and had discovered an underpressured aquifer. Leg 83 verified that this aquifer was still



Geophysical logs from Leg 83, Hole 504B. Hatched line is base of transition between seismic layers 2B and 2C. Below are predominantly dikes; above pillows. Arrows and solid lines are changes in gradients near this transition. Each log shows this transition. Velocities are from sonic log, density from active-source γ-ray log, fracture count and reflectivity are from Borehole Televiewer log, clay hydroxyl content from a cross-correlation between neutron porosity, which measures porosity plus hydroxyls in formation, and density which measures only porosity. Thermal conductivities are measured from cores on board ship and are the only measurements not done *in situ*.

Scientists aboard D/V Glomar Challenger for Leg 83 were Roger Anderson and Jose Honnorez (Co-Chief Scientists), A.C. Adamson, J.C. Alt, K. Becker, R. Emmerman, P.K. Kempten, H. Kinoshita, C. Laverne, M.J. Mottl, R. Newmark and E. Tual.

drawing ocean bottom water downwards into the oceanic crust, but at a slower rate — $1,500\ \mathrm{l\ h^{-1}}$ compared with $6,000\ \mathrm{l\ h^{-1}}$. In the two year period, 50×10^6 kg of sea water have been drawn into the crust.

An apparent discrepancy between the Leg 83 findings and the ophiolite model did turn up, however. According to the literature ophiolite rocks appear to have generally re-equilibrated under increasing temperature metamorphic facies, Leg 83 basalts display only partial recrystallization, showing they have not reached equilibrium. Also Leg 83 rocks do not grade with increasing depth into increasingly higher-temperature facies. Some of the minerals of lowest-temperature alteration and the least altered rocks were found in the middle cores of the dikes complex.

The sequence of alteration has not yet been resolved by analysis on board the *Challenger*. Recovered rocks show the effects of at least two stages of alteration: a greenschist facies (hotter) event depositing actinolite, chlorite and epidote into veins and actinolite, chlorite, sphene and albite throughout the rock matrix, and a zeolite facies (lower temperature) event, characterized by laumontite, epidote, chlorite and smectite. Anhydrite seems to occur with both facies mineral pargenesis in veins and appears to be a late forming mineral. It is not clear whether the stockwork metallogenesis belongs with the hotter or the cooler event. The question still unresolved is whether both events took place at the ridge axis or whether the cooler event is occurring now on the flank of the ridge. Significantly, water in formation pores has the composition predicted to be in equilibrium with currently occurring alteration in the rock. Formation waters therefore do not reflect the greenschist facies (hot) type of event.

This is an important geophysical issue as well, for the plumbing system of the dikes and lower pillows is clearly plugged up by alteration, whereas the top of the crust (layer 2A) is obviously open to aquifer-type flow. Closer to the ridge, was layer 2A thicker and convection more pervasive? Or has convection — even at the ridge axis — always been limited to the upper 500 m of the oceanic crust now at Hole 504B?

Shore-based analysis of Leg 83 results promises much excitement. In any event, the myth of not being able to drill deep in the oceanic crust has been proved to be just that. Leg 83 left Hole 504B clean and ready for even deeper drilling on a possible future leg — layer 3 or bust! ☐

Ocean floor conductivity measured

from T.J.G. Francis

A WIDE range of electrical methods has been used for several decades over land to measure the conductivity of the underlying rocks. But whereas the study of the electrical properties of rocks has become the most important method of geophysical exploration for metal ore bodies, the application of these techniques to the sea bed, even in the shallow waters of continental shelves, has been severely restricted by the high conductivity of seawater. Much effort has been directed to getting round this difficulty and in *Geophysical Research Letters*, P.D. Young and C.S. Cox have now described an active-source electromagnetic sounding experiment carried out on the ocean floor[1]. The technique offers new possibilities for studying the geology of the oceanic crust.

Magnetotelluric sounding, in which the horizontal magnetic and electric fields of naturally occurring electromagnetic signals are observed, has been carried out on the ocean floor since 1965 (ref.2). The conductivity of the ocean eliminates frequencies above about 10 c.p.h. (0.003 Hz) however, so that the method is suitable only for studying the conductivity of the mantle on a scale of hundreds of kilometres and is thus insensitive to the conductivity structure of the crust and uppermost mantle. Using an array towed at the sea surface behind a ship to measure the resistivity of the sea bed on the continental shelf[3], it has been possible to distinguish between unconsolidated sediments and hard rock and to detect the presence of a sulphide ore body, but this method is not thought practicable in oceanic depths.

In the novel active-source electromagnetic sounding experiment of Young and Cox[1], low-frequency signals of 0.25–2.25 Hz were detected at a range of 19 km close to the axis of the East Pacific Rise at 21°N. The transmitting antenna, lowered from a ship, consisted of an 800 m long insulated wire through the ends of which 70 A peak alternating current was passed into the sea. The freely deployed receiver measured the electric field at two 9 m long crossed antennas and at the end of the experiment floated back to the surface for recovery. The observations have been modelled to yield a conductivity structure of the crust and upper mantle to a depth of 30 km beneath the sea floor.

The important thing about the work of Young and Cox is not so much their results, fascinating though they are, as the potential which the technique may have for future studies of the geology of the ocean floor. Our present knowledge of the deeper geological structure of the ocean crust has been obtained largely by seismic methods. Reflection methods have told us most about the structure of the sedimentary layers and refraction about the underlying basement. However, the translation of velocity structures into geology is ambiguous and compressional wave velocities are insensitive to many of the properties of the ocean crust which now interest earth scientists. By contrast, the electrical conductivity of a rock is extremely sensitive to the presence of cracks filled with seawater, to even smaller amounts of partial melting and to the presence of sulphide ore minerals. All have the capacity to increase the conductivity of a rock by two or more orders of magnitude.

The extent to which seawater penetrates newly formed oceanic crust has been a subject of considerable interest ever since it was first demonstrated by Lister a decade ago[4]. Now Young and Cox have demonstrated that close to the East Pacific Rise, the high-conductivity ($0.1\ \mathrm{S\ m^{-1}}$) basalts penetrated with seawater are no more than 1.4 km thick. This result has already received support from large-scale resistivity measurements made on Leg 83 of the Deep-Sea Drilling Project in Hole 504B on the Costa Rica Rift[5] (see previous article). Seawater may penetrate much more deeply into the crust of slowly spreading ridges and active-source electromagnetic sounding is probably the best method for measuring it.

This technique may also provide the means of finding magma chambers beneath the axes of mid-oceanic ridges. The existence of such magma chambers has long been postulated, but finding them has proved difficult, particularly on slowly spreading ridges where seismic refraction experiments have produced negative results[6].

Finally, sulphide ore bodies are now thought to exist in the upper levels of the oceanic crust at a frequency of one ore body of horizontal area 0.1 km^2 per 20 km^2 (ref.7). Attempting to find such ore bodies by drilling would be futile, since on the average it would take 200 holes to discover one ore body. Deep penetration logging of the bore holes could improve these odds, but only by a factor of about four. Active-source electromagnetic sounding is certainly the best available means of finding such bodies once they have become buried by pillow lavas and sediment.

Thus Young and Cox have demonstrated a technique which, if widely deployed, possibly using other frequencies and source–receiver configurations, could provide answers to many of the problems which have eluded solution by more conventional marine geophysical techniques. ☐

Fifty years of substance P

from T.M. Jessell

SUBSTANCE P, the doyen of the common peptides[1], is now 50 years old and on the verge of achieving respectability as a neurotransmitter. Yet by comparison with many other peptides of inferior pedigree, the physiological functions of substance P have remained obscure. Some of the reasons for the slow progress are easy to find. Although many of the peripheral actions and chemical properties were established by von Euler and Gaddum, it took 40 years before substance P was eventually isolated and its amino acid sequence determined. But even with the availability of synthetic material, advances in the chemistry of substance P have been disappointingly slow. Simple modifications in the native amino acid sequence did not immediately generate receptor antagonists or more potent agonists. More fundamental perhaps, the behaviour elicited by the central or peripheral application of substance P has been less easily interpretable than, for example, the elevation of pain threshold associated with administration of opioid peptides or the modification of feeding and drinking behaviour elicited by cholecystokinin and angiotensin.

At a recent CIBA Foundation symposium* there were encouraging signs that some of these obstacles have been, or are about to be, overcome. In particular, it is now apparent that modifications of the C-terminal sequence of substance P can generate receptor antagonists, stable agonists and analogues that are selective for substance P receptor subtypes within the central (CNS) and peripheral nervous systems (see Table 1). By substituting d-amino acids at residues 7 and 9, Rosell (Karolinska Institute) and colleagues have synthesized a peptide analogue that antagonizes the spasmogenic activity of substance P on intestinal smooth muscle and the vasodilatory actions on peripheral vessels. At present, effective blockade of substance P responses can be achieved only at relatively high antagonist concentrations (10^{-5} -10^{-4}M) and partial agonist activity has also been observed in some bioassav systems[2]. However, more potent and specific antagonists can now be anticipated and their availability will undoubtedly prove crucial for evaluating many of the postulated physiological functions of substance P.

Attaching a methyl group to the nitrogen atom in the peptide bonds at residues 8 and 9 and deleting the N-terminal tetrapeptide (Lee, Johns Hopkins Medical School) results in an analogue (termed Di Me C7) which is biologically active and completely resistant to degradation by a membrane-bound endopeptidase that inactivates substance P[3]. Whether the endopeptidase isolated by Lee, or any other enzyme for which substance P can act as a substrate, is actually involved in the inactivation of neuronally released substance P is still unclear. It is conceivable that diffusion alone could effectively terminate the actions of substance P. However, injection of Di Me C7 into the ventral tegmental area of rats (Iversen, University of Cambridge) produces a spectrum of behavioural responses that resembles, but greatly outlasts, the response elicited by substance P itself. The prolonged duration of action of Di Me C7 *in vivo* provides the first indication that substance P-inactivating enzymes may in fact function physiologically.
